Gravitational waves are predicted by Einstein's theory of general relativity to be ripples in the curvature of spacetime which propagate at the speed of light. What the theoreticians would like the experimentalists to do is, firstly, to demonstrate the existence of these waves, either as a continuous flux or in larger spasmodic bursts, and secondly, to analyse the radiation to give them clues for developing their theories further. However this is no easy task. The effects of gravitational waves are small and not easily detected. Gravitational radiation should be noticeable by its effect on large masses. Experimenters first tried to show its existence by setting up massive antennae and looking for a movement induced by a passing gravitational wave. But the effect predicted by current theory is so small that the sort of displacement one is hoping to measure is of the order of 10^{-19} cm for a resonant bar with a mass of about one ton. When one considers that the Bohr radius of a hydrogen atom is about 5×10^{-9} cm and the 'classical' electron radius is about 3×10^{-13} cm, then the difficulties of measuring 10^{-19} cm can be appreciated. On top of that the experimenters need to make repeated measurements of the same system to look for changes in its position, so the measurement processes must not be such as to cause unpredictable changes of the position of the system. We are not used to treating large objects quantum mechanically, but it is obvious that it must be done in this case. So what limits does the theory of quantum mechanics impose on this measurement scheme?

The quantum theory of measurement warns experimental physicists that no matter how carefully a measurement is made it will always change the system being measured. Consideration of the problems this causes for the detection of gravitational waves has led to the identification of quantum nondemolition (QND) variables (Braginsky, Vorontosova & Thorne *Science* **209**, 547; 1980; Thorne *Rev. Mod. Phys.* **52**, 285; 1980; Caves, Thorne, Drever, Sandberg & Zimmerman *Rev. Mod. Phys.* **52**, 341; 1980; Caves *Phys. Rev. Letts.* **45**, 75; 1980). A quantum nondemolition variable is one for which a sequence of precise measurements can be made, the result of each measurement being completely predictable from the result of the preceding measurements (Caves *et al.* op cit.) The logic of this can be understood by considering the system of a free electron as discussed by Braginsky *et al.* If we measure the electron's position in space and so force it into a well defined position then the Heisenberg uncertainty principle relating the properties of position, x, and momentum, p,

$$\Delta x \Delta p \geqslant h/2$$

ensures that the momentum is changed by an unpredictable amount by the position measurement. That might not bother us much if we don't want to know the electron's momentum, but it does have an effect if we want to make a second measurement of the position. In the time interval, t, between the measurements the electron has moved an amount $x_t = (p/m)t$ where m is the mass of the electron. But as p is uncertain by Δp then x_t is uncertain by an amount $(\Delta p/m)t$, that is

$$\Delta x_t \geqslant \frac{ht}{2m\Delta x}$$

where Δx is the uncertainty of the first measurement. So the more accurate the first measurement the less we can rely on the result of a second measurement of position. Braginsky *et al.* go on to apply the same analysis to a large (10 ton) antenna and show that if the first measurement is made to an accuracy of 10^{-19} cm then a second measurement 10^{-3} second later is uncertain by a least 5×10^{-19} cm. So no subsequent measurement can be compared with the first to the full measurement precision. However, if we had decided to measure momentum rather than position, the second measurement would have been as informative as the first. The position uncertainty would have changed according to the uncertainty principle but this would not have fed back into the momentum unless the electron were in a position-dependent potential. In the situation of a free electron or a freely moving antenna, momentum is a QND observable whereas position is not.

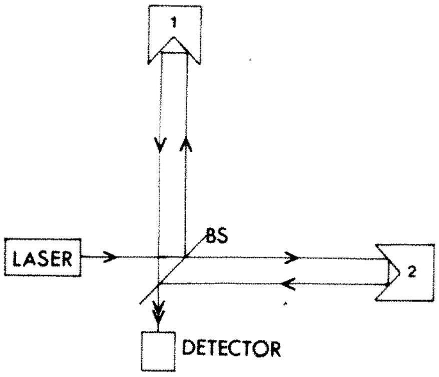
Bridget Marx is in the Division of Mechanical and Optical Metrology, National Physical Laboratory, Teddington, UK.

0028-0836/80/390276-02$01.00

Generally, most observables are not QND observables and there will be 'back-action' from the measurement. This is a problem which must be overcome if such incredibly accurate measurements are to be made. One solution is to find a QND variable to measure and this is the route proposed for the antenna type of gravitational wave detector. As it is not feasible to make sufficiently precise measurements of momentum another variable must be used. Details of how it is proposed to measure the real and imaginary parts of the complex amplitude of a large quantum mechanical harmonic oscillator, both of which are QND variables, are given by Braginsky *et al.* and by Caves *et al.*

Another suggested method for measuring the displacement of masses produced by gravitational waves, is to use a Michelson interferometer. The basic apparatus is shown in the figure. The laser light enters the interferometer, is split by a beam splitter (BS), passes down the two arms to the mirrors mounted on test masses and is reflected back to the beam splitter where it is recombined. The light measured at the detector is a sinusoidal function of the path difference BS1–BS2, and so is sensitive to any differential displacements of the test masses 1 and 2, such as would be produced by a gravitational wave. As the effect of mirror displacement can be amplified by using multiple reflections in each arm of the interferometer this technique is potentially very sensitive. However, this is a position measuring device and so it is subject to the effects of the Heisenberg uncertainty principle just as is the antenna. The problem considered by Caves and earlier by Edlestein, Hough, Pugh and Martin (*J. Phys. E.* **11**, 710; 1978) is how to estimate the measurement limit imposed on this system by quantum mechanics. There is an uncertainty in measuring the light intensity from the interferometer (remember we are looking for a change in intensity to indicate a differential change in BS1, BS2) arising directly from fluctuations in the laser light source. In addition, differential radiation pressure effects from the light on the mirrors could limit the reliability of measurements, especially at high input intensities. This would imply an optimum intensity for an interferometer device.

Do such differential forces exist in real interferometers? The literature on this point is not convincing. Indeed Caves refers to a 'lively but unpublished controversy' on the subject. The problem is fundamental: radiation pressure is a momentum conserving effect due to the particle nature of the light photons, whereas the interference fringes observed with an interferometer are due to the wave nature of light. The wave-particle duality of light, and indeed all particles, has always caused problems. What happens to a photon in the interferometer? An interesting and instructive discussion of this point is given in an article by Frisch (*Contemp. Phys.* **7**, 45; 1965). The important thing to remember is that the problem is very different from the apparently similar experiment of setting up a beam splitter with light detectors in place of the mirrors. In this latter experiment, if a photon were detected at 1 then it certainly wouldn't be detected at 2. So the photon's momentum would be given to either 1 or 2, but not both. However, with the detector placed to monitor the interference pattern — after the beams are recombined — the only assumption that we can make is that each photon goes down both arms of the interferometer, that is that each photon is reflected from both mirrors. If we knew which mirror the photon had been reflected from, we could not observe an interference pattern. This is an experiment directly comparable with the more famous Young's two-slit experiment (see, for example, Bohm *Quantum Theory* Prentice-Hall, 1951), where if we ask which slit the photon came through we can not observe an interference pattern.



A method for measuring the displacement of masses produced by gravitational waves using a Michelson interferometer.

The discussion of the interferometer problem in some of the literature seems to come uncomfortably close to confusing the two-detector and the two-mirror problems.

The whole field of gravitational wave detection is proving to be full of fascinating problems and will no doubt stimulate physicists in all fields of research. It is particularly interesting to note that these attempts to demonstrate the validity of the last great theory of classical physics, that is general relativity, are being limited by effects which are totally due to the new physics of quantum mechanics. ☐

Galileo saw Neptune in 1612

from David W. Hughes

JOVIAN satellites, lunar mountains, saturnian rings, stars in the Milky Way, Sun spots, phases of Venus — the number of significant observations of astronomical objects made by Galileo Galilei is impressive indeed. The coming together of the invention of the telescope and Galileo's brilliant enquring mind obviously led to a bountiful harvest. Did Neptune slip through his fingers? Galileo saw the planet but recorded it as a star in his notebook. Was the discovery of Neptune in his grasp, almost 234 years before Johnn Galle found it in 1846? I don't think so. The rudimentary star maps of the time, the inadequate telescope mountings and Neptune's distance from the Sun make it nigh on impossible. But still, like all scientists are taught today, Galileo recorded in his observation journal not only what he was specifically investigating but also unusual sightings and events.

That Galileo actually recorded Neptune was discovered recently by Charles T. Kowal of the Palomar Observatory, California Institute of Technology and Stillman Drake, the Professor of the History of Science of the University of Toronto. Their findings are reported in this issue of *Nature* on page 311. Prediscovery observations of planets are common and Neptune is no exception, the famous one being by Lalande in 1795. As people were obviously not looking for Neptune in the seventeenth and eighteenth centuries, the only chance of it being accidentally recorded was if it happened to be in close proximity to something that people were looking at. Extrapolating Neptune's orbit back in time revealed that Jupiter, the brightest and most commonly observed planet, actually passed in front of Neptune both in September 1702 and in January 1613. A search of the records of 1702 is a task for the future. Kowal and Drake decided to start by examining Galileo's 1612–1613 observations of Jupiter.

Now Galileo had discovered the four large Jovian satellites Io, Europa, Ganymede and Callisto in January 1610, and had spent much time observing and analysing the orbital movement of this 'miniature solar system'. On 7 September 1612 Galileo put forward a method whereby observations of the satellites of Jupiter from different places on the Earth's globe could lead to a determination of the longitude of that place to an accuracy of about three degrees. This

David W. Hughes is in the Department of Physics, University of Sheffield.

0028-0836/80/390277-02$01.00

would be very useful for the navigation of ships. The idea was to regard Jupiter as a celestial clock whose 'hands' were the four satellites, their positions gave the local time which could then be compared with Florence time (for example) to give the longitude. Galileo was preparing tables to show the satellite positions and observed Jupiter to this end. Kowal and Drake point out that a star near Jupiter was noted on 28 December 1612 and again on 28 January 1613, in a different position, and this star happens to be Neptune. There are no other bright stars in Virgo anywhere near the position of the Jovian-Neptune conjuction of that year. Galileo thought Neptune was a star because it looked just like one in his telescope. The disk of Neptune subtends about 2.4 arc sec at Earth, way below the 1.24 arc min resolution of Galileo's telescope. Two factors can account for Galileo not noticing the movement of Neptune against the fixed star background. First, there was an absence in that area of the sky of bright stars to form that background and second, the mean daily motion of Neptune is about 22 arc sec, much too small to be detected in those days.

Kowal and Drake's discovery is important because it could lead to an improvement in the accuracy of our knowledge of the orbital parameters of Neptune. Neptune orbits the Sun once every 165 years. As it was only discovered 134 years ago it hasn't been seen to go round once yet. Observations of the orbit over long time periods give clues to the gravitational perturbations the planet suffers and these could lead to the discovery of a planet beyond Pluto. The exact time of the 1702 Jovian occultation of Neptune would be extremely useful in this calculation and this is ample justification for a close scrutiny of the astronimical manuscripts of 1702. Hidden in these might be a record of another historic close encounter between these two planets. □

Laser annealing for semiconductor devices

from I. W. Boyd and J. I. B. Wilson

LASERS are used for cutting, drilling and welding metals and ceramics as well as by surgeons, seismologists and spectroscopists. Now the laser annealing of semiconductors is attracting industrial interest and there have been specialist conferences devoted entirely to this aspect of laser technology[1,2]. A recent NATO Advanced Study Institute in Italy covered both the intriguing physics of the laser irradiation of semiconductors, and some of the technical advances which will be possible in micro-circuit fabrication.

Annealing is the heat-treatment used to restore disordered semiconductor wafers to crystalline perfection, after selected 'dopant' impurities have been implanted into the wafers (as energetic ions) to adjust the electrical conductivity. Conventional furnace annealing uses temperatures of $\sim$ 950°C for $\sim$ 30 minutes but has the unfortunate side effect of allowing the dopant atoms to diffuse into the wafer and to spread out laterally. This negates an important advantage of ion-implantation — the high degree of control over the depth and shape of the implanted (doped) region. Each subsequent thermal treatment causes further spreading of dopant and imposes a restraint on the closer packing of devices within an integrated circuit.

Both electron beams and lasers can be used to apply heat locally to semiconductor wafers, with fine spatial and temporal control, so that only part of a wafer may be heat-treated. Lasers, in contrast to electron beams, have no need for a vacuum enclosure or inert gas cover. The actual temperature reached by a sample will depend both on the laser energy and irradiation time, and on the optical absorption properties of the material and its thermal capacity and conductance.

In silicon, visible laser radiation such as that from a laser ruby (used in the first pulsed laser annealing of ion implanted silicon[3]), is strongly absorbed whereas infrared CO_2 laser radiation is only weakly absorbed (by the free charge carriers) until the sample heats up (producing many free carriers). Both pulsed and continuous (CW) lasers of various types, can recrystalize disordered silicon, but by different mechanisms.

CW laser annealing is similar to the conventional furnace process, for regrowth of the crystal lattice takes place in the solid phase. The high temperatures are, however, only maintained for milliseconds because the laser beam is scanned across the sample and there is insufficient time for dopant to diffuse into the bulk of the wafer. Extended structural defects (such as stacking faults and dislocations) are more effectively removed, and more of the dopant is placed in electrically-active substitutional sites, than by furnace treatment. Pulsed lasers are thought to produce a melted region and this allows dopant atoms to migrate over greater distances before the solid/liquid interface moves back towards the surface. Various modes of regrowth are therefore possible for disordered or polycrystalline layers on crystalline substrates, and in some cases surface ripples remain after the laser treatment. Van Vechten[4] has, however, proposed a theory which places more emphasis on the importance of the electron-hole plasma produced by strong laser pulses. This, he suggests, may sufficiently weaken the covalent bonding of the lattice that rearrangement takes place without formation of a liquid phase. The reflectivity of silicon has been observed to increase sharply during pulsed annealing and although this is generally believed to prove that melting has occurred it is not conclusive. Recent Raman scattering measurements during pulsed annealing of silicon have indicated a lattice temperature of only 300°C (ref.5), well below the melting point of $\sim$ 1,400°C.

There are, then, two alternative laser annealing modes, which either can leave implanted ions in their original region, or can allow them to redistribute. In fact, novel phases and solid solutions may be formed, which are impossible to produce by conventional furnace treatment. It is also possible to form good ohmic contacts on materials such as gallium arsenide and indium phosphide, the surfaces of which will begin to decompose if they are heated to the usual temperatures required for alloying contacts. Further, it is possible to deposit metal, dielectric, and semiconductor films directly from a gaseous compound on to a substrate by laser. The laser beam may either be used to heat the substrate to a temperature at which the impinging vapour can decompose, or be used to directly dissociate the gaseous molecules.

Reports of actual devices formed by laser processing are much fewer than those devoted to more basic studies of the techniques, but laser annealed p-n junctions and MOSFET's can be made from silicon which was originally in the poly-crystalline state. There are problems associated with the ever-present oxide layer on silicon because it may have anti-reflection properties for the laser light at certain thicknesses, and will have different thermal expansivity from the underlying melted silicon. It is essential to use a laser system without hot spots in the beam, and with accurate beam steering to avoid distortion of the beam shape. New specially-designed equipment is now on the market.

Advanced technology lasers may eventually replace furnaces, which are more costly in energy, for annealing ion-implanted silicon devices, but it is the novel applications which are the most exciting, and which may allow the routine use of new semiconductor materials. □

Isotopic evidence for the provenance of some Caledonian granites

P. J. Hamilton*, **R. K. O'Nions*** & **R. J. Pankhurst**†

* Department of Earth Sciences, University of Cambridge, Downing Street, Cambridge CB2 3EQ, UK
† British Antarctic Survey, c/o Institute of Geological Sciences, Grays Inn Road, London WC1X 8NG, UK

A combined Nd- and Sr-isotope study of Caledonian granites in Scotland and northern England demonstrates the importance of continental crust in their petrogenesis and places limits on the involvement of contemporary mantle-derived material.

THE continental crust is generally thought to have been generated over a considerable portion of Earth history through the progressive chemical differentiation of the mantle. Thus, all igneous, metamorphic and sedimentary rocks residing in the continents are ultimately 'mantle derived'. However, petrologists usually reserve the term 'mantle derived' for those igneous rocks derived from primitive mantle melts by magmatic differentiation processes without an intermediate solid stage. If, after a period of residence in the continental crust, such mantle-derived igneous rocks are remelted, the resultant magmas would be designated 'continent derived'. The provenance of granites is an important aspect of the fundamental problem of crustal generation and growth. Granites that are wholly or partially mantle derived make a nett contribution to the mass of the continental crust and are therefore an integral part of crustal growth. In contrast, granites with no mantle-derived component only involve intracontinental differentiation with no concomitant change in continental mass.

To distinguish between mantle and continental derivation in a specific instance, it is necessary to recognize (usually from abundances of radiogenic isotopes) whether or not the precursor material has had a significant residence time in the continental crust. In this context, the main problem has been to find adequate criteria to distinguish between mantle and crustal provenance and in the latter case to quantify the crustal residence time of the precursor material. Hurley and colleagues[1-3] pioneered the application of isotope studies to this particular problem using $^{87}Sr/^{86}Sr$ ratios. Only recently has the Sm–Nd system been exploited as a tracer of granite provenance[4,5]. For example, the Tertiary granites of Skye, north-west Scotland, have much lower $^{143}Nd/^{144}Nd$ ratios than predicted Tertiary mantle values, a feature consistent with a large component of their Nd being derived from Archaean basement[5,6]. A reconnaissance investigation of Sm–Nd isotope systematics in Phanerozoic granites (including the Sierra Nevada batholith, Himalayan granites and Hercynian granites of France) by Allègre *et al.*[4] has revealed the presence of continental-derived components in all cases examined.

It must be emphasized that investigations of granite provenance using the isotopic composition of a particular element (such as O, Sr, Nd) only explicitly refers to the provenance of that element whereas the provenance of other constituents can only be inferred. Ideally, therefore, measurements of the isotopic compositions of several elements exhibiting different chemical behaviour during crustal differentiation and evolution are required to make completely general statements about the provenance of a granite as a whole. The present study uses the combined Nd- and Sr-isotope approach for evaluating the provenance of Caledonian granites occurring in Scotland and northern England and in particular assesses in appropriate situations the possibility of Sm/Nd fractionation attending the differentiation and mobilization of pre-existing continental crust.

Caledonian granite magmatism

The term Caledonian granites encompasses granite (*sensu lato*) rocks that were emplaced into the Caledonides over a period of about 150 Myr, starting ~550 Myr ago and associated with the closure of the Iapetus Ocean[7,8] (Fig. 1). Two of the oldest of these are the Carn Chuinneag and Ben Vuirich granites, dated, respectively, at 555±10 Myr (ref. 9) and 514±7 Myr (ref. 10) using U–Pb chronology of separated zircons. These belong to Read's[11] group of Older granites, and were emplaced before the main Caledonian structural and thermal episodes that occurred ~480–460 Myr ago. The post-tectonic (Newer granites of Read) range in age from ~470 Myr (see ref. 12) to ~390 Myr (refs 12, 13) (Fig. 1). More detailed reviews of the chronology of Caledonian granites can be found elsewhere[12,14-16], and geochronological data pertinent to the granites investigated here are summarized in Table 1. The large variation in initial $^{87}Sr/^{86}Sr$ ratios of Caledonian granites (see Fig. 1 in ref. 17) is noteworthy. Initial $^{87}Sr/^{86}Sr$ ratios ≥ 0.710 are characteristic of the pre-tectonic granites and 475-Myr-old granites of north-east Scotland. It is generally agreed that Proterozoic, or older, crust is involved in their generation[10,18], and that they are S-type granites as defined by Chappell and White[19]. No such consensus exists for the provenance of the remaining post-tectonic Newer granites that have initial $^{87}Sr/^{86}Sr$ ratios ranging down to 0.704.

The U–Pb systematics of Caledonian granite zircons investigated by Pidgeon and coworkers[9,10,12] are particularly relevant to the problems of granite provenance. Several granites, including both pre-tectonic granites (for example, Carn Chuinneag[9] and Ben Vuirich[10]) and post-tectonic granites north of the Highland Boundary Fault (such as Strichen[12] and Foyers[12]) have been shown to contain zircons with $^{207}Pb/^{206}Pb$ and U–Pb ages in excess of the age of granite emplacement. These U–Pb data define reverse discordia which have lower intercepts approximating to, or defining, the age of intrusion and upper intercepts corresponding to ages up to at least 1,000 Myr. Such zircons are considered to predate the magmatic event that produced the granites and to have been inherited as refractory constituents from a crustal percursor to the granites[9,10,12,16]. Therefore, in favourable circumstances they may provide an estimate of the age of some component of the granite.

In addition to studies of radiogenic isotopes, oxygen isotope abundances have been measured by Harmon and Halliday[20] in

0028–0836/80/390279—06$01.00

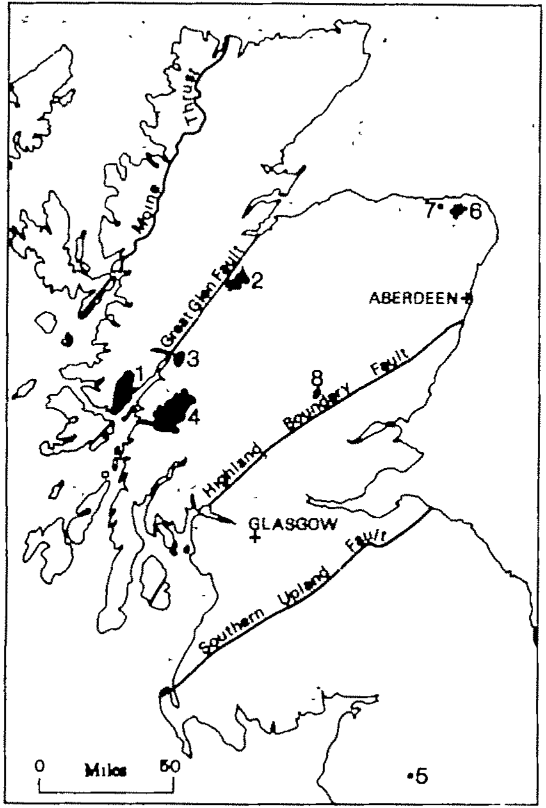

Fig. 1 Map showing the locations of Caledonian granites studied. 1, Strontian; 2, Foyers; 3, Ben Nevis; 4, Etive Complex; 5, Shap; 6, Ben Vuirich; 7, Longmanhill; 8, Strichen.

25 post-tectonic Caledonian granites from both north and south of the Highland Boundary Fault and a more detailed O and Sr isotope study of the Doon, Criffel and Fleet intrusions has also been made[21]. These studies demonstrate the existence of an overall positive correlation between δ^{18}O and ^{87}Sr/^{86}Sr, similar to that previously demonstrated for samples from the Peninsular Ranges Batholith[22]. Harmon and Halliday[20] interpret the correlation in terms of a binary mixing process with one component derived from the mantle or new basic lower crust and the other from a Lower Palaeozoic sedimentary source. Thus, granites possessing low ^{87}Sr/^{86}Sr and δ^{18}O values are considered to be dominated by melts derived from mantle source regions with both negligible crustal residence time and minimal contamination with pre-existing sialic crust (see also ref. 23).

The present study of Rb–Sr and Sm–Nd systematics of selected Caledonian granites includes pre- and post-tectonic examples from north of the Highland Boundary Fault in Scotland and the Shap Granite in northern England (see Fig. 1 and Table 1).

Results

Rb–Sr analyses were carried out at the University of Oxford and the Institute of Geological Sciences, London, and Sm–Nd analyses at the Lamont-Doherty Geological Observatory. The analytical methods used have been described previously[24–27].

New Rb–Sr results for samples measured in the present study are given in Table 2. Initial ^{87}Sr/^{86}Sr ratios (I_{Sr}) (Table 3) have been calculated assuming emplacement ages given in Table 1. I_{Sr} values for the Strontian tonalites and granodiorites exhibit a relatively small range from 0.70534 to 0.70598, whereas that for the biotite granite phase for Strontian is significantly greater at 0.70713. This agrees well with the I_{Sr} value of 0.70700±14 reported by Halliday *et al.*[21] for a sample of this same phase. The Foyers samples in Table 3 exhibit a larger range of I_{Sr} values of 0.70436–0.70819 and were considerably more heterogeneous than the Strontian intrusion at the time of emplacement.

These Rb–Sr data, together with those of Halliday *et al.*[21], are plotted on a Rb–Sr isochron diagram in Fig. 2. The data array for the Foyers granites falls close to the reference line corresponding to the assumed age of emplacement. The remainder of the Foyers' data are also positively correlated but scatter about a line of greater slope. This could reflect mixing between low Rb/Sr–low ^{87}Sr/^{86}Sr and high Rb/Sr–high ^{87}Sr/^{86}Sr components or the inheritance of Rb–Sr systematics from the source region which would correspond to an isotopic event at ~1,000 Myr. Furthermore, the possibility that some of the scatter reflects post-crystallization redistribution of Sr cannot be eliminated at this stage. For Strontian, the Rb–Sr data have been shown to scatter about a line corresponding to an age of 750 Myr (ref. 17), but we note here (Fig. 2) that, relative to a 435-Myr reference line (the emplacement age), it is only the points for the biotite granite which are highly discrepant, perhaps indicating that this unit has a different provenance from the granodiorites and tonalites. It may be relevant that inherited zircon has been reported from the biotite granite phase[16] but not from the other phases in Strontian[12].

Using the emplacement ages given in Table 1, the I_{Sr} values have been computed for the other Caledonian granites studied and are given in Table 3. The total range in I_{Sr} for the granites considered here range from ~0.716 (Strichen, Ben Vuirich, Longmanhill) to ~0.705 (Ben Nevis, Etive).

^{147}Sm/^{144}Nd and ^{143}Nd/^{144}Nd ratios are presented for 19 samples in Table 3, and initial ^{143}Nd/^{144}Nd (I_{Nd}) ratios have been computed using their assumed emplacement ages (Table 1). The I_{Nd} values range from 0.511444 (Longmanhill) to 0.512104 (Strontian). Those intrusions with high I_{Sr} values (Ben Vuirich, Longmanhill, Strichen) have among the lowest I_{Nd} values (Table 3), but there is no other detailed correlation. Note also that in the case of the Foyers intrusion the I_{Nd} values are much less variable than the I_{Sr} values.

The I_{Sr} and I_{Nd} values are also compared in terms of Δ parameters[28] in Table 3. These parameters express the deviations of isotope compositions with the bulk Earth values at the

Table 1 Geochronological data for some Caledonian granites

Intrusion	Age (Myr)	Method	Comments	Emplacement age (Myr)	Ref.
Strontian	435	U/Pb and ^{207}Pb/^{206}Pb	Nearly concordant zircons from granodiorite		12
	1,462 and 381	U/Pb	Reverse discordia for inherited zircons from biotite granite Lower intercept age may reflect Pb loss	435	16
Foyers	Probably predates Lochnagar and Hill of Fare at 415±5 Myr and 413±3 Myr dated by Rb–Sr whole rock. 401±8 Myr K–Ar (biotite)			415	15
Ben nevis	Unpublished Rb–Sr data and 382–399 Myr K–Ar (biotite)			400	15

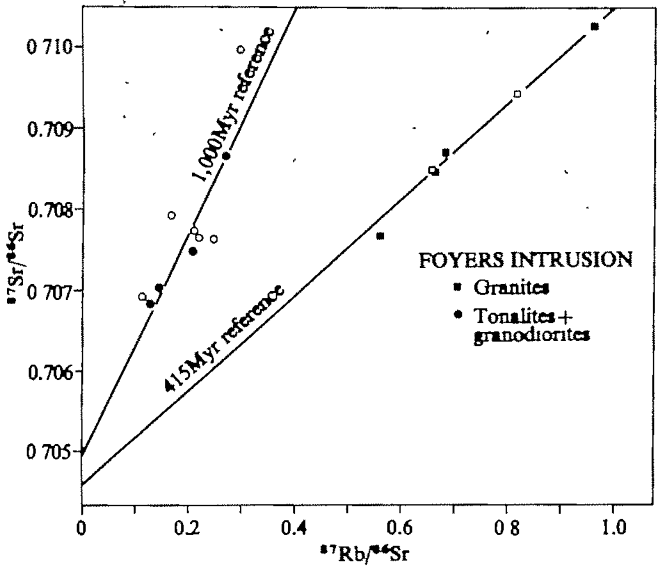
appropriate times of emplacement. In Fig. 3 the Δ values are compared with the bulk Earth, for which $\Delta_{Sr} = \Delta_{Nd} = 0$ at all times. Depleted mantle sources, such as represented by mid-ocean ridge basalts (MORB) or the 505-Myr Bay of Islands ophiolite[29], have negative Δ_{Sr} and positive Δ_{Nd} values. In contrast, the continental crust, which is the complement to depleted mantle, has a mean composition with a positive Δ_{Sr} and negative Δ_{Nd} values, although both positive and negative Δ_{Sr} values are known to exist in high grade metamorphic terrains[5,6]. None of the granites analysed as part of this study have Δ values characteristic of depleted mantle; on the contrary, all have negative Δ_{Nd} and positive Δ_{Sr}, similar to much of the continental crust. In this respect, these data are entirely analogous to those reported by Allègre *et al.*[4], and indicate a crustal contribution to all these granite bodies.

The Sm–Nd isotope systematics of Archaean meta-igneous rocks[6,27,30–35] can often be satisfied by simple two-stage models. The first stage can be considered to start some 4,550 Myr ago and end with a crust–mantle differentiation event at t ($t \geq 2{,}500$ Myr). Isotopic evolution in this first stage is characterized by a Sm/Nd ratio indistinguishable from the average chondrite ratio. The second stage extends from t until the present ($t = 0$). This comparatively simple model often seems contradictory to geological considerations that require more complex multistage



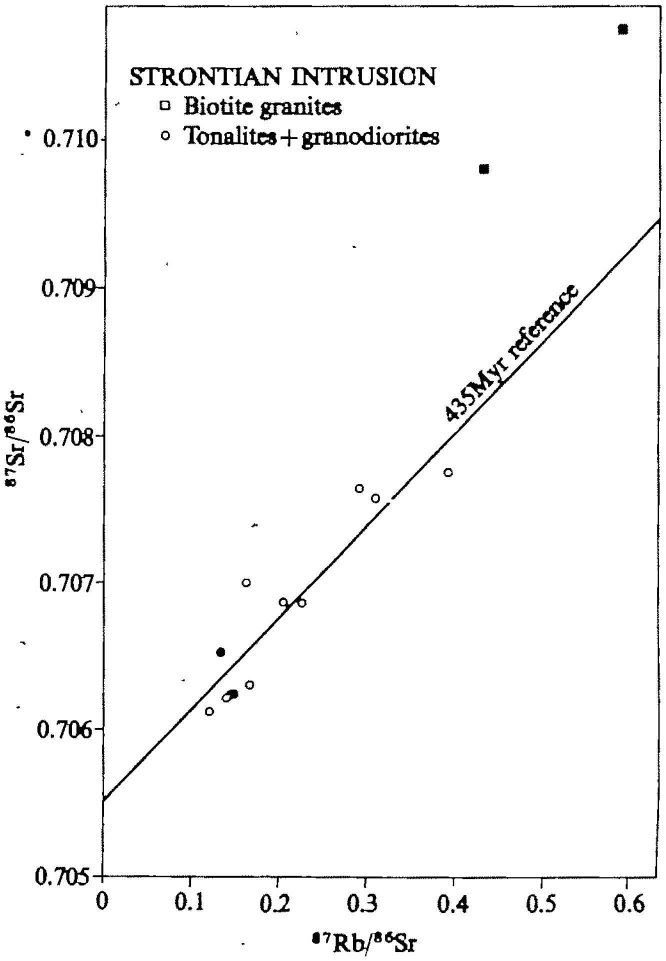


Fig. 2 Rb–Sr isochron diagrams for granite, granodiorite and tonalite phases of the Foyers and Strontian intrusions (Table 2 and ref. 16). The Foyers granites plot close to a 415-Myr reference line (assumed time of emplacement), and the tonalites and granodiorites plot close to a 1,000-Myr reference line. The Strontian tonalites and granodiorites plot close to a 435-Myr reference line (assumed time of emplacement), but the biotite granites do not.

development but merely indicates that the differentiation processes responsible for the production of such rocks occurred over an interval Δt that is not readily resolved from the Sm–Nd isotope systematics.

Model ages (t_{CHUR})[30] have been calculated (Table 3) for each sample assuming such a two-stage evolution. There is no *a priori* reason to assume that these ages should correspond to specific geological events. However, available data indicate that the Sm/Nd fractionation associated with the production of a new crustal segment is likely to be most significant in the history of a given crustal segment, and furthermore suggest that intracrustal differentiation processes involving erosion, sedimentation and metamorphism may have comparatively little effect on Sm/Nd ratios[36–40]. Thus, in some instances t_{CHUR} may provide a reasonable estimate of the time of separation of the Sm and Nd in their precursors from the mantle. t_{CHUR} can be expected to be a minimum age for this event if the mantle reservoir had been previously depleted and had a higher $^{143}\mathrm{Nd}/^{144}\mathrm{Nd}$ ratio than the bulk Earth, or if granitic melt production within the continental crust involved a fractionation of Sm/Nd. Furthermore, if a component derived from the continental crust is mixed with a contemporary mantle-derived component, the t_{CHUR} will not correspond to the provenance age of either component and will, depending on the precise nature of the mixing, usually be a minimum age for the crustal component.

Having noted these limitations, t_{CHUR} model ages range from close to the time of granite emplacement (for example, Shap) to ages much in excess of the emplacement ages (for example, 1,500 Myr for Strichen).

Provenance of Caledonian granites

The presence of inherited zircons and high initial $^{87}\mathrm{Sr}/^{86}\mathrm{Sr}$ ratios have demonstrated that the early Caledonian granites must contain a large component derived from the continental crust[9,10,12,16]. The Sm–Nd isotopic results reported here for the Ben Vuirich, Strichen and Longmanhill granites are entirely consistent with this viewpoint: the Δ_{Sr} and Δ_{Nd} values are very different from those typical of depleted or undepleted mantle, and indicate the existence of a large crustal component. One possible crustal component is the 2,920-Myr (ref. 6) Lewisian basement, which is known from north of the Highland Boundary Fault. Comparison of the Sm–Nd systematics of the Lewisian gneisses[6] with those of these early granites shows that they are not dominated by a Lewisian component. This fact is reflected by the t_{CHUR} ages which, although in some cases considerably greater than the assumed emplacement age, are much younger than the Lewisian. In contrast, the t_{CHUR} ages of the Tertiary Skye granites, which average 2,400 Myr, are considered to contain a large component derived from the Lewisian[5]. U–Pb data reported for inherited zircons in the Ben Vuirich granite define a discordia that intercepts the concordia at 1,316 ± 26 Myr and 514 ± Myr. The upper intercept age is in excellent agreement with the t_{CHUR} age of 1,310 ± 70 Myr. This limits any 'mantle-derived' component in the granite to a negligible proportion and further indicates minimal fractionation of Sm/Nd during remelting of this Proterozoic crustal source. Although less well constrained from zircon data, the same argument may apply in principle to the petrogenesis of the ~475-Myr granites of north-east Scotland.

The origin of the remaining post-tectonic (Newer) granites is more controversial. For example, distribution of inherited zircons (≥ 1,000 Myr old) led Pidgeon and Aftalion[12] to propose a major Proterozoic crustal component in granites north of the Highland Boundary Fault. Caledonian granites south of the fault were ascribed to a Lower Palaeozoic crustal source. In contrast, many other workers[20,23,39–41] have invoked a major involvement, either directly or indirectly, of contemporary (Caledonian) mantle-derived material, with crustal contaminants ranging from Lewisian[39] to Lower Palaeozoic in age.

The Sm–Nd systematics of the Newer Caledonian granites provide some resolution of these possibilities. The Δ_{Nd} and Δ_{Sr} values are compared in Fig. 3*b* with the expected values of depleted mantle source regions in the Caledonian (as represented by the field of mid-ocean ridge basalts computed for 400 Myr ago and by the 505-Myr-old Bay of Islands ophiolite) and the Lewisian gneisses, these being the most extreme compositions likely to be involved. Other potential components, such as Proterozoic or Lower Palaeozoic crustal sources, will be intermediate in isotopic composition. The main question is whether the Δ_{Nd} and Δ_{Sr} values of the granites plotted reflect mixtures between such extreme end-member compositions or whether they are generated from younger continental crust. It is obvious that none of the granites are dominated by Nd and Sr derived from a contemporary depleted mantle source, and even in the case of Strontian granodiorites and tonalites a contribution from

* f is the deviation of measured Sm/Nd ratios from the bulk Earth (or CHUR) value[31].

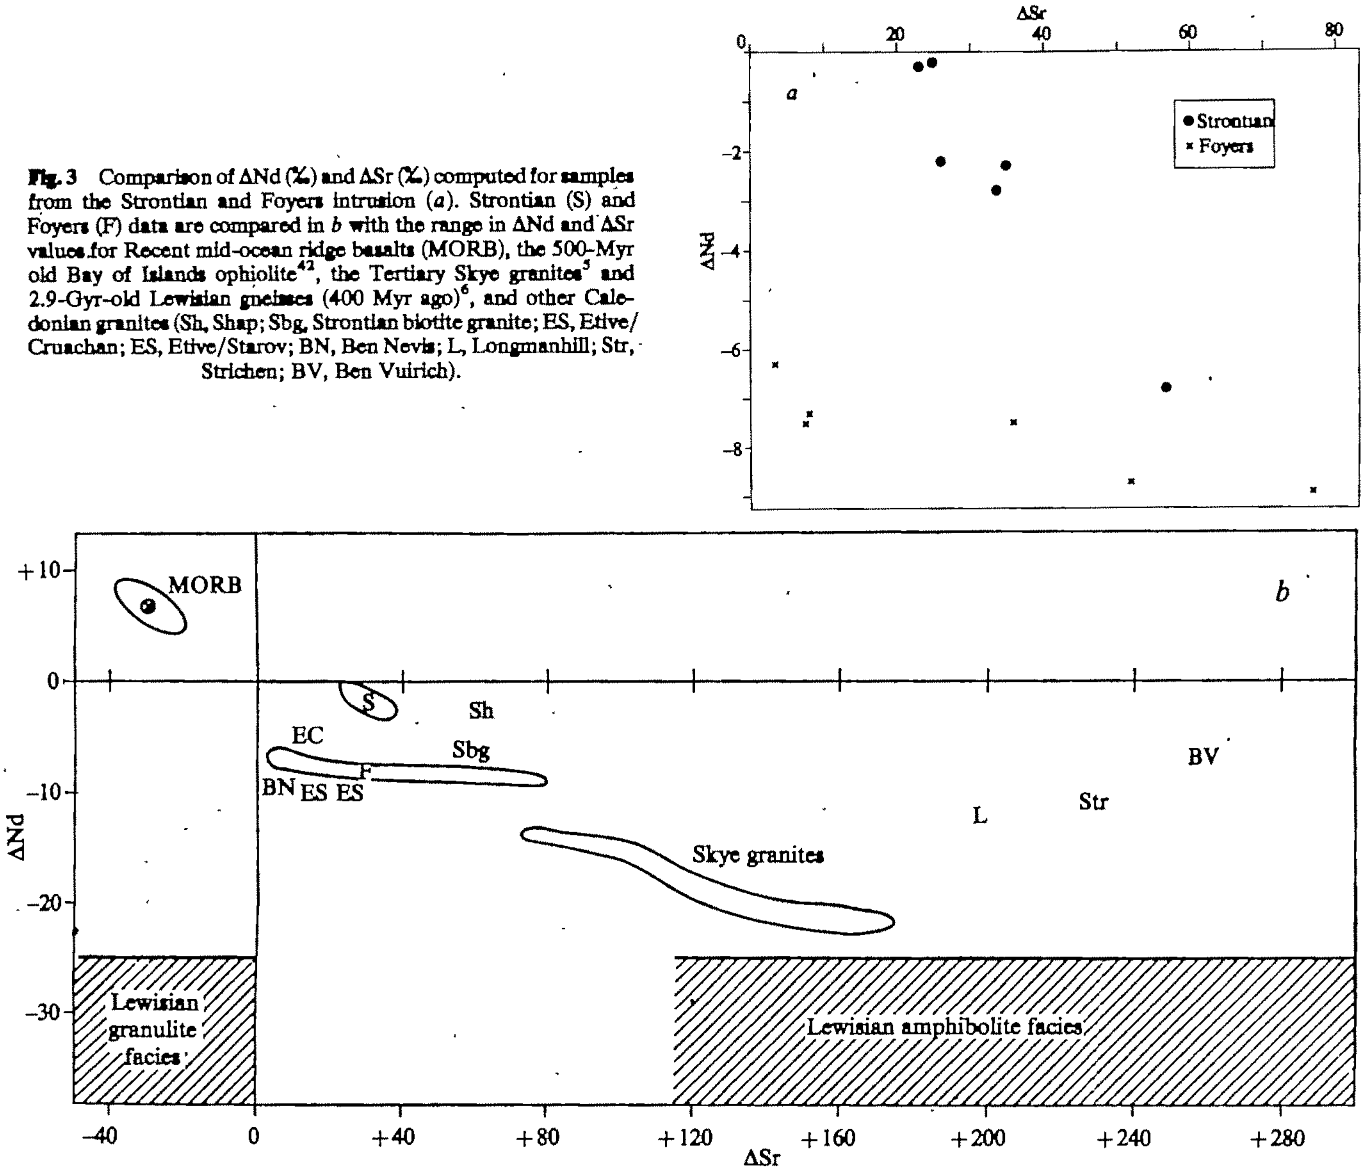

Fig. 3 Comparison of ΔNd (‰) and ΔSr (‰) computed for samples from the Strontian and Foyers intrusion (*a*). Strontian (S) and Foyers (F) data are compared in *b* with the range in ΔNd and ΔSr values for Recent mid-ocean ridge basalts (MORB), the 500-Myr old Bay of Islands ophiolite[42], the Tertiary Skye granites[5] and 2.9-Gyr-old Lewisian gneisses (400 Myr ago)[6], and other Caledonian granites (Sh, Shap; Sbg, Strontian biotite granite; ES, Etive/Cruachan; ES, Etive/Starov; BN, Ben Nevis; L, Longmanhill; Str, Strichen; BV, Ben Vuirich).

this could not exceed ~10‰, although a larger contribution from an undepleted (that is, $\Delta_{Nd} \approx \Delta_{Sr} \approx 0$) source would be permissible. Similarly, the contamination of mantle-derived material with an Archaen crustal source (such as Lewisian) must be restricted to a maximum of ~30% even in the most favourable case (Foyers). However, the trend of Δ_{Nd} and Δ_{Sr} values for the Foyers intrusion (Fig. 3*a*) is incompatible with a simple mixing between mantle and Lewisian endmembers. Rather, the range of Δ values indicates intracontinental differentiation processes, such as sedimentary fractionation of Rb/Sr at relatively constant Sm/Nd, in which case the t_{CHUR} ages (800–1,200 Myr) may give a reasonable estimate of provenance. The broad agreement between the average t_{CHUR} age and the inherited Rb–Sr systematics supports this interpretation, as does the presence of >1,000-Myr-old inherited zircon. For the Strontian intrusion, possible mantle- and continent-derived components are less readily constrained, but the similarity of the Δ_{Nd} and Δ_{Sr} values of the biotite granite to the Foyers samples, together with the evidence for inherited zircon, may indicate a similar Proterozoic crustal provenance at least for this phase.

The Sm–Nd and Rb–Sr data also provide constraints on the provenance of post-tectonic granites that do not contain inherited zircon. The t_{CHUR} ages for the Ben Nevis and Etive granites of ~1,000 Myr are similar to those of the Foyers granite, indicating that their provenance is dominated by Precambrian crust rather than a contemporary mantle source, as has usually been inferred from Sr-isotope data alone. Note, in this respect, that the comparatively low I_{Sr} value for Ben Nevis of 0.7043 in ref. 25 is associated with a δ^{18}O value of 7.8‰, which is at the lower end of the range of δ^{18} values reported by Harmon and Halliday for Caledonian granites[20]. This combination, as interpreted by these authors, reflects a major mantle or new lower crustal component (~70%). However, this conclusion is at variance with the constraint imposed by the t_{CHUR} age of ~1,000 Myr. The interpretation of the I_{Sr}–δ^{18}O correlation for late Caledonian granites as the result of mixing of two components is certainly an oversimplification[42] and low δ^{18}O and low ^{87}Sr/^{86}Sr are not adequate criteria for the recognition of a granite dominated by a contemporary mantle-derived component.

The lack of inherited zircon in the Shap granite[12] and the t_{CHUR} age of 560 Myr suggest that its provenance is not dominated by an old crustal component. It is possible that this intrusion is derived from a contemporary mantle-derived component or from crustal components that have had comparatively short crustal residence times. The Sm–Nd data alone do not favour either of these alternatives, but taken together, the δ^{18}O value of 11‰ and $I_{Sr} = 0.07075$ (ref. 20) suggest a sedimentary rather than a mantle provenance. The tonalites and granodiorites of the Strontian intrusion have both low I_{Sr} values (~0.7056) and low δ^{18}O (~7.2‰)[20]. These parameters, coupled with the t_{CHUR} ages of 400–600 Myr, are quite compatible with a provenance involving a large mantle-derived component. However, in view of the Ben Nevis data, it is not possible to exclude a provenance dominated by a crustal source, albeit one with a comparatively short crustal residence time.

Conclusions

In terms of more general questions of crustal evolution, it is important to ascertain the extent to which granite magmatism (s.l.) reflects intracrustal differentiation in the continents *vis-à-vis* the addition of mantle-derived material to the continents. The results of the present study and previously published isotopic data suggest only minimal, if any, involvement of mantle-derived Sr and Nd components for many of the analysed intrusions. Thus, their formation has involved the recycling of continental crustal materials that have had a prior crustal residence time of $\geqslant 500$ Myr (such as Strichen, Ben Vuirich, Ben Nevis, Etive and Foyers intrusions and the Strontian biotite granite). The Rb–Sr and Sm–Nd isotope data reported here do not directly constrain the provenance of other constituents of the granites present in major, minor or trace proportions: mixing processes can be envisaged whereby the provenance of various elements may indeed differ. However, where indications of provenance using different approaches involving, for example, zircon U–Pb, Rb–Sr and Sm–Nd whole-rock systematics concur (as for Ben Vuirich, Strichen, Foyers), it is more reasonable to assume that all constituents of the granite have the same provenance. Although the isotope systematics of these Caledonian granites indicate a dominance of crustal provenance, it cannot be inferred that the heat required for the melting process was also crustal: this could equally well be supplied from the mantle.

For the remaining intrusions studied there is no unequivocal support for involvement of mantle-derived material that has not had some prior crustal residence. In the case of the Strontian tonalites and granodiorites, involvement of crust with only ~ 100–200 Myr prior residence time is difficult to distinguish from the possibilities or alternatively or additionally involved mantle components. In some cases (such as the Shap granite) a short crustal residence of the precursors is indicated by the comparatively high I_{Sr} and $\delta^{18}O$ values. However, in the case of the Ben Nevis and Etive granites, their t_{CHUR} ages of 800–1,200 Myr suggest that the well documented positive correlation of $\delta^{18}O$ and I_{Sr} for the Caledonian granites may not be simply attributed to mixing of local upper-crustal sediment with a contemporary mantle-derived component.

J. F. Brown and C. Rundles provided some of the samples used in this study. Contribution No. ES 89 of the Department of Earth Sciences, Cambridge. This research has been supported by grants from the NSF and the NERC.

Deformation of the Indo–Australian plate

Jeffrey K. Weissel, Roger N. Anderson & Carol A. Geller

Lamont-Doherty Geological Observatory of Columbia University, Palisades, New York 10964

Intraplate seismicity, deformed oceanic crust and sediments, and local areas of abnormally high heat flow characterize significant internal deformation of the Indo–Australian plate in the northeastern Indian Ocean. The deformation appears analogous to the buckling of an elastic plate with brittle failure at its surface. It is not clear whether the Indo–Australian plate can be resolved into two component parts or whether a new convergent plate boundary is likely to form in the deformed region. The onset of intraplate deformation in the late Miocene seems to be connected to the Himalayan orogenic stage of the collision between India and Asia.

CENTRAL to the concept of plate tectonics are the assumptions that a strong lithosphere overlies a weaker asthenosphere, and that lithospheric plates are undeformed except at their boundaries. Because the evolution of the Earth's surface from the standpoint of plate tectonics has gained widespread acceptance, observations that apparently violate its basic assumptions should be closely examined. Intraplate earthquakes, marine seismic reflection profiling, and heat flow observations delineate an outstanding example of deformation remote from the boundaries of the Indo–Australian plate (which carries both India and Australia, Fig. 1). This article (1) discusses these observations in detail; (2) points to a possible link between deformation in the interior of the Indo–Australian plate and the Himalayan orogeny; (3) speculates on the implications of treat-

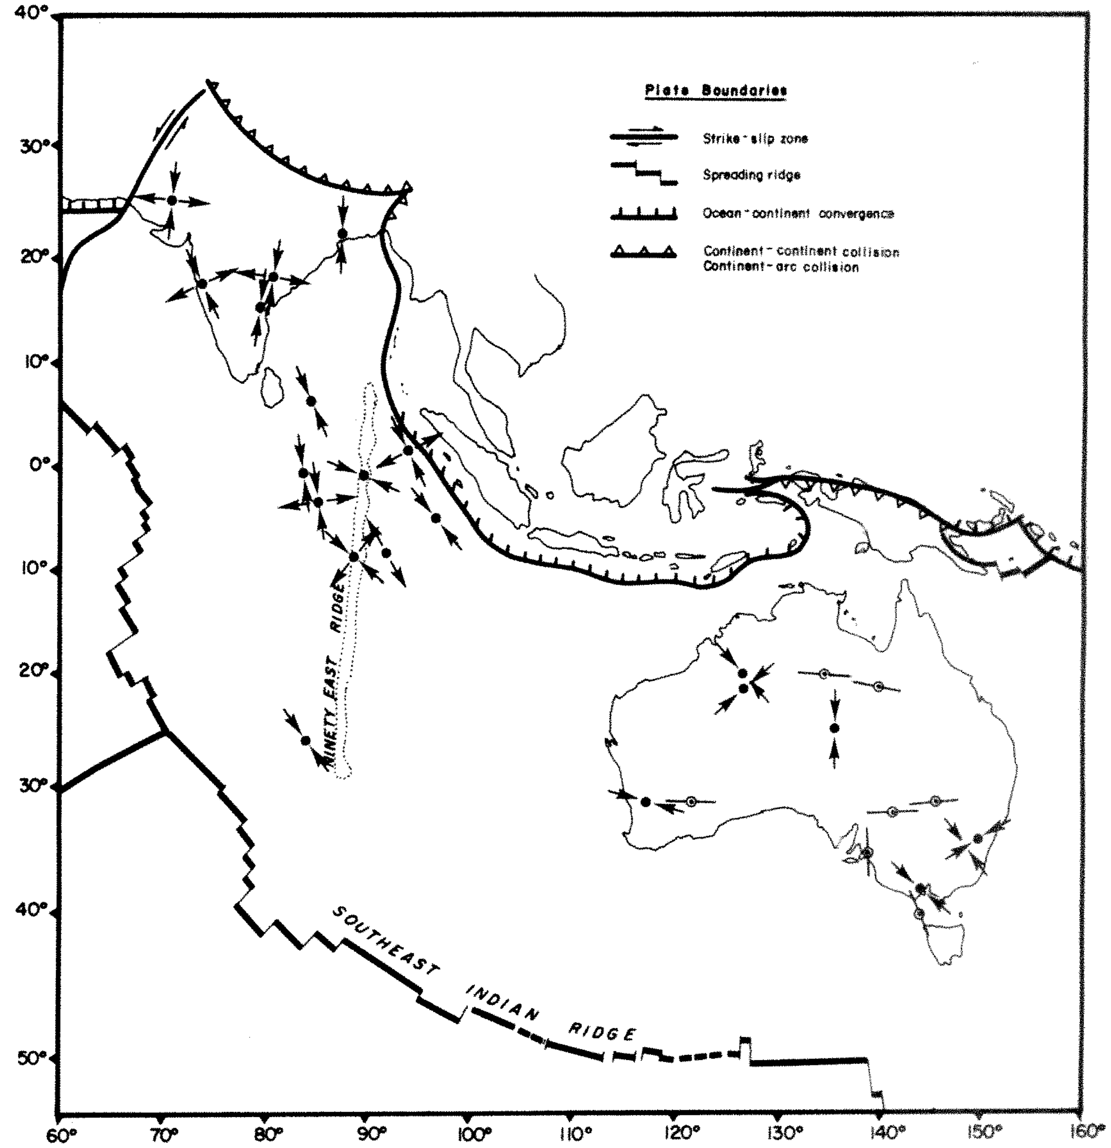

Fig. 1 Directions of principal stress axes for intraplate earthquakes within the Indo-Australian plate[2–8]. Inward-pointing arrows denote the axis of maximum compression; outward-pointing arrows refer to the axis of minimum compression. Also shown (—⊙) are maximum compressional stress directions from *in situ* stress determinations in Australia[9].

ing the deformation as buckling of an elastic plate; and (4) considers whether the intraplate deformation is a precursor of a new convergent plate boundary within oceanic lithosphere of the Indian Ocean.

Intraplate earthquakes and contemporary stress

Seismologists have long noted that the northern part of the Indo-Australian plate displays a high level of intraplate earthquake activity[1–4]. Shallow events occur over a wide band extending from the Indian peninsula through the Australian continent[1–3] and principal stress directions[2,4,5–8] determined for the most significant of these earthquakes are shown in Figs 1 and 2. Except for the single tensional event east of the Ninetyeast Ridge[4] (Fig. 2), principal stress directions and *in situ* stress determinations indicate that the northern part of the Indo-Australian plate is under predominantly horizontal compression. The orientations of the axes of maximum compression change from about N–S in the Indian peninsula to nearly E–W in the Australian continent, a feature predicted by global models in which intraplate stress is determined by assumed plate boundary forces[10].

The significant teleseismicity in this supposedly mid-plate region led Sykes[2] to propose that a new convergent plate boundary may be in the process of forming between Sri Lanka and northwestern Australia. Sykes argued that a new plate boundary would accommodate plate motions that have been resisted by the continuing collision between continental India and Asia. However, Stein and Okal[4] questioned the nascent island arc hypothesis of Sykes[2]. They noted an apparent association between the Ninetyeast Ridge north of about 10° S and several large earthquakes which have occurred since the early part of the century. Stein and Okal[4] proposed that the northern part of the Ninetyeast Ridge is either a plate boundary characterized by left lateral strike slip motion, or that it is the focus of earthquake activity in an area of highly unusual mid-plate tectonics. In either event, the intraplate earthquakes and *in situ* stress measurements (Figs 1 and 2) show clearly that horizontal compression currently characterizes a major portion of the Indo-Australian plate.

Deformation structures

Direct evidence for deformation within the oceanic part of the Indo-Australian plate was found by Eittreim and Ewing[11] from a seismic reflection survey of a small area at the distal end of the Bengal Fan (Fig. 2). The reflection records revealed folding of the sediments and high-angle faulting through to basement along an azimuth of ~100°. Further north in the thicker sedimentary section of the Bay of Bengal, Curray and Moore[12] and Moore *et al.*[13] recognized deformed sediments beneath a prominent unconformity and refracting surface that they could trace throughout the Bay. These previous studies showed that tectonic disturbance of originally flat-lying sediments should be easily seen on seismic reflection records with typical vertical exaggerations of 25 : 1. With this in mind, we examined available seismic records from the northeastern sector of the Indian Ocean (held by Lamont-Doherty Geological Observatory and the National Solar-Terrestrial Geophysical Data Center in Boulder, Colorado) to delineate the geographical extent of permanent deformation within the oceanic portion of the Indo-Australian plate, and to determine the types of structures produced at the surface of oceanic lithosphere deformed under horizontal compression. Clear evidence for intraplate deformation is observed only in seismic reflection records from the southern portions of the Bengal and Nicobar Fans, where deformation of oceanic crust and overlying sediments can be resolved into two parts based on dominant 'wavelengths'.

On a broad scale (100–300 km), acoustic basement (probably oceanic crust) is deformed into 'undulations' with 1–3 km of relief (Fig. 3). Large amplitude (30–80 mGal) free-air gravity anomalies are clearly associated with the broad basement features. Gravity anomalies of such amplitudes and wavelengths will arise if the observed undulations reflect uniform bending of the entire oceanic crust[8]. Sea surface heights measured from numerous GEOS 3 orbital paths across the northern Indian Ocean also reflect the broad-scale basement features interpreted from seismic reflection data and marine gravity data (Fig. 3), although small geoidal undulations with wavelengths 100–300 km are less accurately determined by satellite altimetry than by marine gravimetry[14].

On a smaller scale (5–20 km), seismic reflection data from the southern part of the Bengal Fan and the Nicobar Fan[15] reveal high-angle faulting of acoustic basement (oceanic crust) and overlying sediments, and folding of the sedimentary section. (Note, for example, the faulted basement high 200 km from the left side of Fig. 3 and the general disturbed nature of the sediment cover on this profile.) Two seismic reflection profiles from the southern part of the Bengal Fan, which show typical characteristics of the smaller-scale deformation west of the Ninetyeast Ridge, are shown in Fig. 4.

Of particular importance are the high-angle faults which disrupt the oceanic crust and most of the overlying sedimentary section (Fig. 4*a*, *b*). The involvement of oceanic crust in the faulting precludes movement along a surface of decollement above basement as a cause of the deformation. Spatially, the short-wavelength structures are concentrated at 'deformation fronts' where high-angle faults are particularly closely spaced (see Fig. 4*a*). These deformation fronts, which often form barriers to the southward movement of turbidites over the fan, are separated by less disrupted terrane particularly west of about 86° E.

The seismic profile shown in Fig. 4*b*, which is located between 86° E and the Ninetyeast Ridge, is interesting because it is located very close to the epicentre determined for a $M_s = 6.1$ (ref. 8) strike slip earthquake[5] (Fig. 2). Near the epicentre, high-angle faults which disrupt acoustic basement with throws of the order of hundreds of metres cause little offset of the seafloor (Fig. 4*b*). In fact, 3.5 kHz echosounder data show that these faults offset the sea floor and immediate sub-sea floor reflectors by only 9–18 m. Offsets that increase with depth suggest that the

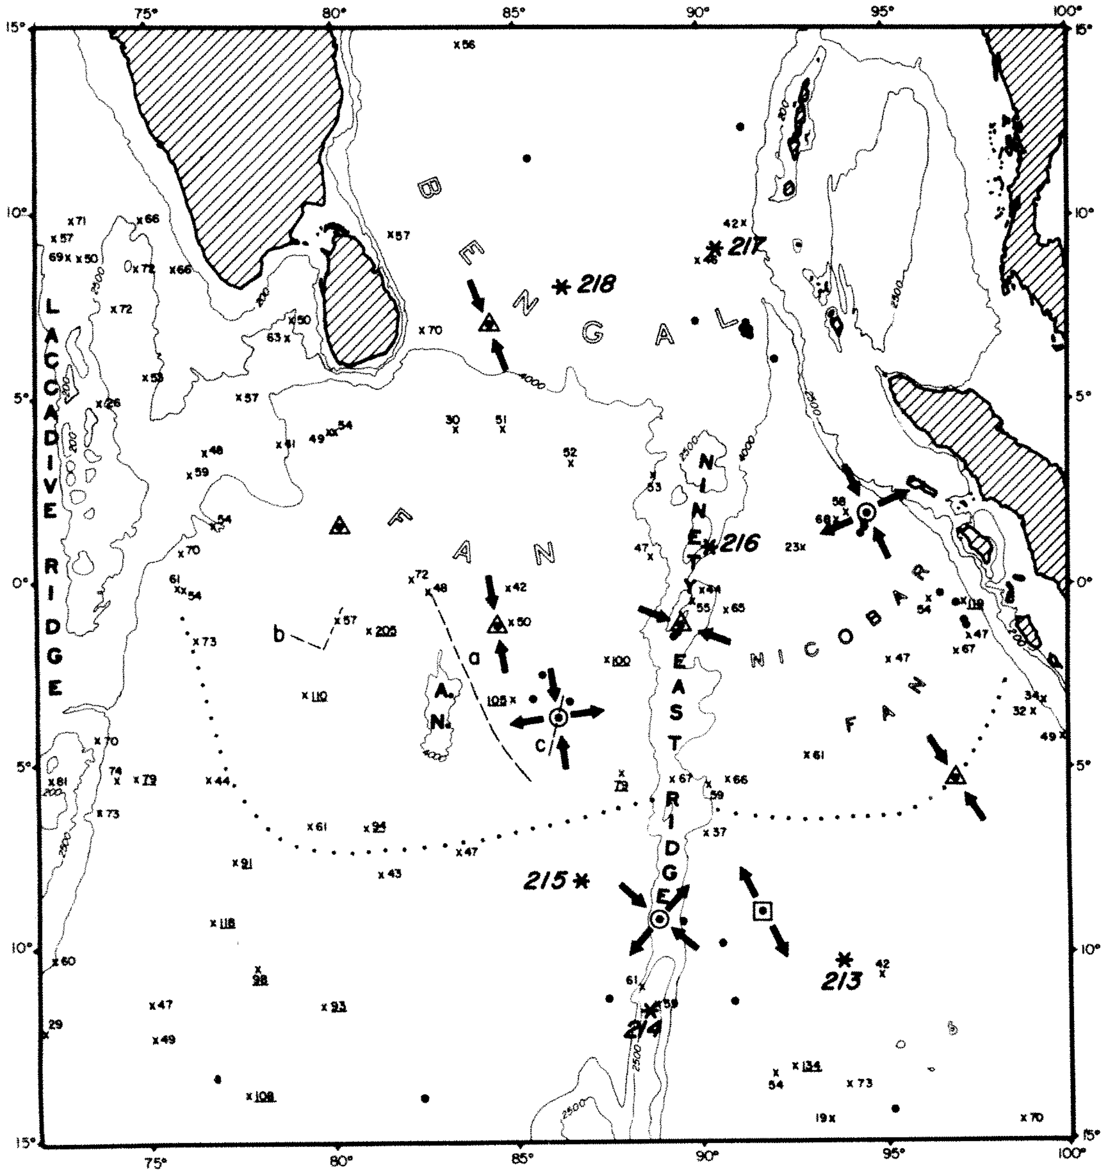

Fig. 2 Directions of principal stress axes for intraplate earthquakes[2–8] and heat flow values[20,34] in mW m^{-2} (numbered crosses) in the northern Central Indian Ocean. [Note that 41.87 mW m^{-2} = 1 HFU (μcal cm^{-2} s^{-1})]. ●, Intraplate earthquakes. ▲, Focal mechanisms with thrust faulting; ⊙, with strike slip faulting; ⊡, normal faulting[4]. Unexpectedly high heat flow values are underlined. *, DSDP sites. The southern limit of fan deposits is shown roughly by the dotted line. Dashed lines locate seismic reflection profiles shown in Figs 3 and 4. AN, Afanazy Nikitin seamount group.

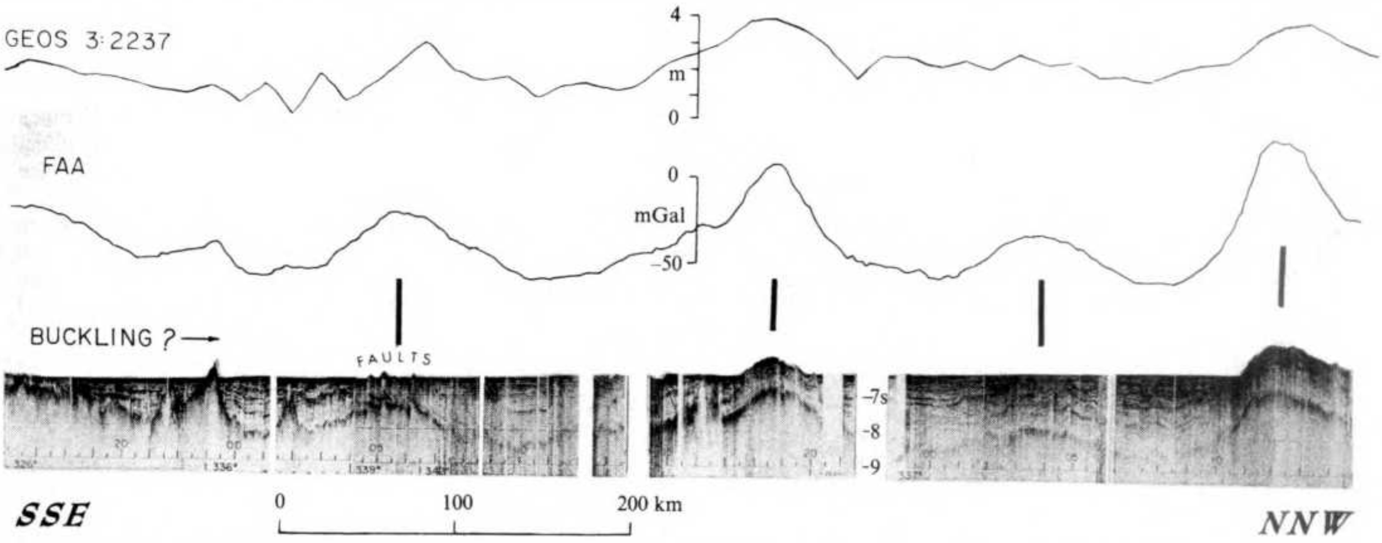

Fig. 3 Broad-scale deformation of the oceanic crust beneath the southern portion of the Bengal Fan (profile a in Fig. 2). Large-amplitude free-air gravity anomalies (FAA) and small-amplitude geoidal undulations (GEOS 3:2237) correlate with the basement deformation.

faults may be growth structures. The small scale structures show a preferred structural asymmetry; the north side is generally upthrown on the high-angle faults and the asymmetric folds, which are likely caused by drag on faults, are generally southward-verging.

Sediments below a prominent unconformity show geometrically conformable structures while above this unconformity the intensity of deformation decreases towards the sea floor (Fig. 4*a*, *b*). At DSDP Site 218, which is further north in the Bay of Bengal (Fig. 2), a widespread unconformity and refracting surface separating locally deformed strata from overlying fan turbidites was found to be uppermost Miocene in age[13,16]. It is likely that this is the major unconformity observed in the seismic reflection records as all Lamont-Doherty piston cores which penetrated the section beneath the unconformity over the southern part of the Bengal Fan contained uppermost Miocene or older faunal groups (ref. 17 and G. Blechschmidt, personal communication). We suggest, from drilling and coring results and the seismic reflection data, that intraplate deformation began in late Miocene time, and that this event is recorded by a prominent unconformity in the sedimentary section of the Bengal Fan.

Both the broad- and small-scale structures provide convincing evidence for deformation remote from the generally accepted boundaries of the Indo–Australian plate. Figure 5 is a map of the broad- and small-scale structures based primarily on single-channel seismic reflection data and gravity data. Several points should be noted. First, the trends of the basement 'undulations' change from ENE–WSW near the Ninetyeast Ridge to E–W or even WNW–ESE in the southwestern part of the Bengal Fan. Second, the basement undulations show culminations and saddles along their trends. Third, the broad structures appear disrupted by the major fracture zone at 86° E which offsets E–W trending magnetic lineations left-laterally by about 850 km (ref. 18). Acoustic basement is shallower on the eastern side of this fracture zone by about 1 km. Fourth, between the 86° E fracture zone and the Ninetyeast Ridge, the trends of the small-scale folds and faults may differ from the trends of the broad basement undulations (Fig. 5). Given the difficulty of tracing individual faults or folds from track to track with the available data distribution, however, this last point should be regarded as tentative.

The available seismic reflection records show that sediment and upper crustal deformation extends from the southern part of the Bengal Fan across the Ninetyeast Ridge into the northwestern Wharton Basin. Compared with the structures observed in the Bengal Fan, deformation of Nicobar Fan sediments in the Wharton Basin appears less severe[15], but seismic reflection coverage is more extensive west of the Ninetyeast Ridge. Seismic profiles over the Ninetyeast Ridge reveal high-angle faulting[19], although the crust of the Ninetyeast Ridge is not as extensively disrupted as the oceanic crust beneath the Bengal Fan. This is unexpected considering the apparent association of relatively large-magnitude earthquakes and the northern portion of the Ninetyeast Ridge[4], and we return to this point below.

Heat flow

The third geophysical parameter which reflects significant tectonic activity within the Indo–Australian plate is heat flow. Presently available geothermal measurements in the northern part of the Indian Ocean (Fig. 2) are mainly random values obtained with the Ewing thermograd (Lamont-Doherty Geological Observatory), or with the Bullard probe (Scripps Institution of Oceanography)[20]. Most heat flow observations lie within the 50–60 mW m^{-2} range predicted for the late Cretaceous through early Eocene crust in the northeastern Indian Ocean[18] by the cooling half-space model for oceanic lithosphere[21]. However, several measurements (that are judged reliable[20]) within the region of deformation delineated by seismic reflection, and some apparently outside that region, yield heat flow values considerably higher than expected (underlined values in Fig. 2). The mean of these high values (107 ± 36 mW m^{-2}) is appropriate for heat flow in lithosphere much younger than the early Eocene–late Cretaceous age established for this region from magnetic lineations[18]. The occurrence of abnormally high values scattered amongst normal values in a mid-plate region is indeed unusual, these are the only excessively high values in old lithosphere in the entire Indian Ocean[20].

Measurement of anomalous heat flow in the oceans is not unusual in itself. Active hydrothermal convection of seawater affects fully one-third of the ocean floor[22]; values lower than the predicted heat loss are expected in such geothermal regimes, as unmeasured heat is being carried from the sea floor by convecting fluids. However, in areas with a thick, uniform sedimentary cover (such as the areas covered by fan deposits in Fig. 2), heat loss by convection is unlikely to occur[23,24]. To explain abnormally high values scattered among expected values, local heat sources in addition to the normal heat flux from the lithosphere must contribute to these values. We believe that the additional heat required is associated with the intraplate deformation and we speculate that heat generated by friction on faults in the crust during earthquakes might be involved. If this is the case, there should be a close spatial correlation between the most

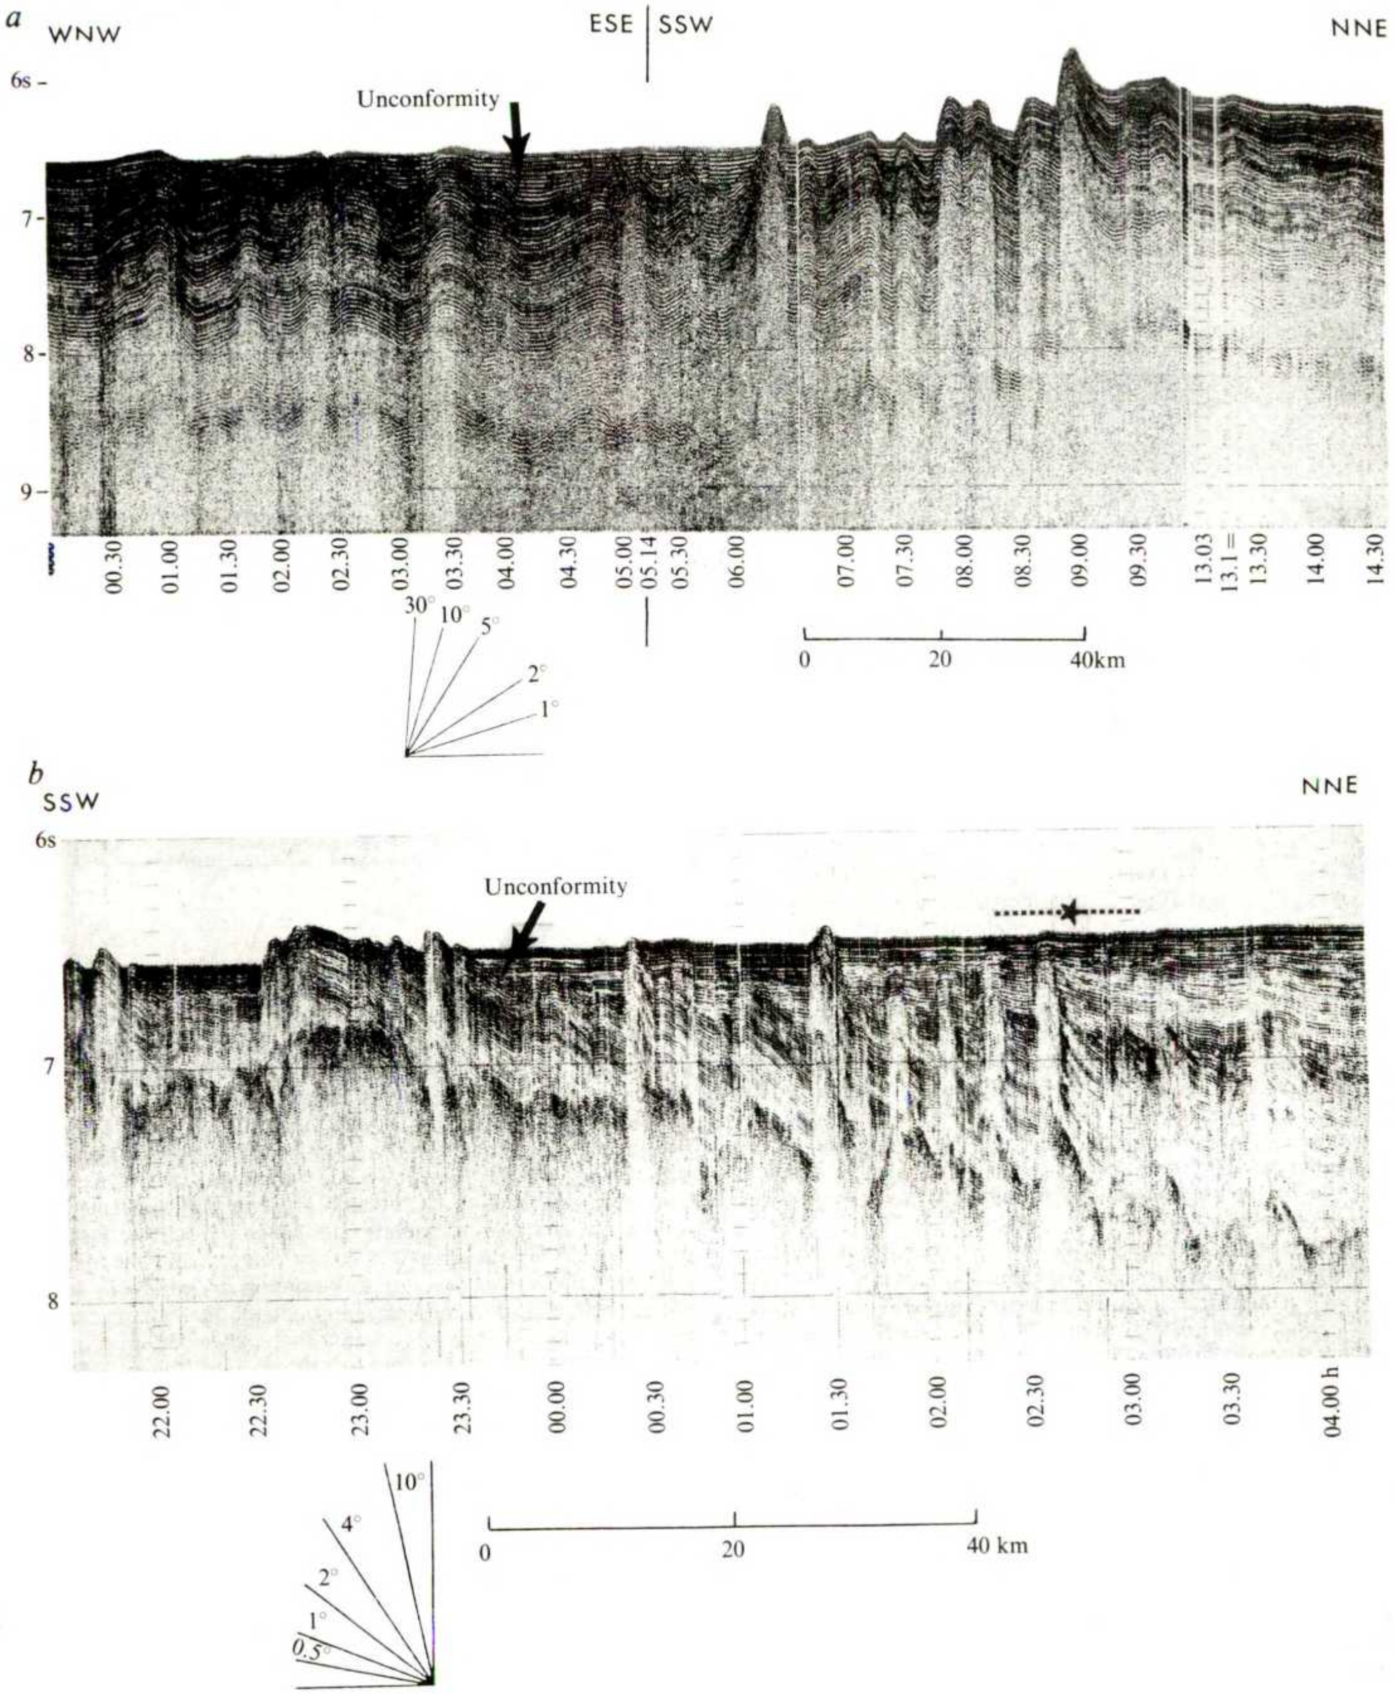

Fig. 4 *a*, Single-channel seismic reflection profile which crosses a promifnt deformation front in the southwestern portion of the Bengal Fan (profile b in Fig. 2). Note the course change near the middle of the profile. On the WNW–ESE track segment, sediment structures have wavelengths that are long compared to those for structures along the SSW–NNE track segment, indicating an approximate E–W structural grain in the area of this profile. The major unconformity marked by the arrow is probably uppermost Miocene in age (refs 13, 16, 17 and G. Blechschmidt, personal communication). VE ~ 20 : 1. *b*, Single-channel seismic reflection profile that passes very close to the epicentre of a strike slip intraplate earthquake (profile c in Fig. 2) denoted by star and broken line. The major uppermost Miocene unconformity is particularly clear on this profile. Note the difference in fault offsets of basement and of the sea floor in the vicinity of the epicentre. VE ~ 22 : 1.

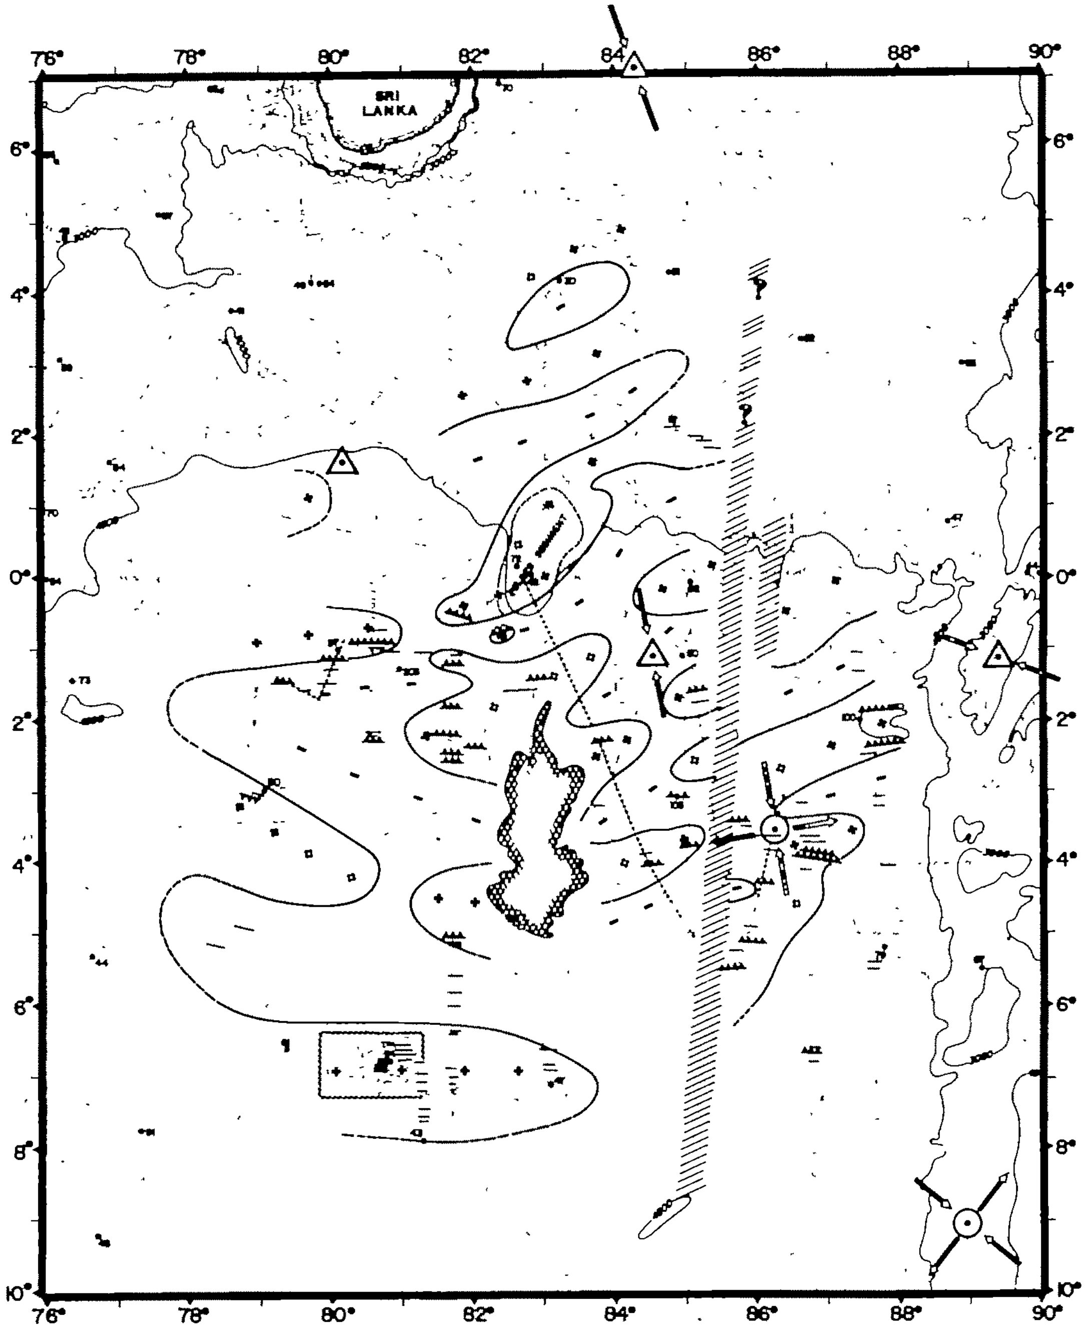

Fig. 5 Broad-scale basement structures are outlined by the heavy lines. Plus signs denote relative highs and minus signs relative lows. Saw-tooth symbols denote outcrop of major high-angle faults with the saw teeth on the upthrown side. Minor high-angle faults are the lighter lines. Numbered dots are heat flow values[20,34] taken from Fig. 2. Principal stress directions for intraplate earthquakes are also from Fig. 2. A major fracture zone at about 85° E with 850 km of left-lateral offset[18] is denoted by the single hatching. The Afanazy Nikitin seamount group is outlined by cross-hatching. Ships' tracks are shown by light dotted lines while the heavy portions denote profiles shown in Figs 2–4. The boxed area at 7° S, 80° E is the survey area of Eittreim and Ewing[11].

tectonically disturbed areas and abnormally high heat flow values. This speculation remains to be tested because available heat flow measurements are too widely spaced (Fig. 2).

Limitations of the data

Because seismicity, seismic reflection data and heat flow define regions of intraplate activity of different geographic extents, an examination of the limitations and special characteristics of these three geophysical parameters is warranted here.

The use of single-channel seismic reflection data to map the geographic extent of deformed oceanic crust and the types of structures produced by tectonic stress is limited by several factors. First, the sound sources used to acquire most of the data available to us were too small to penetrate completely through the thick sedimentary section in the Bay of Bengal. Second, while seismic records with large vertical exaggerations provide a good qualitative picture of the structures developed in response to tectonic stress, a quantitative determination of the dips of the observed high-angle faults is not obtainable. Thus, whether the faults are normal or reverse cannot yet be determined. Third, although the deformation of the Indo–Australian plate recorded in seismic reflection data from the southern part of the Bengal Fan is undoubtedly important, it is possible that other regions of the plate have undergone significant deformation which is not readily apparent in single-channel seismic data. It must be realized that thick stratified sediments provide ideal conditions for examining deformation structures acoustically whereas the same amount of crustal deformation might be difficult to detect in areas devoid of sediment cover or in areas with a thin acoustically transparent pelagic drape.

The time window resolved by each parameter is another factor to be borne in mind when comparing the geographic extents of deformation indicated by earthquake seismology, heat flow, and seismic reflection. Earthquakes have been recorded only for the most recent fraction of geological time. Yet, earthquakes reveal stress information from continental as well as oceanic areas (Fig. 1). Abnormally high heat flow values observed today (Fig. 2) may reflect movements in the crust that occurred long ago compared to the time span of earthquake seismology. Assuming that these anomalous values are expressions at the sea floor of frictional heat generated at the surface of the crust by intraplate earthquakes, we can determine the time taken for conduction of a frictional heat pulse to the sea floor. For a sediment column 1-km thick and an assumed thermal diffusivity of 10^{-2} cm^2 s^{-1}, the peak value of anomalous heat flow reaches the sea floor $\geq 10^5$ yr after generation of the heat pulse in the oceanic crust[25]. The longest time window is resolved by seismic reflection data because seismic profiles portray the entire history of sedimentation and intraplate deformation in the interior of the Indo–Australian plate. As noted above, the disruption of post-Miocene sediments decreases towards the sea floor (Fig. 4*a*, *b*), so that at seismic sound source frequencies, deformation of sediments which have been deposited during the time spanned by historical seismology is not detectable. However, offsets of the sea floor and immediate sub-sea floor reflectors of several metres can be resolved using high frequency (3.5 kHz) sound sources.

Discussion

The evidence presented above for the internal deformation of the Indo–Australian plate allows us to develop a working hypothesis to explain these observations. Several aspects of this have been touched on by previous workers[2-4,11,26].

Intraplate compression capable of causing widespread deformation within the Indo–Australian plate probably arose in late Miocene time, according to DSDP and piston core evidence. Assuming that intraplate stress is sensitive to forces applied at plate boundaries and to the base of the plates[10], we speculate that a major tectonic event could have effected changes in forces acting on the Indo–Australian plate in Miocene time, triggering the observed intraplate deformation. The inception and growth of the Himalayan chain in post-Oligocene time has been cited as a significant change in the collisional tectonics between India and Asia[26-28]. From initial contact in the Eocene until early Miocene, deformation was accommodated along a contact zone between India and Asia, whereas intra-continental thrusting within the Indian block has occurred since the early Miocene[27]. If the second or Himalayan stage of collision between India and Asia greatly increased resistive forces along the plate edge and these were transmitted to the interior of the plate as large horizontal compression, a late Miocene onset of intraplate deformation might reasonably be expected. As suggested originally by Curray and Moore[12], the sedimentation and deformation histories of the deep sea fans of the northern Indian Ocean likely reflect major tectonic events in the collision between India and Asia.

Whatever the history of the intraplate compression, its magnitude has been sufficient to deform oceanic lithosphere into broad undulations (Fig. 3), and produce brittle failure in the oceanic crust (Fig. 4*a*, *b*) over a large area in the northern Indian Ocean (Fig. 5). The general appearance of the deformation is that of a buckled plate (Fig. 3). Assuming that a thin elastic plate of Young's modulus 6.5×10^{11} dyn cm^{-2} is buckled under horizontal compression into a wavelength of 160 km, we determine an apparent elastic thickness for the plate of 12 km and a buckling stress[29] of 24 kbar. However, experiments in rock mechanics indicate that yielding by fracture occurs near the surface of the plate and deformation by flow occurs deep within the lithosphere before such high stresses determined from elastic models are attained[30,31]. The fact that brittle deformation is widely observed in seismic profiles over the region of intraplate deformation suggests that the upper part of the plate has been exposed to stresses in the kbar range. An interesting outcome of the buckling calculation is the anomalously thin effective elastic thickness implied by the wavelength of the undulations. Observations of lithospheric flexure in the oceans have shown that the effective elastic thickness increases with the age of the lithosphere at the time of loading[32]. At the onset of intraplate deformation in late Miocene time, the oceanic lithosphere beneath the southern Bengal Fan would normally have an effective elastic thickness[32] of 20–30 km. This is greater by a factor of ~2 than the 12 km obtained by treating the intraplate deformation as a buckling effect. Assuming that the elastic plate model applies to the real Earth, this discrepancy may indicate either that since the interior of the plate came under large horizontal compression several million years ago the original elastic 'core' of the oceanic lithosphere has been reduced in thickness by yielding at the top and bottom of the plate, or oceanic lithosphere responds to uniform horizontal compression in a way that is different to its response to surface loads.

The large region of permanent strain inferred from seismic reflection data suggests that if the Indo–Australian plate consists of two distinct plates at present, convergence between these plates may be accommodated in a complicated, non-uniform way over a zone several hundred kilometres wide rather than along an obvious plate boundary. This point is important to plate kinematics considerations, as Minster and Jordan[33] found that by treating the Indo–Australian plate as two plates, they could overcome systematic misfits between their model for present-day plate motions (which included a single Indo–Australian plate), and observed Indian Ocean spreading rates and directions. They showed that the observed rates and directions around the Indian Ocean are consistent with about 1 cm yr^{-1} of NW–SE convergence between an 'Indian' plate and an 'Australian' plate along the northern part of the Ninetyeast Ridge[33]. An order of magnitude calculation by Stein and Okal[4] using seismic moments of large events on the Ninetyeast Ridge, produced left lateral slip at a rate of 2.2 cm yr^{-1} along the ridge, consistent with the convergence rate determined by Minster and Jordan[33]. Although both sets of calculations have limitations, the general agreement between them suggests, at first glance, that the northern part of the Ninetyeast Ridge is a resolvable strike-slip plate boundary between the two parts of the Indo–Australian plate. Aside from the question of continuity of this plate boundary, the slip rate along the Ninetyeast Ridge determined by Stein and Okal[4] would relieve all strains predicted from the calculation of Minster and Jordan[33] without any internal deformation of the lithosphere away from the Ninetyeast Ridge. The observations discussed here show that all tectonic displacement between an 'Australian' and an 'Indian' plate is not accommodated by slip along the northern part of the Ninetyeast Ridge, even though strains accumulated through intraplate deformation away from the Ridge are not determinable from the available data.

Finally, do the observations, particularly the seismic reflection data, indicate the impending formation of an intra-oceanic lithosphere subduction zone as suggested by Sykes[2]? While both the broad undulations and the brittle deformation observed in seismic records (Figs 3 and 4) can be attributed to large horizontal compressions within the plate, fracturing of the crust occurs on high-angle faults and not on shallow-angle thrusts that might herald the beginnings of subduction. During our examination of the available reflection data from the north-east Indian Ocean, we found only one example (near 4° S; 87° E) of possible shallow underthrusting (from south to north) throughout the entire region of intraplate deformation within the Indo–Australian plate. We feel that this question cannot be answered at present.

We thank Bhoopal Naini for his contribution to the early phases of this study. John Bodine, Terry Engelder, Dennis Hayes, Klaus Jacob, Lynn Sykes, and Tony Watts critically read the manuscript. This work was supported by NSF grant OCE 79-25070. Lamont-Doherty Geol. Obs. contribution no. 3024.

Actin in the inner ear: the remarkable structure of the stereocilium

The actin filament bundle in the stereocilium of the cochlear hair cell has liquid transverse order, but paracrystalline axial order. A single bonding rule, which determines how a cross bridging protein links neighbouring filaments, accounts for this unusual structure. Such liquid order is possible for bundles of other filamentous proteins.

CRYSTALLINE order consists of chemically identical subunits arranged in identical environments. In such an arrangement, we can conclude that the bonding rule for any one subunit is the same as that for all other subunits, even though the details of the atomic interactions between subunits may be unknown. In biological structures the exact equivalence of crystalline bonds is quite often relaxed to a condition of quasi-equivalence[1]. In a quasi-equivalent structure, chemically identical subunits are deformed slightly so that bonds can be formed between subunits which are in almost but not exactly identical environments. In such a structure all subunits make essentially the same specific contacts and thus can be described by a single bonding rule. The concept of the specific bond, which leads to the equivalent or quasi-equivalent arrangement of subunits, has been the basis for understanding the organization of macromolecules in a number of protein-containing structures such as the spherical and rod-shaped viruses, microtubules, and actin filaments.

Biologists, however, do not often find the regular order seen in the examples above. In micrographs of many cellular structures such as the terminal web in the cells of the intestinal brush border[2], the organization is accompanied by great disorder. Compared to such disordered structures, the bundle of actin in the stereocilium of the inner ear of the alligator lizard appears highly ordered. Yet, to the protein crystallographer, who is accustomed to the near perfect regularity of crystals, the most striking feature of this bundle would be its disorder. The stereocilium is an organizational intermediate between the regular order of the icosahedral viruses and the irregular order of the terminal web. It is interesting because it gives us insight into the organization of partially disordered structures.

The stereocilia or hairs of the hair cells, which extend outward from the apical surface, are elongated processes responsible for the transduction of sound; that is, motion of the stereocilia caused by sound produces changes in the membrane potential of the hair cell. Structural studies of the hair cells in the cochlea of the alligator lizard[3,4] show that each hair cell contains about 75 stereocilia of varying size with the largest having a length of 30 μm and a diameter of 0.8 μm. Within each stereocilium is a large polar bundle[5] of more than 3,000 actin filaments which shows an irregular liquid order in transverse section[6] (Fig. 1*a*). Surprisingly some transverse sections show a periodic motif we call festooning, which starts at one edge of the stereocilium and continues to the other (Fig. 1*b*). How can such long-range lateral periodicity arise in a structure with no discernible lateral order? The answer lies in the helical symmetry of the actin and provides insights into the structural principles governing actin bundles and bundles of helical filaments in general.

What is festooning?

The motif seen in the images consists of scalloped rows of actin filaments rather like the folds in drapes pulled to the side of a window. The scalloped rows lie one on top of the other to create the festooned motif. The separation between rows is of the order of 100 Å and seems to be constant in all stereocilia. In contrast, the period of the festooning is large, being of the order of 1,000 Å. In a single section cut through all 75 of the stereocilia that extend from a single hair cell, the direction and period of festooning are generally constant from one stereocilium to the next, but often different for stereocilia from neighbouring hair cells. In an occasional hair cell, however, the stereocilia are disturbed so that, instead of all being exactly parallel to each other, they extend at different angles. In such cells both the period and the direction of the festooning vary considerably. For example, in Fig. 1*c* stereocilium A has a period of 2,400 Å and in a neighbouring stereocilium, B, the direction of the festooning is rotated nearly 90° and the period is 960 Å.

What gives rise to festooning? If the motif simply and directly reflects a corresponding structural organization of the linked actin filaments, then different patterns of festooning would have to correspond to different structural organizations within the stereocilia. Alternatively, we propose that all stereocilia have a single common structure and the different motifs arise from

0028–0836/80/390291—06$01.00

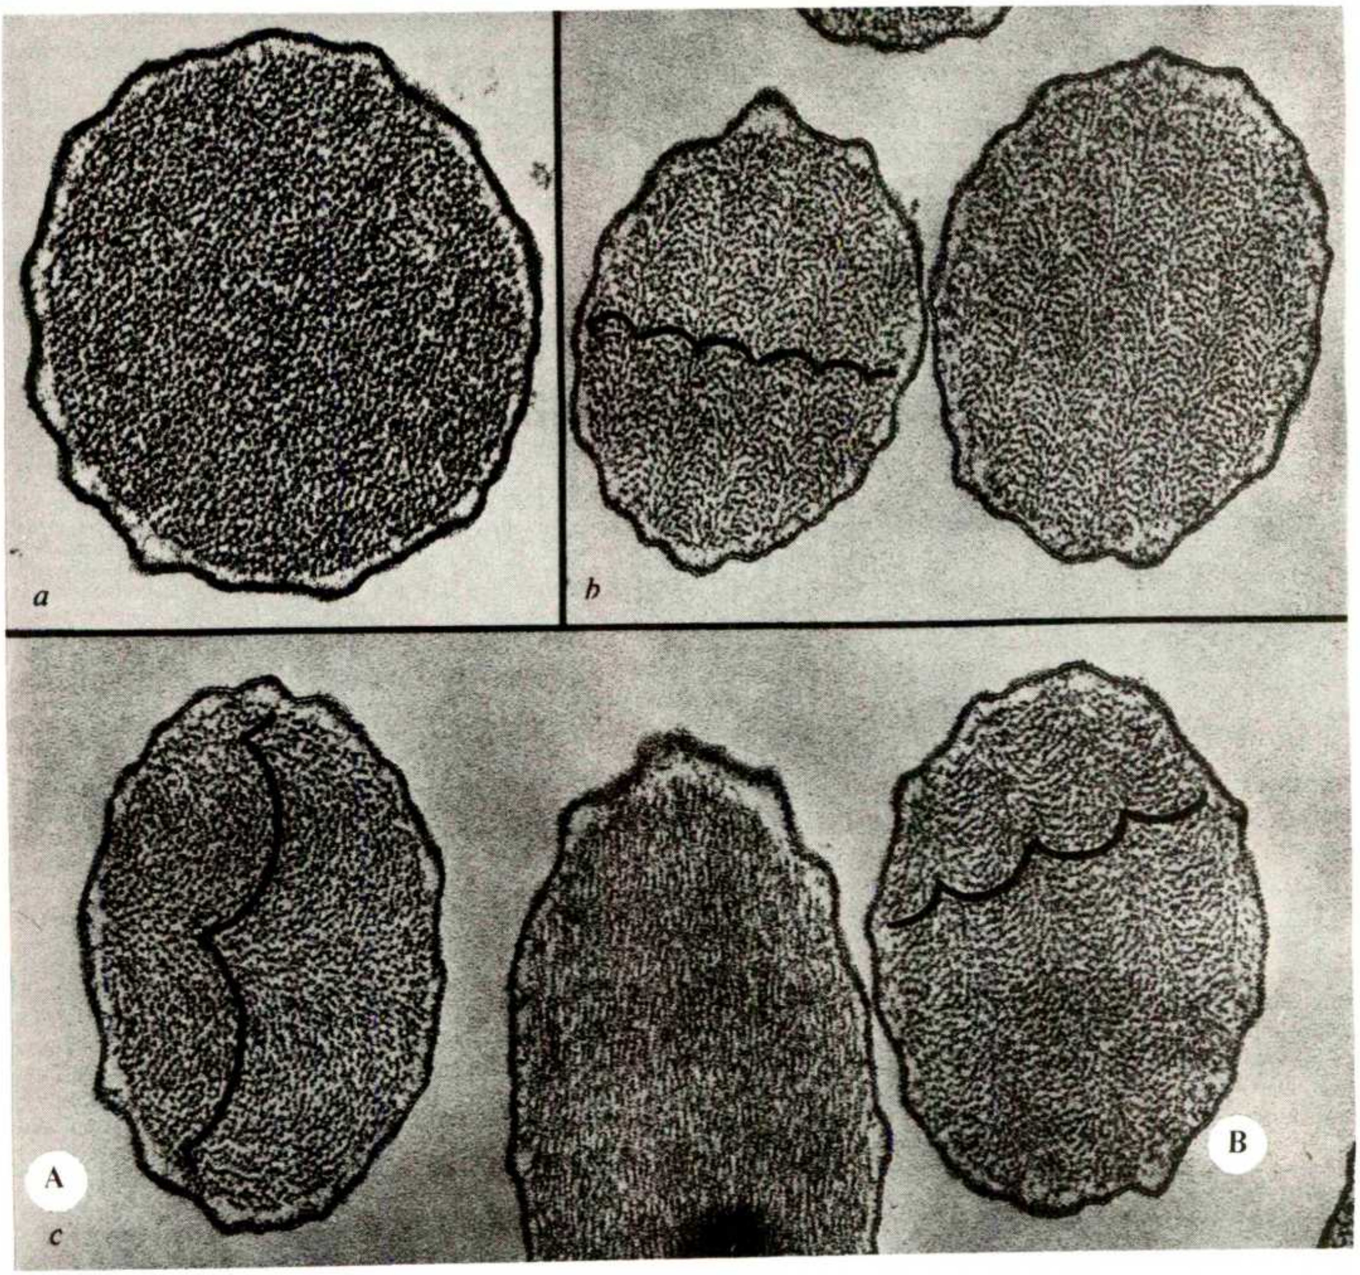

Fig. 1 *a*, Thick transverse section (375 Å or thicker) of a stereocilium from the cochlea of the alligator lizard. Thick sections give no hint of a long-range spatial periodicity but show a liquid arrangement of filaments having a mean interfilament spacing of 100 Å. Optical diffraction patterns of such sections confirm the liquid order showing a pattern consisting of a single diffuse ring. *b*, Thin transverse section of two stereocilia. This section, which is of the order of 200 Å thick, shows a scalloped or festooned pattern with a period of 680 Å. Note that the period and direction of the pattern are the same in both stereocilia. *c*, Thin transverse section of a group of stereocilia. In this cell the orderly and parallel arrangement of stereocilia has been disturbed. As a result the period and direction of festooning are different for different stereocilia. The period in stereocilium A is 2,400 Å and that in B is 960 Å. All magnifications are 120,000.

different orientations of the stereocilia relative to the plane of section. Many features of festooning are explicable as a consequence of taking a thin oblique section through layers of parallel rods, where each successive layer is rotated with respect to the previous layer. This was observed by Bouligand *et al.* for arrangements of chromatin fibres[7]. In the same way, if the crossbridges linking filaments are helically arranged, the axial pattern of crossbridges will be converted into a transverse motif by a slight tilting of the plane of section off a true transverse direction. This is similar to Reedy's discussion[8] of thin sections of insect flight muscle in which a motif having a long period is seen to arise from the periodic crossbridging of myosin to actin. If this explanation is correct for the stereocilium, the period of festooning should depend on the angle of the section relative to the axis of the stereocilium and the direction of the festooning on the direction of the tilt of the stereocilium relative to the knife in the microtome. Differences in the images of different stereocilia then would not indicate differences in structure but rather differences in the magnitude and direction of tilt of the stereocilium relative to the plane of section. Moreover, the festooning should disappear when the section thickness reaches the axial repeat period of the crossbridges.

Bundles with hexagonally arranged filaments

In order to see how these predictions were made, we examined the nature of crossbridges in needles, another bundle of actin filaments formed *in vitro* from sea urchin egg extracts[9,10]. In the needles, actin filaments are linked together by a second protein, fascin. The lattice that describes the positions of the filaments is a hexagonal one. The pattern of crossbridges between filaments, however, cannot be truly hexagonal since the actin filaments to which they are attached do not have hexagonal symmetry. If actin had hexagonal symmetry, it would be possible to construct a crystalline bundle in which all crossbridges are in equivalent, hexagonally related positions. Because actin is helical, however, some of its subunits are in approximately the correct position to make such bonds, so that if 13° of bending is allowed, crossbridges can be formed to link every actin filament to its six nearest neighbours. The resulting structure is thus formed from nearly equivalent or quasi-equivalent bonds.

In the needle, the locations of crossbridges are easily found by finding the positions of pairs of bonding sites on neighbouring filaments in the array. Figure 2*a* shows three filaments taken from a hexagonal array. Let us begin by arranging filaments A and B so that a crossbridge is made at position 2. In the hexagonal array, the bonding rule requires that crossbridged filaments be in axial register and be separated by the appropriate distance (about 85 Å). Using this bonding rule, we find we can also make crossbridges between filaments A and C at position 7 and between filaments B and C at position 11. Some bending of crossbridges is needed to achieve bonding at the different sites, but the amount of bending required, which varies depending on position, is never more than about 13°. The bonding scheme is shown diagrammatically in Fig. 2*b* and from it we see that all neighbouring filaments are linked together. Note that although the diagram is for the first 14 subunits, the crossbridging occurs along the entire length of the bundle so that for any pair of actin filaments, there will be one crossbridge per 375 Å repeat.

How can such a bonding scheme lead to festooning in a bundle? Imagine we cut a thin nearly transverse section through a bundle as is shown diagrammatically for one row of filaments in Fig. 3*a*. The section is thin relative to the axial repeat of the crossbridges, and the plane of section is tilted relative to the bundle axis. At the left-hand edge the crossbridges contained in the section point towards 3 and 9 o'clock. As we progress in the section to the right, the crossbridges included in the section point towards 5 and 11 o'clock. Continuing to the right, the included crossbridges again change direction to 7 and 1 o'clock and then, to complete one repeat of the pattern, to 3 and 9 o'clock. The pattern of crossbridges seen looking down on the section is shown in the top line of Fig. 3*b*. If we extend this pattern from one row to that expected for a hexagonal bundle, we get the festooned pattern shown in Fig. 3*b*. The festooning arises from a conversion of the axial periodicity of crossbridges into a transverse period by the tilt of the almost transverse section. We can make a number of predictions:

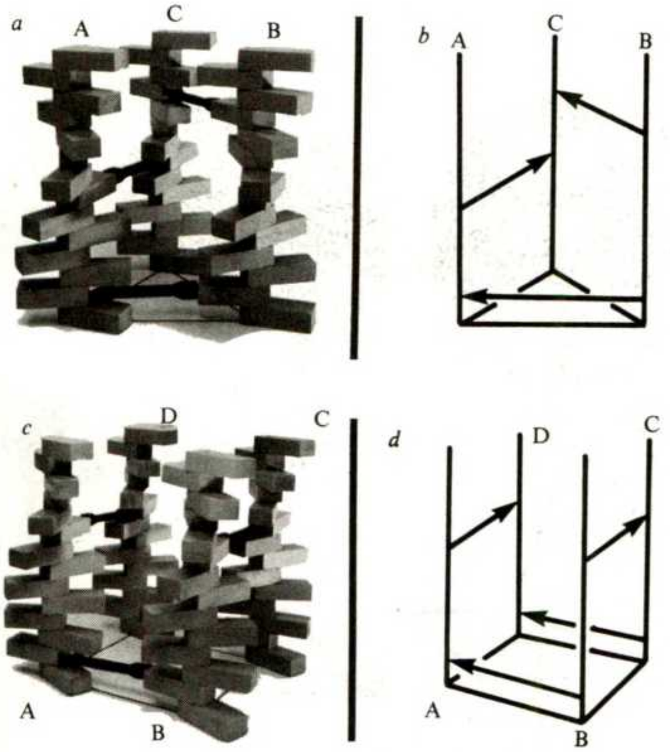

Fig. 2 *a*, Model depicting the arrangement of crossbridges in hexagonally arranged filaments. Three model filaments having the helical symmetry of actin are sitting on three vertices of a hexagonal lattice. The filaments are rotationally set so that the lowest subunit or block on each is pointing in the same direction. The bonding rule, arbitrarily chosen, allows a crossbridge (black arrow) to join the outer end of a subunit on one filament to an inner end on a neighbouring subunit. Such a crossbridge linking filaments A and B is seen at subunit 2, the next to lowest subunit. Because of the helical symmetry of the models, a crossbridge also links filaments C and A at subunit 7 and filaments C and B at subunit 11. The crossbridges which link these three filaments together will link together all the filaments in a hexagonal array. *b*, Schematic drawing of the crossbridging scheme depicted in *a*. *c*, Model depicting the arrangement of crossbridges in tetragonally arranged filaments. Four model filaments identical to those in *a* are sitting on the vertices of a tetragonal lattice. The filaments are rotationally set so that the lowest subunit in each is pointing in the same direction. The bonding rule, which is the same as that in *a*, allows a crossbridge at subunit 2 between filaments A and B and between filaments D and C. Filaments A and D and B and C are crossbridged at subunit 9. With this bonding rule, all the filaments in a tetragonal lattice can be crossbridged. The point of this figure is that the same bonding rule can crossbridge either a hexagonal or a tetragonal array of filaments. *d*, Schematic drawing of the crossbridging scheme depicted in *c*.

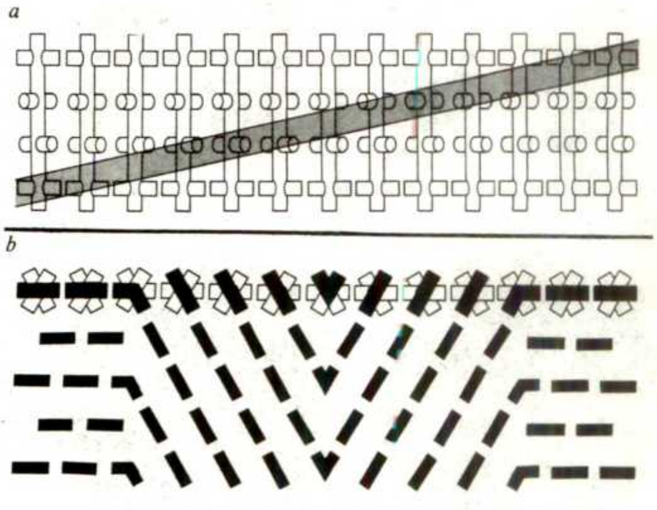

Fig. 3 Scheme showing how festooning arises. *a*, Thin section taken through a single row of filaments—side view. A row of filaments is shown schematically with the crossbridging material drawn in as a series of rods projecting from the cylinder. The portion of the row included in the thin section is indicated by the grey area. *b*, Top view of thin section. If the thin section is viewed from the top, the pattern indicated by blackened bars would be seen. In the upper row the crossbridges not included in the section are drawn in for reference but are not blackened. This row corresponds to the row of filaments in *a*. The remaining rows complete the pattern expected for a hexagonal array of filaments. Thus the second row from the top is shifted left half the interfilament spacing. Row three is a repeat of row one and so on. The result is a festooned pattern.

(1) The pattern should disappear as the section thickness approaches the repeat of 375 Å, since each section will contain crossbridges from one filament to all of its neighbours.

(2) The direction of the festooning depends on the orientation of the knife relative to the axis of the bundle.

(3) In a pair of serial sections of thickness, *t*, the festooned pattern should shift by *t*/375 of its period. Thus if we cut 125-Å sections, the pattern should shift laterally by 1/3 of a festoon in consecutive or serial sections. The period and direction of the motif remain unchanged.

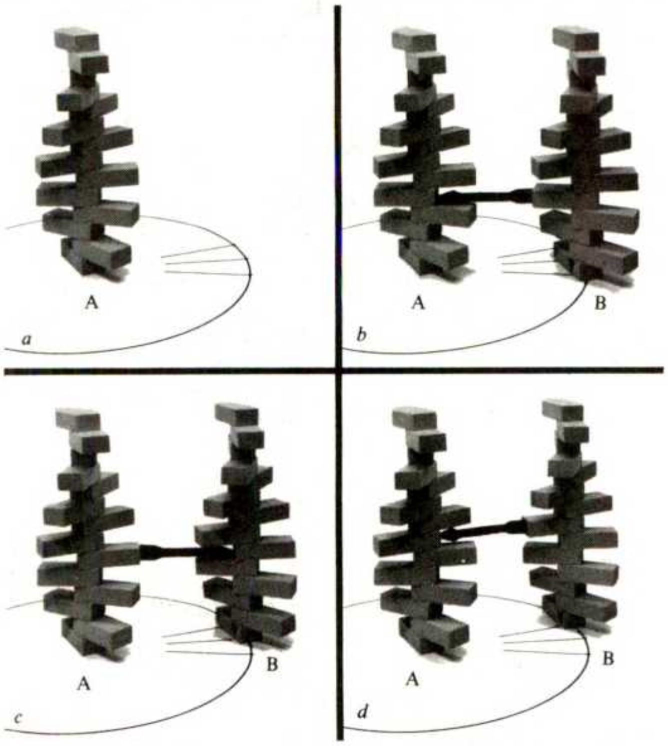

Fig. 4 Model showing the potential of helices to be crossbridged. *a*, Single model filament at the centre of a circle indicating the bonding distance. Three radial lines are drawn to indicate three positions separated by the equivalent of about 10 Å. *b*, Crossbridge formed between a pair of filaments. If a second (outer) filament is placed at the first position and rotationally set so it is in register with the central filament, then, given the bonding rule (see Fig. 2), a crossbridge can be formed at the fifth subunit from the bottom. *c*, Crossbridge formed when the outer filament is moved to second position. If the outer filament is moved around the central filament by the equivalent of 10 Å (or 13°), the most favourable position for a crossbridge is at the sixth subunit from the bottom. Note that the outer filament is moved so that the two filaments remain in register. *d*, Crossbridge expected when the outer filament is in the third position. In the third position, the most favourable subunit for crossbridging is the seventh one from the bottom. Note that as the outer filament moves around the central one in a counter-clockwise manner (as viewed from the top), the most favourable position for a crossbridge rises on the central filament. Continuing this process, we conclude that the outer filament can be crossbridged to the inner one at any position along the circle if a modest amount of crossbridge bending is allowed.

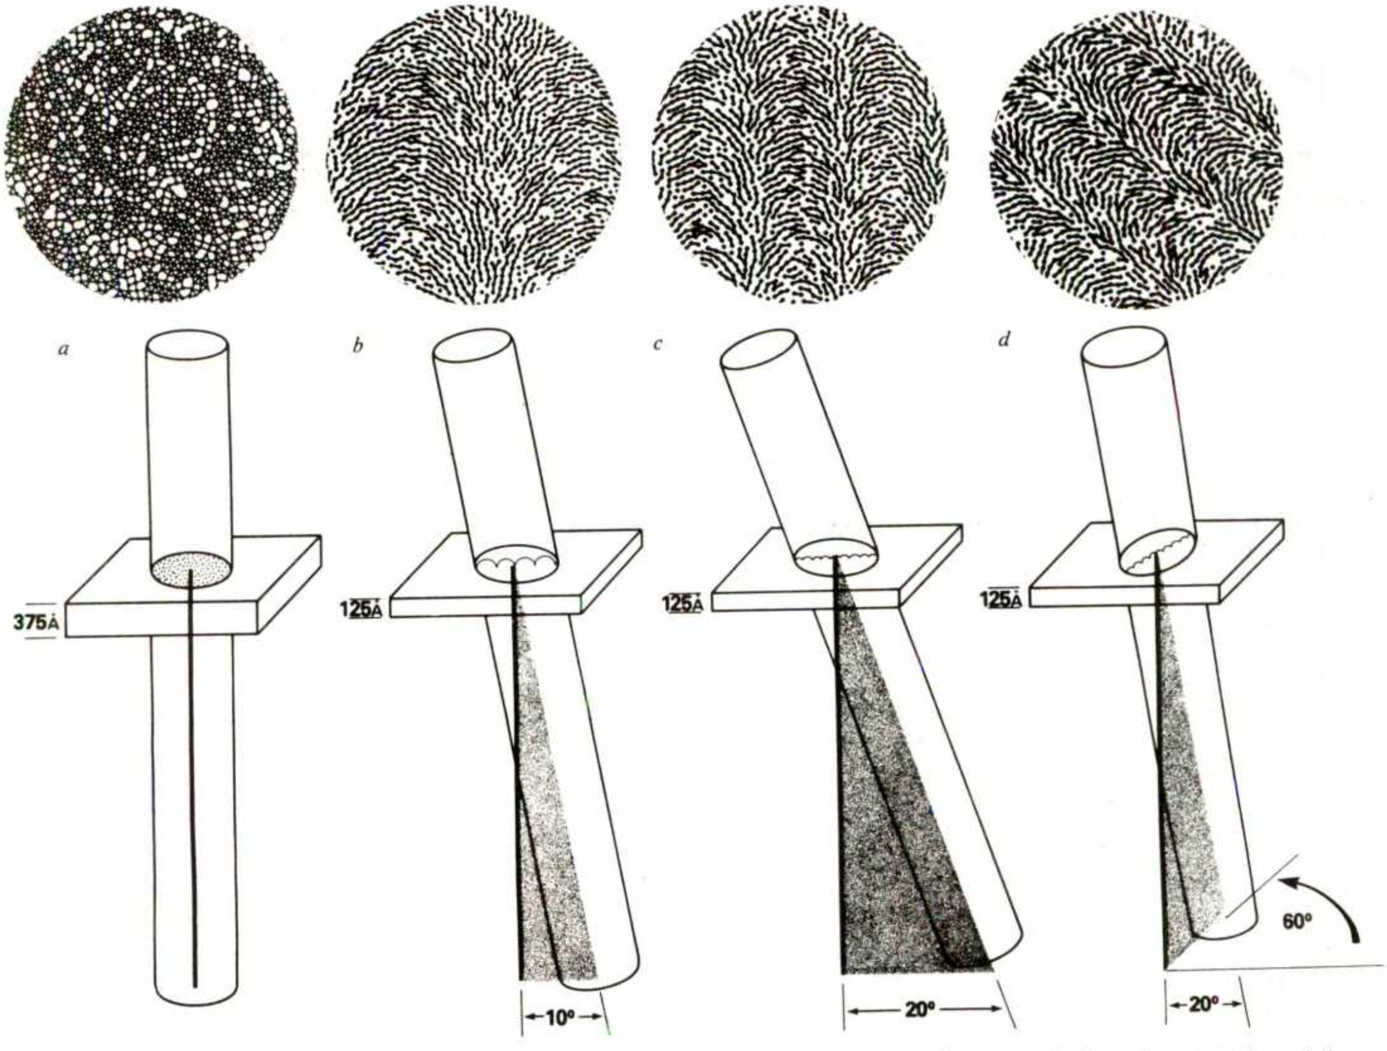

Fig. 5 *a*, Computer simulation of a thick section. If the section thickness is at least the crossbridge repeat of 375 Å, no festooning is seen since crossbridges pointing in all directions from each filament are included in the section. The computer has generated a liquid array of filaments and crossbridges and simulated a 375-Å thick section. *b*, Computer simulation of a thin section cut at a tilt of 10°. The same array of filaments is used as in *a*, but the computer simulated a 125-Å thick section cut at a tilt of 10°. The result is a festooned pattern having a long repeat. *c*, Computer simulation of a thin section cut at a tilt of 20°. Since the tilt is in the same direction the pattern runs in the same direction but has a finer period. *d*, Computer simulation of a thin section cut at 20° tilt but direction of tilt rotated 60°. The effect is to rotate the direction of the pattern 20° but leave the period unchanged.

(4) The period of festooning, *l*, should depend on the tilt of the section relative to the bundle. More specifically, the period should be equal to the axial repeat, *d*, of the crossbridges divided by the sine of the angle by which the bundle is tilted off the normal to the plane of the section, that is, $l = d/\sin\theta$. For actin, $d \simeq 375$ Å and thus a festooning period of 1,000 Å corresponds to a tilt of $\sin^{-1}(375/1{,}000) \simeq 22°$.

(5) The scalloping in the pattern in Fig. 3*c* has its convex side up. If the hand of the helical arrangement of crossbridges is reversed, the pattern would reverse to one with its convex side down. Thus, the asymmetry of the motif can be used to determine the hand of the crossbridges, which depends on the hand of the actin filaments.

In a previous paper[6] we verified these predictions experimentally, but we were unable to understand how the predictions could be valid when the actin filament locations, as seen in transverse section, had no regular order. Although there is no such order in transverse sections, in longitudinal sections we found that actin filaments appeared paracrystalline; that is, they had their cross-over points in register. The question is therefore: how can a bundle of actin filaments maintain itself in perfect longitudinal register yet be disordered in transverse section?

Our key to resolving the paradox came from our study[10] of the bonding rule for the crossbridging of filaments in the hexagonally packed bundles such as the needle from extracts of sea urchin oocytes, in which all filaments are in register. The axial register of the filaments is a requirement because if the filaments were rotated or translated relative to each other, none of the bonding sites, as shown in Fig. 2*a*, would be in the correct orientation and at the correct height to allow crossbridging. Thus, our ability to crossbridge filament A to B, B to C and C to A depends on the cross-over points being in register.

Bundles with tetragonally arranged filaments

What is special about this bonding rule is that we can also make a bundle in which the filaments lie on a tetragonal lattice instead of a hexagonal one. In Fig. 2*c*, the filaments A, B, C and D are placed at the corners of a square. They are arranged so that A is crossbridged to B and C to D at position 2. This is the same crossbridge that is formed at position 2 in the hexagonal bundles. In the tetragonal arrangement we find that at position 9 we can make a crossbridge from A to C and from B to D thus linking together the bundle. The amount of bending of crossbridges is similar to that required in the hexagonal case. Only two crossbridges, however, are made in the first 14 subunits instead of three as is the case in the hexagonal bundle. What we have shown is that the same specific bonds can generate either a tetragonal or a hexagonal bundle.

We can generalize from these two types of bundles by extracting the rules that govern the crossbridging between a pair of filaments. In Fig. 4 the two filaments are placed together so that the cross-over points are in register so that the filaments can be crossbridged. In Fig. 4*b*, a crossbridge can be made at position 5. This crossbridge can still be made if we move filament B about 10 Å along the circle drawn around filament A. At this point less crossbridge bending is required if we change the crossbridge from position 5 to position 6 (Fig. 4*c*). When we again move by 10 Å, the crossbridge changes to position 7 (Fig. 4*d*). The bending of the crossbridges varies depending on the relationship between the two filaments and on the symmetry of the actin, that is the number of subunits per turn. For actin filaments having the symmetry of those in the stereocilium (2.159 units per turn), the crossbridges need be bent no more than 13°, which is the same value found in the fascin crossbridges in the needle. The important point is that two actin filaments can be crossbridged if they are in register and are separated by the length of a crossbridge; or, in other words, if we draw about a filament a circle whose radius is equal to the length of a crossbridge, a second filament put anywhere on the circle can be crossbridged to the first filament provided that the two filaments have their cross-over points in axial register.

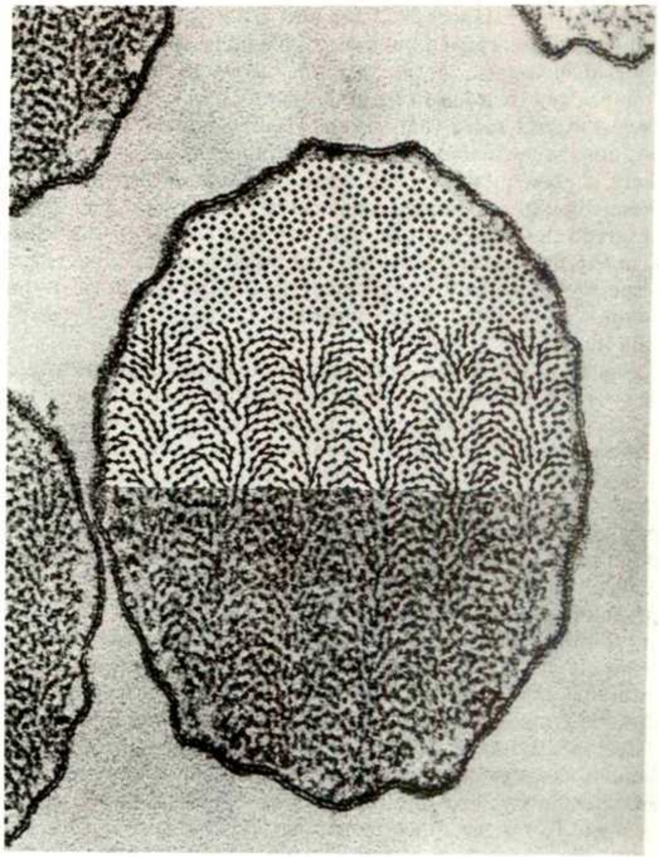

Fig. 6 Composite of the computer-generated array of filaments, filament plus crossbridges, and a thin section of a stereocilium. The top half of the stereocilium has been replaced by a computer-generated thin section that mimics the true pattern. The computer-generated section corresponds to a 150 Å section cut at an angle of 35°. The crossbridges in the upper part of the display are omitted so that the liquid arrangement of filament axes can be easily seen. ×155,000.

Bundles with a liquid arrangement of filaments

With the bonding rule formulated in the preceding sentence, we can generate a liquid-like bundle with specific crossbridges. To demonstrate this, we generated a liquid-like arrangement of filaments using a Monte-Carlo random number generating method. For specifying filament locations, a 512 by 512 element grid, with a scale of 1 grid element = 10 Å, was used. The probability of locating a filament at a given grid position increased as a function of the number of other filaments to which it could be crossbridged. A radial probability function, $P(r)$, was created which incorporated volume exclusion (for $r < 70$ Å, $P(r) = 0$, so no two filaments could be closer than 70 Å apart). $P(r)$ also had a large peak at the crossbridging distance, 100 Å, to reflect the likelihood for two neighbouring filaments to be crossbridged to each other. The grid was scanned, element by element, with the probability of creating a filament at a given grid element equal to P_T, where

$$P_T = 1 - \exp\left[-\sum_i P(r_i)\right]$$

$P(r_i)$ is the radial probability function evaluated for all filaments,

i, located at distances, r_i, from the given grid element. The summation was carried out over all filaments within a radius of 15 grid elements. In the resulting array all filaments were crossbridged to at least one other filament, but, due to volume exclusion, not more than seven. Figures 5*a* and 6 show the positions of the filaments generated by this technique. Note that there is no regularity in the array. The spatial distribution of these computer-simulated filaments is strikingly similar to that observed in the stereocilia. This was true both with regard to filament density and isotropy, and was confirmed by visual inspection as well as comparison of the Fourier transform of the computer-generated array with that of thick sections of stereocilia (Fig. 1*a*).

Figure 5*a* shows the array with all the crossbridges as would be seen in a thick section. These crossbridges are easily drawn in as, according to the scheme illustrated in Fig. 4, all filaments separated by the appropriate distance can be crossbridged. Note how extensively crossbridged the array is. Let us now examine thin sections of the array. The model tells us how the height of a particular crossbridge in the array depends on the direction it points. We set the array so that all crossbridges pointing from 3 to 9 o'clock lie at a height, $h = 0$. If we took a thin section perpendicular to the bundle at $h = 0$, we would find that all the crossbridges which point from 3 to 9 o'clock would lie in this plane. If we look at the next section above the first, we would find that the crossbridges in that section would point in a direction rotated counterclockwise to that in the section at $h = 0$. Thus, in thin sections that are perfectly perpendicular to the bundle, the festooning would not be seen but rather we would see filaments joined into parallel line segments by the crossbridges. If, on the other hand, the sections were cut off the perpendicular, the crossbridge direction would change continuously as the section passes through different heights within the bundle. As we start the section at $h = 0$, the crossbridges would point from 3 to 9 o'clock. As the section moves up, the direction of crossbridges included in the sections shifts in a counterclockwise direction which produces the curved line segments seen in the festooned motif. This effect shows up beautifully in the computer displays. In these displays we varied the angle and direction of tilt of the bundle relative to the plane of the section. Figure 5*b* shows the equivalent of a 125-Å section taken at a tilt of 10°, and Fig. 5*c* shows the same section for a tilt of 20°. Note the change in the period but not direction of festooning. In Fig. 5*d* the direction of tilt is altered by 60° but the tilt is kept at 20°. Note that the direction of festooning, but not its period, changes.

With the computer-generated model we are thus able to produce the festooning seen in electron micrographs of thin sections of the stereocilium (Fig. 6). This model has the following features which mimic the behaviour of the stereocilium on sectioning.

(1) Sections much less than 375 Å in thickness show festooning whereas those about 375 Å lose their festooned motif.

(2) In serial sections the festooning appears to shift laterally by an amount which is proportional to the section thickness.

(3) A change in tilt produces a change in the period of festooning.

(4) In longitudinal sections the filaments are in perfect register.

(5) In Fig. 5*b* the festooned motif has its convex side upward. If the hand of the actin and the crossbridges were reversed, the convex side would be down. Actual tilting of the stereocilia during sectioning, as shown in Fig. 5*b*, shows exactly the convex side-up festooning we predicted. This confirms the hand of the arrangement of crossbridges shown in Fig. 4 (that is, as the filament changes position from that in Fig. 4*b* to Fig. 4*d* the crossbridge moves up rather than down the filament). Thus, the paradox of how one can get crystalline axial order and liquid transverse order is resolved. A liquid-like bundle of filaments with helical symmetry can be crossbridged together with specific bonds, provided that all the filaments are in register. Turning the statement around, we propose that a single crossbridge between any two filaments will force them into register. As this constraint applies to each successive filament in the bundle regardless of their lateral order, the self-assembled bundle must have all its filaments in register. Thus, no external structure is needed to align the filaments; they do it themselves.

What are the biological advantages of a liquid arrangement? Presumably, such a bundle can be put together more quickly than the corresponding hexagonal bundle as the restrictions on placement of filaments in the former are much less than in the latter. For example, the formation of cell extensions such as the actin-containing filopodium[11] can take place much more rapidly because the actin filaments need not make and break connections to become hexagonally packed, a process which takes considerable time. In needle formation, at early times the needles lack transverse order much as the stereocilia of the lizard. On incubation the ordering increases until, after many hours, hexagonally packed filaments are observed[12].

In the hexagonal bundle, the number of crossbridges is a maximum. With increasing disorder in filament position, there will be decreasing numbers of crossbridges. In the limiting case of a very disordered bundle, the paucity of crossbridges will lead to reduced rigidity. This may provide a mechanism for building of bundles of different rigidity or for altering their rigidity after assembly. Exposure to prolonged intense sound produces limp stereocilia, and perhaps this results from alterations in the crossbridges[13].

We have shown that the concept of specific bonding applies to the actin bundles with liquid lateral order in which all crossbridges are in almost identical environments. The potential for such organization is a consequence of the helical symmetry of the actin filaments in which the radial orientation of subunits allows bonding to take place at any angular position around a filament. What is particularly interesting is that the bonding rule for a pair of filaments, at least as we have outlined it here, does not determine the lateral organization. The resulting bundle may be hexagonal as in stereocilia of the chicken (data not shown). Alternatively, using the same bonding rule, the bundle may have only liquid lateral order as in the stereocilia of the alligator lizard. The regularity of filament arrangement would thus not appear to be a consquence of the bonding properties of the actin and its crossbridges. Rather, we suppose that control over this aspect of organization is determined by the conditions at the time of assembly.

Finally, our conclusions about crossbridging between actin filaments can apply equally well to the crossbridging of other helical filaments, for example microtubules or intermediate filaments.

We thank Emma Jean Battles for processing the tissue and cutting sections, Betti Goren for drawing in Fig. 5, and Bill Saunders for photography of the models. We also thank Penny Caponigro and Louise Seidel for help in preparing the manuscript. This work was supported by grants NSF GB22863 to L.G.T. and NSF PCM78-15913 and NIH GM21189 to D.J.D. E.E. is supported by a Dretzin fellowship.

Resolution, reconstitution and kinetics of the primary action of a hormone receptor

Yoav Citri & Michael Schramm

Department of Biological Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

The β-adrenergic receptor (R) and the GTP binding protein (G) with which the receptor interacts were obtained in separate soluble fractions. Their recombination produced a hormone responsive system. In the presence of hormone the encounter of R with G in the reconstituted membrane occurs much faster than the subsequent R-induced activation of G.

THE interaction of a hormone or neurotransmitter receptor with the next component along the pathway of signal transmission can be defined as the primary action of the receptor. Resolution of its participating components and subsequent reconstitution are essential to the understanding of the molecular mechanism of receptor function. Unfortunately, this initial step has not been sufficiently characterized even for the much studied insulin[1], acetylcholine[2] and α-adrenergic receptors[3].

There is, however, considerable information about the activation sequence of the β-adrenergic receptor[4,5]: the hormone–receptor complex (R°)[6,7] activates a guanyl nucleotide binding component (G) by introducing GTP into it[8,9]. The activated G (G*) interacts with the catalytic unit (C) of the adenylate cyclase to form the active enzyme (G*C)[10]. Hydrolysis of the bound GTP terminates activation[11]. Replacement of GTP by the hydrolysis-resistant analogue Gpp(NH)p produces a persistently active enzyme complex (G*C)[12]. The process may be described by the following steps:

$$\text{(1)} \qquad R^\circ + G \xrightarrow{k_1} R^\circ G$$

$$\text{(2)} \qquad R^\circ G + \text{Gpp(NH)p} \xrightarrow{k_2} R^\circ + G^* \quad (G^* = G_{\text{Gpp(NH)p}})$$

$$\text{(3)} \qquad G^* + C \xrightarrow{k_3} G^*C$$

Step (1) is the encounter of R° and G in the membrane; step (2) is the R°-induced introduction of Gpp(NH)p into G; and step (3) is the interaction of G* with C to form the persistently active adenylate cyclase. k_1, k_2 and k_3 are the forward rate constants of steps (1)–(3) respectively.

The function of R has so far been investigated only by measuring adenylate cyclase activity in the intact cell membrane. On the basis of such kinetic studies, many models for the action of R in the activation of adenylate cyclase were proposed[4,13–15]. It is, however, extremely difficult to reach definitive conclusions from such studies because the relative amounts of R, G and C in the membrane are fixed and because the function of R is not measured directly in its primary action on G (Steps (1) and (2)), but rather, indirectly, through the action of G* on C (Step (3)).

We have now succeeded in obtaining separate solubilized preparations of R and of G, both free of functional C. Various amounts of the two preparations can be combined to reconstitute functional systems with the desired R to G ratios. When hormone and Gpp(NH)p are added, persistently activated G* is produced. The amount of G* is subsequently measured in a separate system, by its implantation in the membrane of cells which contain an excess of C but no functional G[16–18]. The kinetics of R action on G are found to be first order with respect to R concentration, and zero order with respect to G concentration. The nature of receptor function is discussed in the light of these findings.

Resolution and recoupling of R and G

Solubilization of a functional receptor and its implantation in a cell membrane have been recently reported from our laboratory[19]. Since the solubilized fraction had both R and G activities, we searched for a preparatory step to obtain a membrane preparation which would contain R but no G or C. It was found that treatment with strong alkaline buffer (pH 11.9) eliminated essentially all G and C activity of the membrane, leaving R undamaged. Subsequent treatment of the alkali extracted membrane with deoxycholate produced solubilized R free of G and C. The solubilized G preparation, essentially free of R and C, was obtained by cholate extraction[20]. Mixing of the soluble R preparation with the soluble G preparation, followed by removal of detergents and phospholipid treatment, gave a functional hormone responsive system. The entire procedure of solubilization and reconstitution is shown schematically in Fig. 1. The primary action of the β-adrenergic receptor is studied in the reconstituted system by measuring its product G*. The amount of G* is determined by the proportional enhancement of adenylate cyclase activity in cyc⁻ cells which lack functional G. This activity will be referred to as 'G activated' (Figs 2–5).

Table 1 Specific activities of R in the reconstituted system and in erythrocyte membrane preparations

Systems and treatments	Amount of R* (a)	Rate of G activation† (b)	Specific activity of R‡ (b/a)
I Reconstituted RG, activated by hormone + Gpp(NH)p, fused with cyc⁻	85	12	0.14
II NEM treated membranes activated by hormone + Gpp(NH)p and fused with cyc⁻	169	56	0.33
III Membranes activated by hormone + Gpp(NH)p	72	23	0 32
IV Membranes activated by hormone + Gpp(NH)p fused with each other	72	12	0.17

Systems were activated (2 or 3 min) with 10 μM isoprenaline + 10 μM Gpp(NH)p at 30 °C. Activation was terminated with 10 μM propranolol and after 0 5 min, 10 μM GTP was added. The systems were immediately placed in ice. Adenylate cyclase was measured either directly or after fusion with cyc⁻ cells ('Rate of G activation'). The amount of receptor (R) was determined by binding of ^{125}I-hydroxybenzylpindolol[14] System I: reconstitution was produced by R and G mixing 1 : 1 (v/v) (as described in Fig. 1). System II: membranes were treated with *N*-ethylmaleimide selectively to inactivate the catalytic unit (C)[18,19] After activation, as described above, membranes were treated with phospholipids (40 μl ml^{-1} containing 1 mg protein), pelleted and fused with cyc⁻ cells (Fig. 1). System III. membranes were activated as above, washed once and assayed for adenylate cyclase activity. System IV. membranes activated as in III went through the fusion process, without cyc⁻ cells, and were then assayed for adenylate cyclase

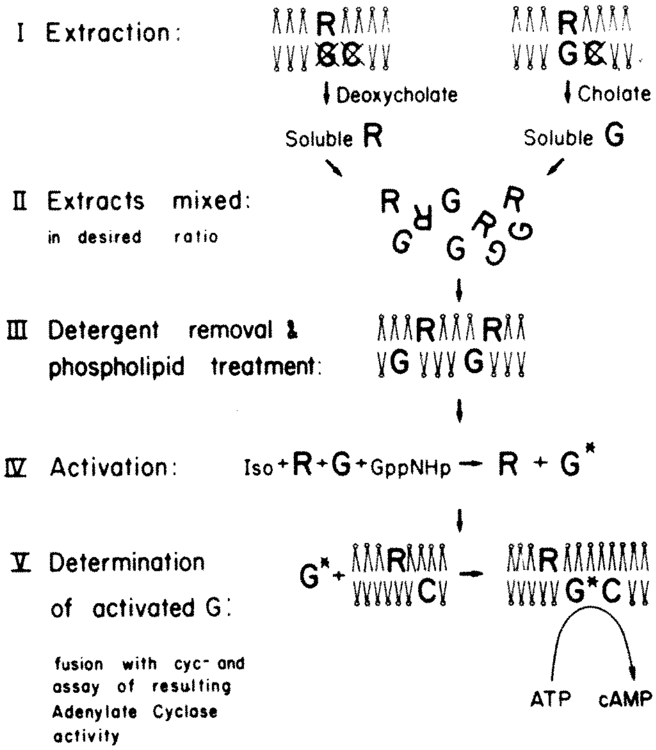

Fig. 1 Scheme describing the differential solubilization and reconstitution of the β-adrenergic receptor and the guanyl nucleotide binding protein. R is the β-adrenergic receptor; G is the guanyl nucleotide binding unit; G* is the Gpp(NH)p activated G unit, and C is the adenylate cyclase catalytic unit. *Receptor extraction*: Turkey erythrocyte membranes[19] were washed with 10 mM MOPS buffer, *p*H 7.5, containing 1 mM mercaptoethanol, and were suspended at 1 mg ml^{-1} in 50 mM phosphate buffer, *p*H 11.9, containing 2 mM EDTA. The suspension was kept for 20 min at 4 °C, centrifuged at 27,000 *g* for 15 min, and resuspended in 20 mM MOPS buffer, 1 mM mercaptoethanol, in half the previous volume. The G unit is lost during this treatment together with 50% of the membrane protein. The alkali extracted membranes, when fused with cyc$^-$ cells, contribute only negligible amounts of G as measured by adenylate cyclase activity. The alkali extracted membranes were treated with phospholipid (10 mg ml^{-1} soybean phospholipid in 10 mM Tris HCl buffer, *p*H 7.5, 1 mM EDTA, sonicated twice for 5 min under N_2), as previously described[19], only that 0.2 ml phospholipid was added per ml of membrane suspension. After incubation at 4 °C in presence of 10 mM $MgCl_2$, 20 μM isoprenaline was added, and the membranes were incubated for 15 min at 30 °C with occasional stirring. The suspension was cooled at 4 °C, centrifuged at 18,000 *g* for 10 min, and resuspended in solubilization buffer[19] at one-ninth the original volume (which served for alkaline extraction). The membranes were solubilized by the addition of one volume of sodium deoxycholate, 12 mg ml^{-1}, in solubilization buffer[19]. The supernatant, after centrifugation at 200,000 *g* for 30 min, served as the soluble R preparation (0.4 mg protein per ml). *G unit extraction*: The procedure was adapted from that of Sternweis and Gilman[20]. Turkey erythrocyte membranes were washed and resuspended at 10 mg protein per ml in cholate solubilization buffer (20 mM HEPES, *p*H 8.0, 2 mM mercaptoethanol, 1 mM $MgCl_2$, 0.2 mM EGTA, 20 μM phenylmethylsulphonyl fluoride). One volume of 20 mg ml^{-1} cholate in the above buffer was added, the suspension was shaken for 30 min at 4 °C, and centrifuged at 200,000 *g* for 30 min. The supernatant served as the G preparation (0.9 mg protein per ml). The procedure apparently inactivated the catalytic unit. *Mixing of solubilized R with solubilized G*: To produce the desired ratio of R:G, the appropriate volumes of the two extracts were mixed. Controls containing only G or only R were mixed with the complementary pure detergent solution instead of the complementary extract. *Detergent removal*: Polystyrene SM-2 beads were added as previously described[19]. The preparations were subsequently treated with phospholipids, 150 μl ml^{-1}, as described above. *Activation*: The phospholipid-treated preparations were incubated at 30 °C with the synthetic hormone isoprenaline (10 μM) or the receptor blocker propranolol (10 μM) plus the non-hydrolysable GTP analogue guanosine 5′-(β, γ-imino)-triphosphate (Gpp(NH)p) (10 μM). After the desired time period, activation was terminated by addition of 10 μM propranolol and 10–100 μM GTP. The mixture was kept at 4 °C for 20 min. After centrifugation at 18,000 g for 10 min, the pellets were frozen in liquid N_2 and stored at −70 °C. These pellets had no detectable adenylate cyclase activity. *Determination of activated G*: Each pellet described above was fused [19,32] with 3×10^7 cells of the mutant cyc$^-$ S49 lymphoma which lacks functional G (refs 16, 17). The resulting increase in basal adenylate cyclase activity was measured in presence of 2 μM propranolol. This activity, referred to as 'G activated', can be attributed solely to the amount of activated G which was transferred by fusion to cyc$^-$ membranes. R of the cyc$^-$ cells (section V above) has no function in this assay. The resulting basal adenylate cyclase activity was directly proportional to the amount of activated G placed in the fusion system. The total amount of G (non-activated plus activated) implanted in the cyc$^-$ membranes was determined by measuring adenylate cyclase activity in presence of 0.1 mM isoprenaline plus 0.1 mM Gpp(NH)p. Adenylate cyclase activity in presence of 10 mM NaF also gave a measure of G units transferred by fusion. These assays were performed at 37 °C for 30 min[33]. *Yield of R and of G*: The β-adrenergic receptor in the R preparation was 0.3 pmol per ml of extract, as determined by binding of ^{125}I-hydroxybenzylpindolol[34] after detergent removal. The G preparation is estimated to contain 2.5 pmol GTP binding sites per ml. The calculation is based on a 50% yield in the cholate extraction, as determined by fusing the extracted turkey erythrocyte membranes with cyc$^-$ cells and assaying adenylate cyclase activity (F^-). The original content of G in the native membrane is taken to be 1 pmol of hormone induced ^{3}H-Gpp(NH)p (ref. 35) or ^{3}H-GTP[9] binding sites per mg of protein.

Hormone activation of the reconstituted R–G system is shown in Fig. 2. Dramatic hormone-induced activation of G is exhibited only by the system which was produced by combining the R and G preparations. The individual preparations of R and of G show only a slight hormonal response. Fluoride activities serve as an independent measure for the amount of G fused into the cyc$^-$ membranes. The R preparation produces no detectable fluoride activity and is therefore considered essentially free of G. The G preparation produces fluoride activity as high as the R plus G system, indicating a similar efficiency for both systems in the transfer of G units to the cyc$^-$ cell membrane by the fusion process. Hence, the only explanation for the very low hormone-induced G activity in the separate preparations of R and of G is the paucity of the G component in the R preparation and the R component in the G preparation.

Efficiency of R–G recoupling

The amount of G activated (G*) per minute by a unit amount of R may be used as a measure of the productive interaction of R with G (specific activity of R). As shown in Table 1, the specific activity of R in the reconstituted system is almost half that of the native turkey erythrocyte membrane (compare systems I and II in Table 1). It is also shown that the specific activity of R measured in the erythrocyte membrane, through its native catalytic unit, is comparable with that measured through the catalytic unit of the cyc$^-$ cells (Table 1, systems II and III). However, this observation should be treated cautiously because the experiments involve the unknown parameters of fusion efficiency with cyc$^-$ cells and the turnover numbers of the catalytic units of cyc$^-$ and turkey erythrocyte membranes. Note also that absolute activities fluctuated considerably in different experiments throughout the present study. The major variables responsible seem to be detergent effects during solubilization and reconstitution, and competence of different batches of cyc$^-$ cells. Therefore, absolute activities are comparable only for different systems within the same experiment.

Kinetics of R–G activation

The availability of separate preparations of R and G presented a unique opportunity to study the kinetics of their interaction as a function of their concentration in the reconstituted membrane.

Figure 3 shows the progress of G activation over an extended time period. It is apparent that the systems containing the larger amount of R exhibit a higher rate. In contrast, the concentration of G does not seem to affect the rate of its activation by R. The cause for the two phases in the kinetics of activation is not yet apparent.

To test the kinetics of the R–G interaction more rigorously, systems with a constant amount of R and different amounts of G were reconstituted. Initial rates of G activation were determined by limiting the activation time to 5 min (see Fig. 1, step IV). Figure 4 clearly demonstrates that the concentration of G had no effect on the initial rate of its activation. The kinetics are zero order with respect to G concentration. The apparent lower initial rate in the two systems containing the lesser amounts of G is due to activation of all the G units within the 5 min incubation period. This is evident from the addition of isoprenaline plus Gpp(NH)p to the final adenylate cyclase assay which does not result in additional activation (Fig. 4, open circles, second activation). The addition of isoprenaline plus Gpp(NH)p in the adenylate cyclase assay also demonstrates that the amounts of G transferred to cyc⁻ cells are directly proportional to the amount in the reconstituted system (Fig. 4, second activation).

Figure 5 shows the effect of R concentration on the initial rate of G activation. The rate is directly proportional to the amount of R and is thus first order with respect to R. Limitations of the system did not permit the R/G ratio to increase to the point of saturation, where the initial rate of G activation might reach a maximum. It is interesting that a similar dependence on R concentration was observed in intact turkey erythrocyte membranes after graded inactivation of R by an affinity label[15].

Analysis of kinetics

In the process of hormone activation of adenylate cyclase R° must meet G, and G* must associate with C (see steps (1)–(3)). If the association of R° with G is rate limiting (step (1)), then the rate of G activation should be dependent on the concentrations of both R and G. On the other hand, if the activation of G by R (step (2)) is rate limiting, then the concentration of RG complex would determine the rate. In the latter case, step (1) must occur much faster than step (2) and, therefore, all R will be in the RG form (when [G] > [R]). Thus, first order kinetics with respect to R concentration and zero order with respect to G concentration are predicted. As shown by the present findings (Figs 4, 5), the latter possibility holds true; step (2) is rate limiting. We therefore conclude that in the reconstituted R–G system, the rate of G activation by R is determined by the step of Gpp(NH)p introduction into the RG complex rather than by the rate of encounter of R with G.

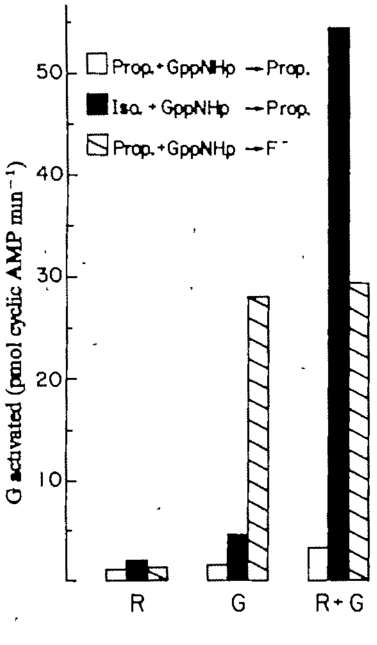

Fig. 2 Hormone-induced activation of G in the resolved and in the reconstituted preparations. Systems were reconstituted as described in Fig. 1 legend. At the mixing stage (step II, Fig. 1) the soluble G extract was combined (1:1 v/v) with deoxycholate, 6 mg ml^{-1} (marked as system G), or with the soluble R (marked as system R+G). The system marked R was prepared by mixing the soluble R extract (1:1 v/v) with 10 mg ml^{-1} cholate. All the systems were then treated as described in Fig. 1 legend, and 0.5-ml portions of each were activated (step IV, Fig. 1) with isoprenaline (black bars) or propranolol (open and crossed bars) for 5 min at 30 °C before addition of Gpp(NH)p for 30 min. Activation was terminated by addition of 10 μM propranolol. After 5 min, 1 ml of ice cold buffer (20 mM MOPS, *p*H 7.5, 1 mM mercaptoethanol, 10 μM GTP, 10 μM propranolol) was added to all systems. The pellets produced by centrifugation were fused with cyc⁻ cells. Adenylate cyclase was determined in presence of propranolol (open and closed bars) or NaF (crossed bars)

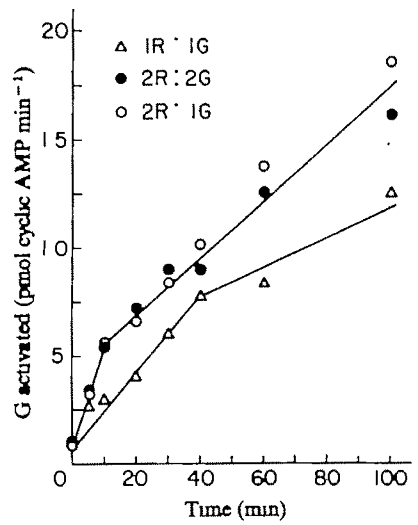

Fig. 3 Kinetics of G activation by the β-adrenergic receptor in reconstituted systems. Preparations (step II, Fig. 1) were mixed in the following ratios: R:G, 1:1 v/v (●); R:G:cholate solution, 2:1:1 v/v/v (○); and R:G:cholate solution:deoxycholate solution, 1:1:1:1 v/v/v/v (△). The systems were treated as described in Fig. 1 legend and activated (step IV, Fig. 1) with isoprenaline plus Gpp(NH)p. At various times 0.5-ml aliquots were taken and added to 1 ml of ice cold buffer (20 mM MOPS, *p*H 7.5, 1 mM mercaptoethanol, 0.1 mM GTP, 10 μM propranolol). The amount of G activated in the samples was determined in presence of propranolol as described in legends to Figs 1 and 2. The relatively low activities in this experiment are due to a low yield of the G preparation used for the reconstitution. This is shown by measurement of total G (determined in presence of Gpp(NH)p plus isoprenaline in the adenylate cyclase assay). Total G activities were (average of all the samples): 10.2 pmol min^{-1} (1R:1G), 20.4 pmol min^{-1} (2R:2G), and 13.2 pmol min^{-1} (2R:1G).

Extrapolating from these experiments with the reconstituted system to the native membrane, either step (2) or (3) could determine the rate of the overall process. An estimate of the apparent rate constant k_2 for step (2) (see legend to Fig. 4) gave a value that was in the same range as the rate constant values calculated for the overall activation process in the native membrane[11,15]. It is therefore possible that step (2) is rate limiting in the overall process of hormonal activation of adenylate cyclase. However, further experiments will be needed to verify this suggestion.

The mobile receptor hypothesis[21] was applied to the β-adrenergic receptor system[13] and it was suggested that the rate of encounter between the receptor and the adenylate cyclase might be the rate limiting step of the activation process. The hypothesis[21] predicted the independent existence of the hormone receptor[6]. However, the RG complex and the rate of G activation were not considered at the time. As these findings indicate that the R–G encounter is not rate limiting in the reconstituted system, a re-evaluation of previous models seems worthwhile.

Experiments on the overall process of adenylate cyclase activation in the native membrane indicated that a small amount of R could activate a larger amount of enzyme[15,22]. The present work shows that R acts catalytically in activating at least 10 times its own amount of G (Figs 2–5). The activation of G by R proceeds in the absence of functional C (ref. 18, legend to Fig. 1). Thus, the catalytic function of the β-adrenergic receptor in the overall process of adenylate cyclase activation seems to be a mere reflection of its primary action on G.

Conclusions

The present study describes the reconstitution of the R–G interaction using solubilized, resolved preparations of R and of G. Kinetic properties of the R–G interaction were revealed which could not be studied in the native membrane where the concentrations of R and G cannot be manipulated and where the concurrent interaction of G with C compounds the analysis. The experiments imply that in the presence of hormone, all R is in

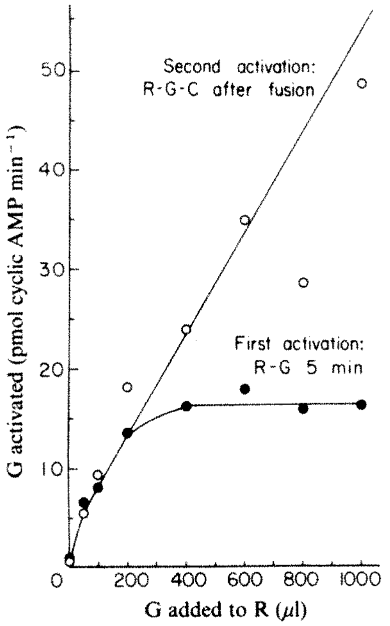

Fig. 4 Initial rates of G activation as a function of G concentration in the reconstituted system. R (0.5 ml) was mixed with different amounts of G (abscissa). In each system the volume of G added was made up to 1.0 ml by addition of 10 mg ml^{-1} cholate. After reconstitution, as described in Fig. 1 legend, 1.0-ml aliquots were activated for 5 min (as in Fig. 3) and fused with cyc$^-$ cells. Systems were assayed with propranolol to show the amount of G which had been activated (first activation) (●). In addition, aliquots from each system were subjected to a second activation with 0.1 mM isoprenaline plus 0.1 mM Gpp(NH)p in the adenylate cyclase assay (○). k_2: The rate constant of step (2) in the text was calculated from the initial rate of G activation shown above, and the yield of G and R in the respective extracts (Fig. 1). R is all in the RG form (see text); therefore $k_2 = 1.4$ min^{-1}.

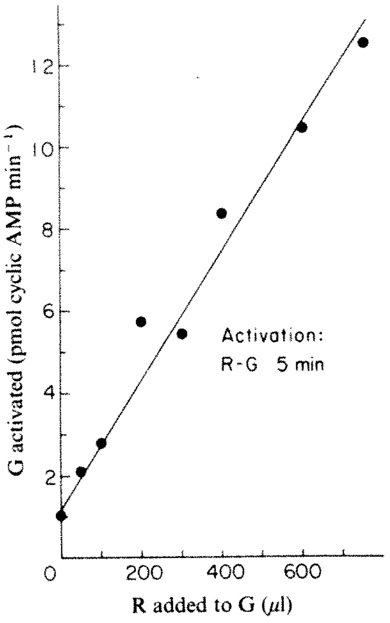

Fig. 5 Initial rates of G activation as a function of receptor concentration in the reconstituted system. A constant amount of G, 750 μl, and increasing amounts of R (abscissa) were mixed and reconstituted. The volume of R was made up to 750 μl with 6 mg ml^{-1} deoxycholate. All other manipulations were as described in Fig. 4 legend.

the RG complex form. This conclusion is supported by recent findings that the hormone induces co-elution of R and G from a gel filtration column[23]. As the R–G interaction has not been studied to date with purified components, the possibility cannot be excluded that unknown additional factors might be involved. It should also be noted that differences between the β-adrenergic receptor of turkey erythrocytes and that of other tissues have been reported[14,24]. However, recent studies suggest that these differences are not fundamental[25,26].

The resolved R and G as well as the reconstituted R–G preparation seem to have considerable potential for future studies on hormone receptor action at the molecular level. A few important questions might be tackled. Are the differences in thermodynamic parameters between the binding of hormone and of blocker[27] due to the hormone-induced primary action of R with G? Does the reconstituted R–G system possess the hormone-induced GTPase activity[28] or is C required for this reaction? What are the specific phospholipid requirements for R and G functions?

The interaction of R with G takes place within a two-dimensional phospholipid bilayer which serves as the solvent. Manipulation of this solvent such as treatment with *cis*-vaccenic acid[29,30] greatly influences the kinetics of adenylate cyclase activation. It is possible, therefore, that more extensive dilution of R and G by phospholipid addition or other manipulations might affect the properties of the system. Unfortunately, there is little information about kinetics of interaction of protein molecules in biological membranes. Rogers and Strittmatter[31] published elegant studies on the interaction of NADH cytochrome b_5 reductase with cytochrome b_5 in native and reconstituted membranes. However, this system may not be a close analogy to the hormone-activated adenylate cyclase. The cytochrome and the enzyme reducing it are anchored in the membrane but the active groups interact in the water phase. In contrast, the β-adrenergic receptor transmits a transmembrane signal and, apparently, interacts with the G unit within, or on, the inner side of the membrane. It is hoped that the approach used in this work will be applicable to the study of other receptor response mechanisms and that the reconstituted R–G system can serve as a paradigm for protein–protein interactions in biological membranes.

Double-stranded DNA copies of the RNA gene coding for the haemagglutinin glycoproteins from human H2 and H3 pandemic strains of influenza virus have been cloned. DNA sequence analysis provides the first reported complete nucleotide sequence of an H2 haemagglutinin gene and a partial sequence (45%) of the H3 gene. The H2 haemagglutinin gene consists of 1,773 nucleotides containing an uninterrupted coding sequence of 1,686 nucleotides specifying a protein of 562 amino acids. Comparison of the amino acid sequences of these haemagglutinins with those of other H3 and avian strains reveals the extent of sequence changes in antigenic shifts and drifts.

THREE main properties of influenza virus haemagglutinins have prompted analyses of their structure. These glycoproteins are responsible for binding virus particles to cells during infection[1] and possibly mediate virus-cell membrane fusion[2-4]; antibodies which react with the haemagglutinin neutralize virus infectivity[5] and, as a consequence, viruses which have the potential to cause new epidemics or pandemics of disease in an immune population have antigenically novel haemagglutinins; and finally, as the major glycoprotein component of virus membranes they share features of biosynthesis, processing and structure with integral membrane proteins of eukaryotic cells and thus serve as models for studying these proteins. Because of these properties, we and others[6-11] have been determining the primary structures of several haemagglutinins. To complete this determination we have synthesized and cloned in a prokaryotic vector complementary DNA copies of haemagglutinin virion RNA. Haemagglutinins used were from strains A/Japan/305/57 (H2 subtype) and X-31 (H3 subtype). We report here the complete nucleotide sequence of the Japan haemagglutinin gene and a partial sequence (45%) of the X-31 gene. Comparison of the derived amino acid sequences with those from other members of the H3 subtype A/NT/60/68/29C[10] and A/Victoria/3/75[9] and with a haemagglutinin from the avian Hav 1 strain A/FPV/Rostock[8] allows correlation of structure and function for the haemagglutinin molecule.

Cloning and DNA sequence of haemagglutinin genes

The influenza haemagglutinins chosen for analysis were from the high-yielding recombinant virus strains A/Japan/305/57: A/Bel/42: A/PR/8/34 (H2N1)[12] and X-31 (H3N2)[13]. These strains contain haemagglutinin genes from the originally isolated strains A/Japan/305/57 (H2) and A/Aichi/2/68 (H3). Total virion RNAs (vRNAs) from the two influenza recombinants were purified and polyadenylated at their 3′ termini using ATP:RNA adenyltransferase[14]. An average of about 50 adenylate residues were added to each RNA molecule. The polyadenylated vRNAs were then used as templates for reverse transcription of single-stranded (ss) DNA copies using oligo(dT)$_{12-18}$ as primer[15]. The products were separated in denaturing conditions on agarose gels into eight discrete bands whose sizes indicated that they were essentially full-length copies of the genomic RNA segments[16] (Fig. 1*a*). In a number of experiments approximately 3-5 μg of cDNA was synthesized using 10 μg of template RNA.

At this point different strategies were chosen for cloning X-31 and Japan nucleic acid sequences. Cloning of X-31 sequences involved direct insertion[17] of poly (dA)-tailed vRNA/cDNA hybrids[18] into the *Pst*I site of plasmid vector pBR322[19] after poly(dT) tailing[18] of the linearized plasmid. However, no full-length cloned copies of the HA gene were obtained. Subsequent experiments with the Japan strain involved the production of double-stranded (ds) DNA copies before insertion into the *Pst*I site of plasmid pAT153 (a derivative of pBR322 with a 622 base pair deletion)[20].

Single-stranded DNA copies of Japan vRNAs were converted to the double-stranded form[21] utilizing the ability of the cDNA to form 3′-terminal hairpin loops[22] to prime DNA polymerase I. Subsequent cleavage of the hairpin loops yields non-covalently joined ds cDNAs. Figure 1*b* shows the resolution on denaturing agarose gels of the ds cDNAs before and after S_1 nuclease treatment. The hairpin-linked ds cDNAs migrated to positions corresponding to approximately twice the molecular weight of ss cDNAs. After S_1 nuclease treatment, most of the ds cDNAs were converted to species which co-migrated with full-length first-strand cDNAs. The ds cDNAs were separated on a sucrose gradient and fractions containing full-length species were selected and tailed with poly(dC) using terminal transferase[18]. The tailed ds cDNAs were inserted into the *Pst*I site of pAT153 after poly(dG) tailing[18] of the linearized plasmid.

Transfection of hybrid plasmids into *Escherichia coli* χ1776 (ref. 23) was by the procedure of Hanahan (personal communication). This method yields $3\text{-}5\times10^7$ transformants per μg of supercoiled plasmid DNA. Transfection with recombinant pBR322 (10 ng vRNA-cDNA insert) or pAT153 (10 ng ds cDNA insert) yielded ~500 tetracycline-resistant bacterial colonies. This corresponds to a transformation efficiency of 2×10^4 transformants per μg of tailed, annealed DNA. The colonies from each transformation were picked and replicated to test ampicillin sensitivity. Approximately 60% of the colonies were Tet^r, Amp^s indicating that they contained recombinant plasmids. These plasmids were grown on nitrocellulose filters and analysed by a modification of the *in situ* colony hybridization procedure[24] using a ^{32}P-cDNA probe for influenza

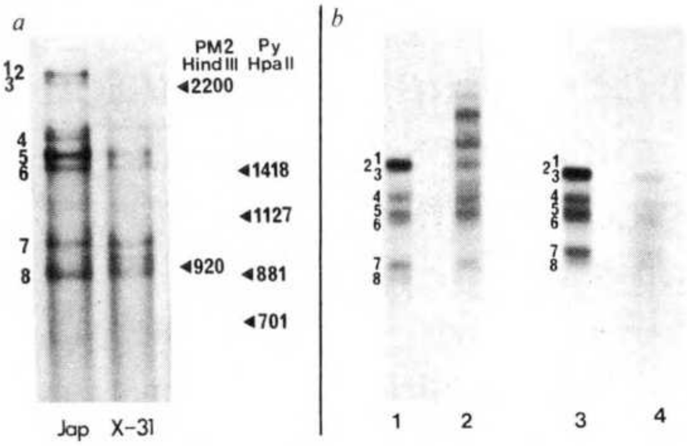

Fig. 1 Characterization of cDNA copies of Japan and X-31 vRNAs. *a*, Separation of cDNA copies of Japan and X-31 vRNAs by agarose gel electrophoresis; polyadenylated vRNAs were reverse transcribed into ss ^{32}P-labelled cDNAs in reaction mixtures containing 50 mM Tris-HCl, *p*H 8.3, 10 mM $MgCl_2$, 140 mM KCl, 30 mM β-mercaptoethanol, 0.5 mM dGTP, 0.5 mM dATP, 0.5 mM TTP, 0.25 mM dCTP (2 μCi μmol^{-1}), 10 μg ml^{-1} oligo(dT) 12–18 (P.-L. Biochemicals), 10 units ml^{-1} rat liver ribonuclease inhibitor (Searle), 50 μg ml^{-1} polyadenylated vRNA and 360 units ml^{-1} AMV reverse transcriptase (a gift from J. Emtage (Searle)). After incubation for 60 min at 42 °C the reaction was terminated by placing the mixture on ice. The cDNAs were separated by electrophoresis on 1.4% agarose gels in 30 mM NaOH, 1 mM EDTA and autoradiographed. The positions of restriction fragments of PM2 (*Hin*dIII) and polyoma (*Hpa*II) virus DNAs are shown as molecular weight markers. *b*, Electrophoretic resolution of Japan ds cDNAs before and after S_1 nuclease digestion. Single stranded ^{32}P-cDNAs prepared by reverse transcription (lanes 1 and 2) were converted to the ds form (lane 2) and digested with S_1 nuclease (lane 4) by the procedure of Wickens *et al.*[21]. Analysis by electrophoresis on agarose gels was as described in *a*.

sequences prepared by reverse transcription of vRNAs using calf thymus primers as random primers[25]. 50–80% of the colonies on nitrocellulose filters contained influenza sequences.

To identify which gene segments were represented in the cloned recombinant plasmids, Japan and X-31 vRNAs were separated in agarose gels, transferred to and immobilized on diazotized paper[25] and probed by hybridization with ^{32}P-labelled recombinant plasmid DNA prepared by nick translation[27]. After autoradiography, clones containing the various vRNA genes were identified (Fig. 2). Restriction endonuclease mapping of plasmids which contained HA sequences indicated that clone 2G10 had an insert corresponding to ~95% of the haemagglutinin gene from the Japan strain and clone 4F12 contained an insert corresponding to ~45% of the X-31 HA gene (Fig. 3).

To obtain a clone containing the missing portion of the Japan HA gene, the *Eco*R1-*Pvu*II restriction fragment from the distal end of the 2G10 insert was used to prime synthesis of a cDNA copy from Japan vRNA template. Using the methods described above, a clone (ExB6) containing the missing sequences was identified and mapped by restriction endonuclease digestion (Fig. 3). Finally, a clone (pJHA) containing the entire Japan HA gene nucleotide sequence (except the last 11 nucleotides) was constructed (Fig. 3). Experiments are in progress to use this cloned gene for expression of haemagglutinin protein in prokaryotic and eukaryotic cells.

Determination of the DNA sequence of the cloned inserts was carried out using the procedures of Maxam and Gilbert[28]. Figure 3 shows the distances sequenced on various restriction fragments. To determine if any of the sequences at the 5′ end of the vRNA were not represented in the clones, or if the cloning procedure had resulted in mutations at this end[8], the 36-base pair *Sau*3A-*Pst*I restriction fragment near the right-hand end of the ExB6 insert was purified, labelled and used as primer for reverse transcription of vRNA template. The single, labelled DNA product was sequenced and the result indicated that only the last 11 nucleotides of the 3′ non-coding region of the Japan vRNA are not represented in the cloned inserts. There were no alterations in the sequence due to the cloning procedure.

Figure 4 provides the completed nucleotide sequences of the complementary RNA strands corresponding to the message coding sequences of the Japan and X-31 genes. Finally, Fig. 6 lists the amino acid sequences derived for the haemagglutinins from Japan, X-31[11], 29C[10], Victoria[9] and Fowl Plague (FP)[8] viruses.

Structure of the haemagglutinin gene

The Japan haemagglutinin gene is 1,773 nucleotides long. The coding region (1,686 nucleotides) begins with an AUG and ends with an UGA terminator. This is followed in the non-coding region by two in phase and one out of phase UAA triplets. Two of the three reading frames contain frequent termination codons so that only one frame is open for translation. The coding portion of the gene exists as a continuous block of nucleotides. The codon usage is similar to that found for the Victoria[9] and FPV[8] haemagglutinin sequences.

There are untranslated regions at both the 5′ (43 nucleotides) and 3′ (44 nucleotides) ends of the haemagglutinin gene (messenger or cRNA strand). The terminal sequences have been determined previously by direct RNA sequencing[29,30] or by sequencing of reverse transcripts[31] and these results confirm that our cloned inserts contain the complete vRNA sequence at the 3′ end and miss only 11 nucleotides at the 5′ end. The first 14 nucleotides at the 5′ end of the HA cRNA and the last 21 nucleotides at the 3′ termini are identical in all the strains that have been sequenced[8–11]. Previous direct RNA sequence analysis of the 5′ ends of vRNA and cRNA transcripts of the eight influenza gene segments from a number of different viral strains showed that, in all cases, the terminal 12–13 nucleotides are closely conserved and that the 5′ and 3′ ends display inverted partial complementarity[29]. This structure may have a role in the process of viral replication. Emtage *et al.*[32] have shown that there is an adventitious prokaryotic-like ribosome binding site near the 5′ end of the cRNA which may be functional during expression of the cloned gene in *E. coli*. This sequence is also

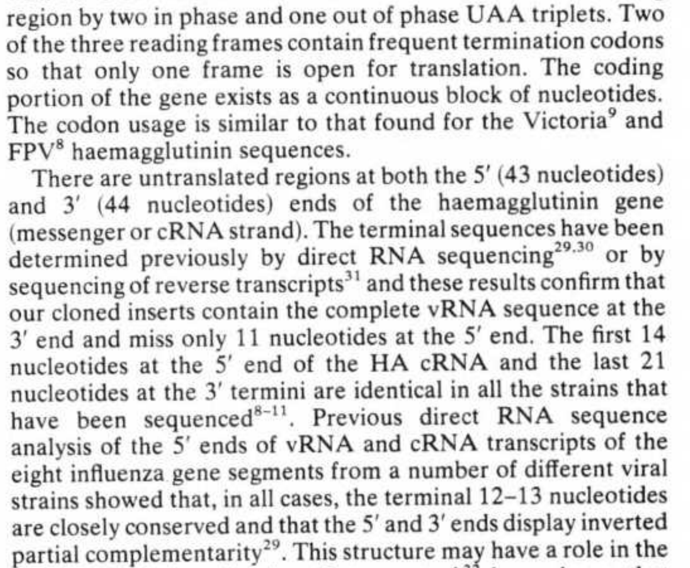

Fig. 2 Assignment of cloned inserts to viral RNA segments. Recombinant plasmid DNA preparations from the numbered clones were labelled with ^{32}P by nick translation[27] and hybridized to fractionated vRNAs immobilized on diazotized paper[26]. The positions of the eight vRNA genes were identified by hybridization with the appropriate ^{32}P-labelled cDNAs prepared by reverse transcription of total X-31 or Japan vRNAs[25].

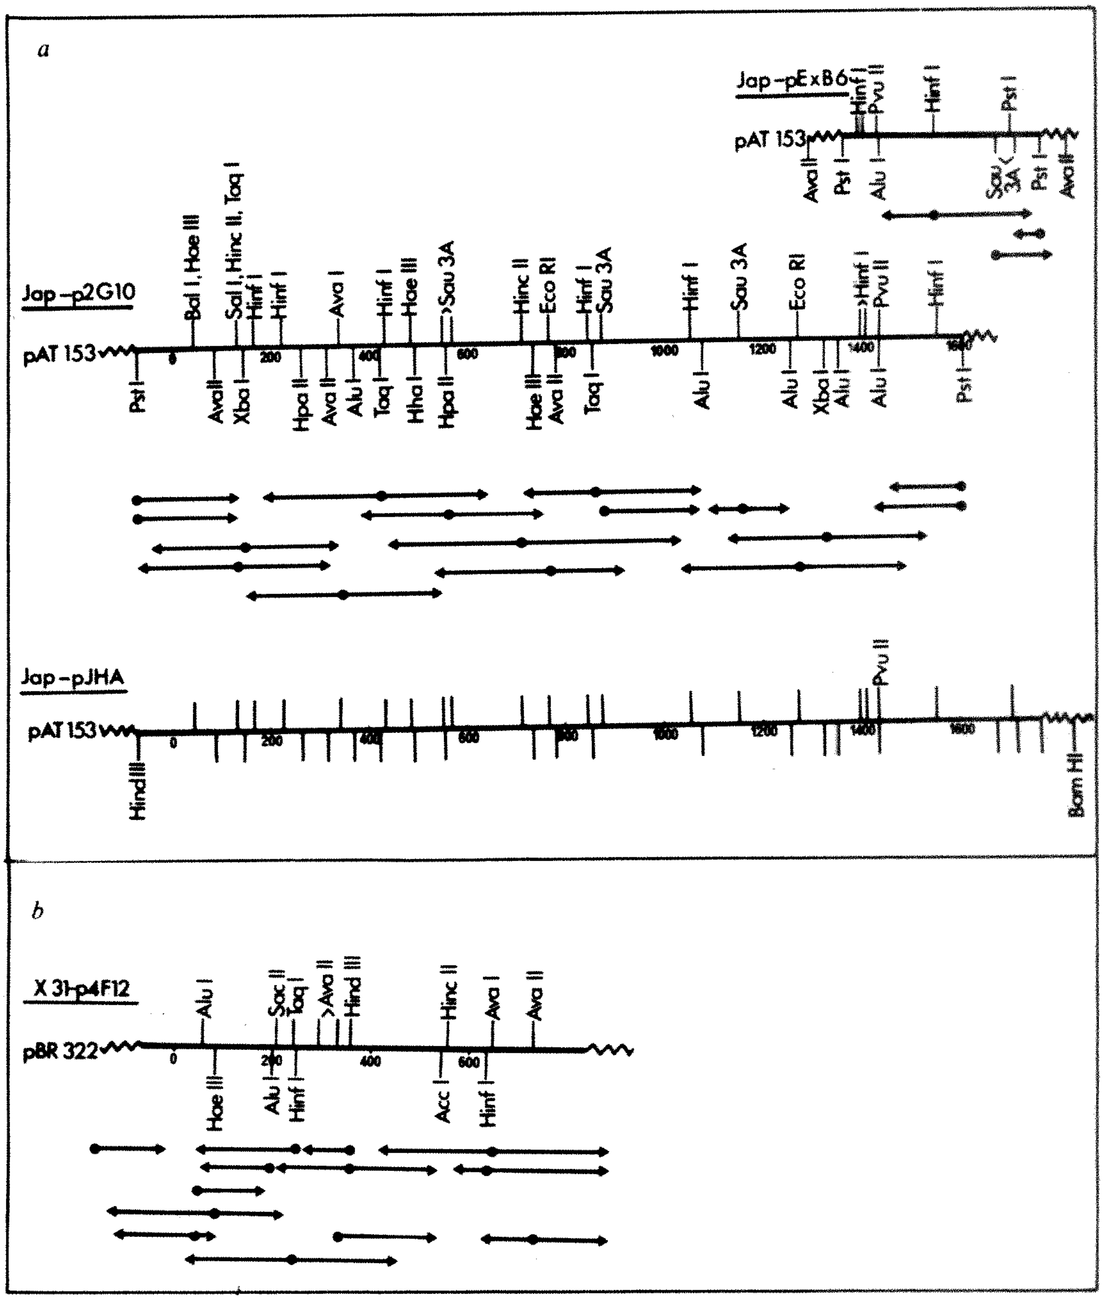

Fig. 3 Restriction enzyme maps of *a*, Japan and *b*, X-31 haemagglutinin gene inserts in recombinant plasmids. The construction of clones p2G10, pExB6 and p4F12 is described in the text. Conditions for all restriction enzyme digestions were as described in the catalogue of New England Biolabs. The distances and directions sequenced on various restriction fragments are shown by arrows. Clone pJHA contains a copy of the entire Japan HA gene except for the last 11 nucleotides of the 5′ non-translated region of the vRNA. It was constructed from the p2G10 and pExB6 clones as follows: the gene insert in p2G10 was excised with *Pst*I and *Hin*dIII linkers were attached to the ends[52]. The *Hin*dIII-*Pvu*II restriction fragment was purified. Similarly the gene insert in pExB6 was excised by cutting the flanking pAT153 sequences with *Ava*II and *Bam*HI linkers were attached to the ends[52] before purification of the *Pvu*II-*Bam* restriction fragment. The *Hin*dIII-*Pvu*II and *Pvu*II-*Bam* fragments were then ligated between the *Hin*dIII and *Bam*HI sites of pAT153 using T4 DNA ligase. After transfection of the ligated mixture into χ1776 a clone pJHA containing the composite full-length insert was obtained and characterized.

present in the human influenza HA genes but the greater distance between it and the AUG codon suggests that it may not function in expression of these genes in bacteria[33]. The remainder of the untranslated regions vary in length and in sequence and show little evidence of common origin or function.

Structure of the haemagglutinin protein predicted from the nucleic acid sequence: cleavage of the polypeptide

The haemagglutinin glycoprotein is synthesized in infected cells as a single polypeptide precursor which is converted by proteolytic cleavage into two disulphide-bonded polypeptides HA1 and HA2[34,35]. The Japan haemagglutinin precursor consists of 547 amino acids and a single arginine residue is removed during formation of HA1 (324 amino acids) and HA2 (222 amino acids)[6]. In this respect Japan haemagglutinin differs from FPV haemagglutinin[8] as at the equivalent site there is a sequence of six charged amino acids which are probably removed during processing. The difference in structure at this site may explain why FPV is susceptible to cleavage activation in a wider range of host cells[36].

Hydrophobic regions of the haemagglutinin

The hydrophobic sequence at the new NH_2 terminus of HA2 which is generated by this cleavage is highly conserved in influenza haemagglutinins[37] and also shows a high degree of similarity to the NH_2 terminus of the F1 subunit of Sendai virus fusion protein[4], which is revealed after cleavage activation of infectivity and fusion activity. Previously we have suggested that these sequences may have a functional role in interaction with and penetration of the cell membrane during infection.

The HA primary translation product contains two additional hydrophobic regions which are present in all the virus strains. These are the signal sequence at the NH_2 terminus and the presumed membrane insertion sequence at the COOH terminus. The nascent Japan HA polypeptide chain contains a hydrophobic signal peptide[6,30,38] which is probably involved in the transport of the polypeptide across the endoplasmic reticulum. This peptide is cleaved off when the process of membrane transfer and insertion is complete. The DNA sequence reported here defines a 15-residue peptide containing 14 uninterrupted non-polar amino acids before the known NH_2 terminus of HA1[6] and agrees with the data of Air[31] and with our previous data from direct RNA and amino acid sequence analyses[30]. The H3 haemagglutinins[9–11] probably also have a signal peptide of 16 amino acids containing 14 uninterrupted non-polar residues since the glutamine residue at position 17 is probably the NH_2-terminal amino acid of the mature protein[7]. Again, although amino-acid sequence data is not available for FPV, homologies at the NH_2 terminus of HA1 suggest that FPV haemagglutinin has an 18 amino-acid signal peptide containing a core of 11 hydrophobic amino acids[8]. It is striking that the proposed signal peptides of the haemagglutinins from the H2, H3 and avian subtypes show no homology with each other, indicating that it is the hydrophobicity and not specific sequence that is important for membrane association. The size and non-polar character of these prepeptides are similar in other membrane or secreted proteins[39].

The third hydrophobic sequence at the COOH terminus of the primary translation product and of HA2 is probably involved in anchoring the protein in the lipid envelope[37]. The haemagglutinins from the H2, H3[9-11] and FPV[8] strains have 41, 27 and 26 non-polar amino acids, respectively, preceding charged amino acids near the COOH terminus. There is some similarity between these sequences but it is significantly less than that found in the rest of HA2. It may be that, as in the case of the signal peptide, it is hydrophobicity and not specific sequence that defines the interaction with the membrane. It is of course not possible to define from these data which amino acids are embedded in the lipid bilayer, but it seems likely that there are no more than 10–12 residues on the inner face of the virus envelope, suggested by the location of charged amino acids at position 10 (H3)[9-11] and 11 (FPV)[8] amino acids from the COOH terminus. The only charged amino acid at the COOH terminus of Japan HA2 is four residues from the end. Similar numbers of hydrophobic amino acids span the lipid bilayer in HLA heavy chain[40] and glycophorin A[41]. However, in these cases the internal hydrophilic tails (approximately 30 residues) are longer.

Conservation of amino acid sequence and location of cysteine or cystine residues

It is now possible to compare the complete amino acid sequence of haemagglutinins from two subtypes of human influenza virus and an avian virus[8-11]. In Fig. 5, the protein sequences have been aligned using a computer program[42] to optimize the homology. The alignment involves only a few small insertions or deletions in the sequences, except at the NH_2 terminus of HA1 where the H3[9-11] haemagglutinins have 10 or 11 extra amino acids and at the cleavage site between HA1 and HA2 where the single arginine residue in the human sequences is replaced by six charged amino acids in the avian FPV haemagglutinin. As shown in Fig. 5 and Table 1, there is considerable sequence homology between the haemagglutinins of all three subtypes (30%). The similarity is even more marked between H2 and Hav1 haemagglutinins (43%), H2 and H3 haemagglutinins (42%) and Hav1 and H3 haemagglutinins (48%). Within the H3 subtype there is 95% sequence homology between the 1968 (X-31) and 1975 (Victoria) isolates. There is a much greater degree of conservation in HA2 than in HA1. Although there can be extensive variation in amino acid sequence (especially in HA1), the results of these observations on the constant size of the haemagglutinins and comparative studies of their secondary structure[43] suggest that all haemagglutinins have a similar three-dimensional structure. This idea is emphasized by the striking conservation of the location of the cysteine residues (Fig. 6) which is probably due to constraints on the folding of the molecule and formation of disulphide bridges. The only portion of the molecule in which there is any variation in the location of the sulphydryl residues is at the COOH terminus where the H3[9-11] and Hav1 haemagglutinins have more cysteines than the H2 protein. Since these residues are probably embedded in the lipid bilayer, their positions may not be constrained by the requirement for formation of disulphide bonds. We have shown that in Japan haemagglutinin all 12 cysteine residues in the external protein spike are involved in disulphide bridges, of which only one (Cys 4-Cys 462) is an interchain link between HA1 and HA2 (unpublished results). The secondary structure formed by the remaining three cysteines, which are either in the lipid bilayer or on the inner side of the membrane, has not yet been elucidated. It is clear, however, that although the COOH terminus, which may be on the inner side of the membrane, could interact with the viral matrix protein, the two cysteine residues at positions 2 and 5 from the terminus of HA2 do not form disulphide bonds linking the two proteins.

Table 1 Conservation of amino acids in haemagglutinin sequences

Amino acids conserved in haemagglutinin sequences of	HA No. (%)	HA1 No. (%)	HA2 No. (%)
All 3 strains (H2, H3, Hav1)	165 (30)	72 (22)	93 (42)
H2 (Japan) and H3 (Victoria)	229 (42)	118 (36)	111 (50)
H2 (Japan) and Hav1 (FPV)	235 (36)	118 (36)	117 (53)
H3 (Victoria) and Hav1 (FPV)	263 (48)	119 (36)	144 (65)
Total	547	325	222

Glycosylation of the haemagglutinins

The haemagglutinin molecule is glycosylated during transport from the endoplasmic reticulum to the plasma membrane of the infected cell[44]. Figure 6 shows the positions of the predicted

Fig. 4 Complementary RNA sequences of haemagglutinin genes derived by sequence analysis of the cloned gene inserts in plasmids 2G10, ExB6 and 4F12.

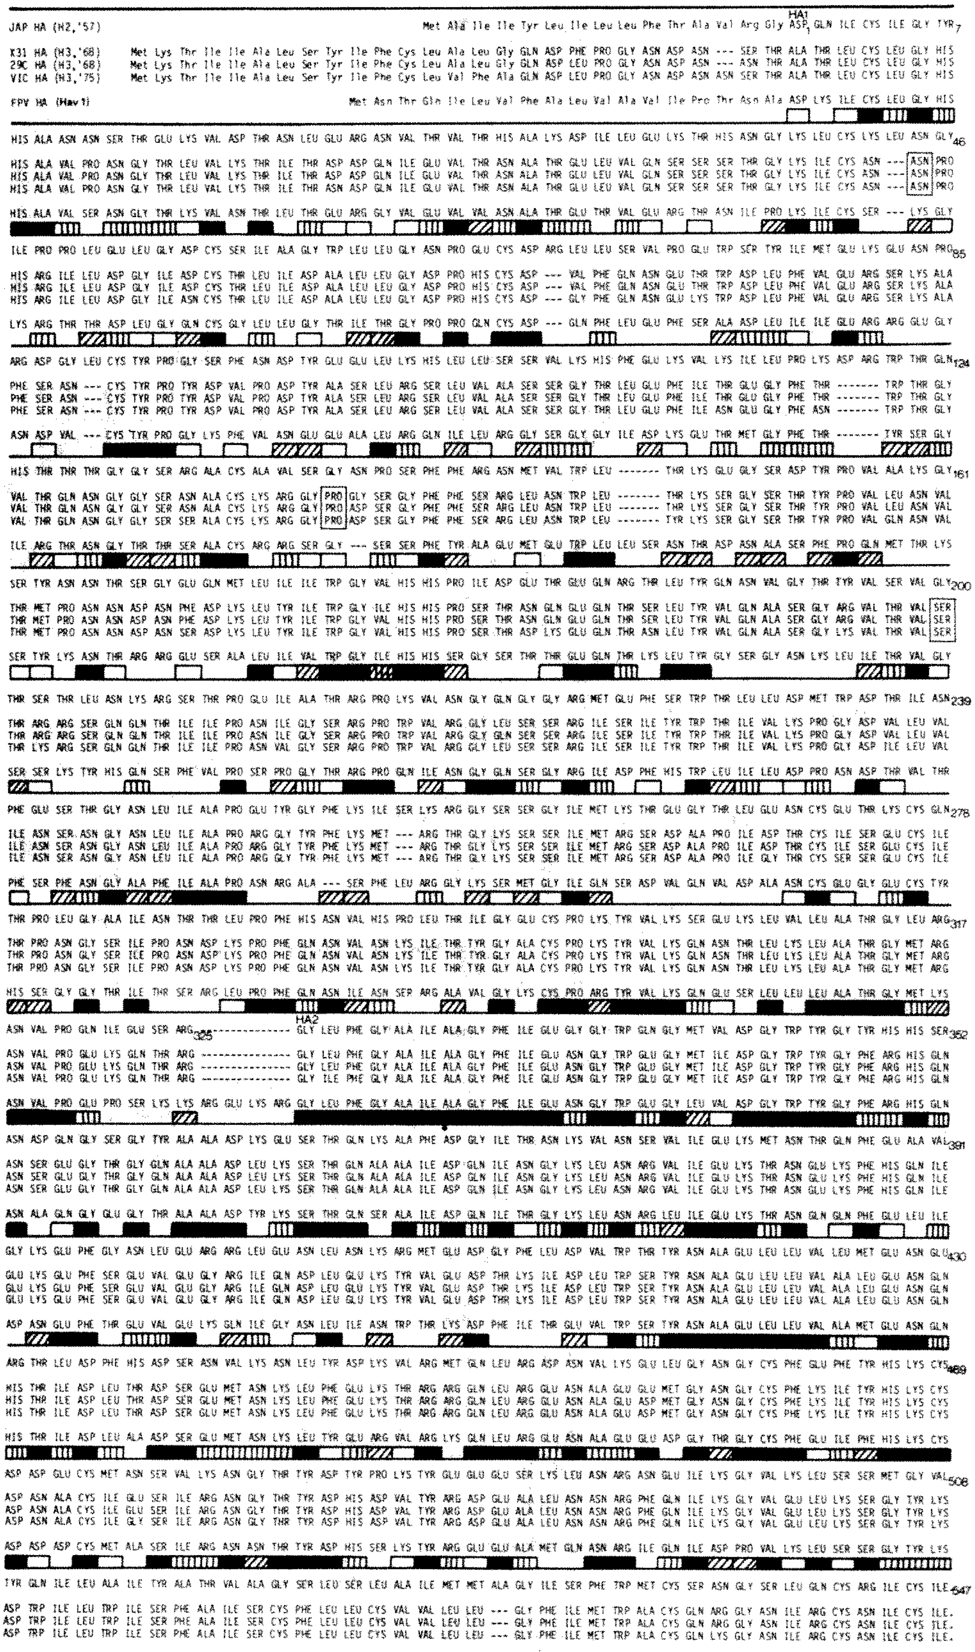

Fig. 5 Amino acid sequences of influenza haemagglutinins. The amino acid sequences of the Japan (H2) and X-31 (H3) haemagglutinins are compared with the sequences from other strains: Victoria (H3)[9] NT60/29C (H3)[10] and Fowl Plague Virus (Hav1)[8]. The COOH terminal amino acid sequence of the X31 haemagglutinin which was not determined by us is from Verhoeyen *et al.*[11]. The sequences have been aligned to maximize homology which is shown between ■, H2, H3 and Hav1 proteins; ▨, H2 and H3 proteins; □, H2 and Hav1 proteins; and ▥, H3 and Hav1 proteins.

carbohydrate attachment sites Asn-X-Ser or Thr[45] in the haemagglutinin sequences. We have confirmed that five of the six possible sites on Japan haemagglutinin are indeed glycosylated (unpublished results). The absence of carbohydrate at the remaining site (Asn$_{139}$-Pro-Ser) is consistent with reports that such a sequence is not glycosylated in other proteins[45]. It remains to establish whether all the other possible sites in the H3 and Hav1 haemagglutinins are in fact glycosylated. Although there is some conservation of the number and position of the carbohydrate residues, there is clearly some latitude for variation in their location. As shown in Fig. 6, there is even variation in the possible attachment sites between haemagglutinins of the H3 subtype. A possible constraint would be a requirement that the carbohydrate should be on the outside of the molecule. Confirmation of such a constraint awaits analysis of the three-dimensional structure of the molecule[46].

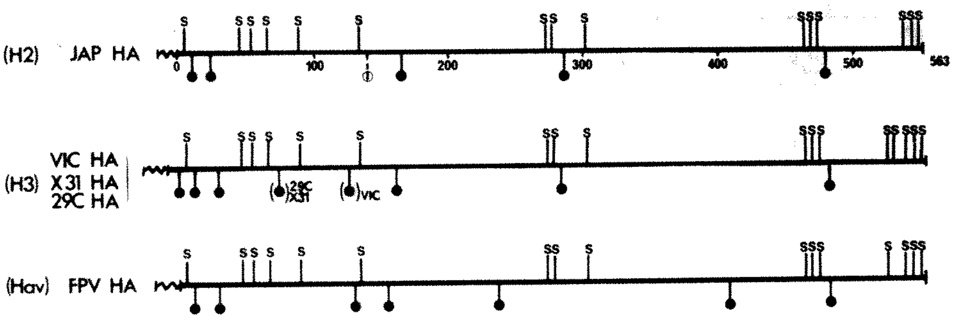

Fig. 6 Schematic representation of the positions of cysteine residues and glycosylation sites in the haemagglutinin amino acid sequences. $\overset{s}{|}$ Cysteine residue; $\overset{\circ}{|}$, carbohydrate side chain;

Antigenicity, shift and drift

The greater degree of variation in HA1 than in HA2 is consistent with the observations[47,48] that the major antigenic sites are located in HA1 and that it is variation in these sites which allows the virus to escape from neutralizing antibody. Between the major shifts in antigenic structure which define the beginning and end of each pandemic era, the haemagglutinin undergoes a series of changes, due to the pressure of increasing antibody prevalence in the population, known as antigenic drift.

The changes responsible for antigenic drift accumulate with time and field strains isolated several years apart from within a single pandemic era (for example, H3 : 1968 to present) show a large number of amino acid changes in peptide mapping studies[49]. In this study we can deduce additional characteristics of the process of antigenic drift by comparing the nucleic acid and protein sequences of the haemagglutinins of the H3 subtype. Clearly, drift occurs by a simple stepwise mutation of the HA nucleotide sequence. There are 65 nucleotide differences between the X-31 (ref. 11) (1968) and Victoria[9] (1975) haemagglutinin genes, resulting in 28 amino acid changes. Although all but one of the amino acid changes could have occurred via single base changes, in five cases double mutations have occurred. The two 1968 isolates (X-31 and the laboratory variant NT60/29C) differ by eight nucleotides and six amino acids. In four cases, the new amino acid is the same as that in the Victoria protein. Similarly, of the 482 amino acids known from the protein chemistry analysis of the haemagglutinin from the 1972 isolate A/Memphis/102/72 (refs 7, 53), 21 amino acids differ in the X-31 protein, although 12 of these amino acids are the same in the NT60 or Victoria haemagglutinins.

It is likely that some of the changes which occur in the haemagglutinin may be antigenically neutral or may cause antigenically significant alterations in distant parts of the protein. So far, it has not been possible to correlate the locations of antigenic sites with the positions of amino acid substitutions. Indeed, the variation within subtypes in a pandemic series is so major that nucleic acid and/or amino acid sequence information from even a large number of field isolates would not provide unequivocal information on the antigenic sites. To simplify this system other workers have used monoclonal antibodies directed against antigenic sites in HA to select variants *in vitro* and thus to mimic antigenic drift[50]. Such studies have so far indicated three or four regions of the HA1 which may constitute antigenic sites. The positions which change in these variants are boxed in Fig. 5.

The more dramatic changes which constitute an antigenic shift are illustrated by a comparison of the amino acid sequences of the H2 and H3 pandemic subtypes (Fig. 5). Clearly the H3 haemagglutinin cannot have arisen by stepwise mutation of the gene of the previous H2 pandemic type and they are so different that it is impossible to map the various antigenic sites by comparing their primary sequences. Furthermore, the fact that the haemagglutinins of the two human strains are no more similar to each other than to that of the avian strain makes it impossible to establish a genealogical tree which would define the evolutionary relationship between them. Recombination or reassortment of haemagglutinin genes between influenza viruses of humans and those of domestic or wild animals has been suggested as the mechanism of antigenic shift[51]. The data presented here are not inconsistent with such a theory.

Hybrid plasmids were transfected into and propagated in *E. coli* χ1776 in containment conditions approved by the British Genetic Manipulation Advisory Group.

Massive black hole binaries in active galactic nuclei

M. C. Begelman*, R. D. Blandford† & M. J. Rees‡

* Department of Astronomy, University of California, Berkeley, California 94720
† Theoretical Astrophysics, California Institute of Technology, Pasadena, California 91125
‡ Institute of Astronomy, Madingley Road, University of Cambridge, Cambridge CB3 0HA, UK

Most theoretical discussions of active galactic nuclei (including quasars) attribute their energy production either to an accreting black hole or to a precursor stage—for instance a dense star cluster or a supermassive star—whose inevitable end point is a massive black hole[1]. We explore here the possibility that some active nuclei may contain two massive black holes in orbit about each other. This hypothesis suggests a new interpretation for the observed bending[2] and apparent precession[3] of radio jets emerging from these objects and may indeed be verified through detection of the direct consequences of orbital motion.

There are straightforward reasons for surmising that supermassive binaries exist[4,5]: mergers between galaxies appear to be frequent; cD galaxies in clusters and small groups were quite probably formed in this manner[6–9]; and there is direct evidence that the nearby active galaxy Centaurus A is a merger product[9]. If most galaxies contain massive black holes in their nuclei—relics of earlier activity—then they will settle, under dynamical friction, in the core of a merged stellar system. Many cD galaxies do indeed contain double or multiple cores that may have been formed in this way[10]. There are other scenarios for binary black hole formation. For instance, a rotating super-massive star may undergo bar-mode instability and fission into two components that both collapse[1].

The dynamical evolution of a pair of massive black holes in the violently relaxed core of a newly merged galaxy proceeds through several stages.

(1) The black holes are probably surrounded by dense stellar clusters; that within the less massive galaxy should be denser and will survive intact until the nuclei merge. Dynamical friction is extremely efficient[6] and the cores merge and undergo violent relaxation in a characteristic galactic dynamical time $t_{\rm gal} \sim 10^8$ yr.

(2) The captured hole sinks toward the centre of the stellar distribution on the dynamical friction time scale:

$$t_{\rm df} \sim \frac{6\times 10^6}{\log N}\left(\frac{v_{\rm c}}{300\ {\rm km\ s^{-1}}}\right)\left(\frac{r_{\rm c}}{100\ {\rm pc}}\right)^2 m_8^{-1} \quad {\rm yr} \qquad (1)$$

where the core is presumed to have a central velocity dispersion $v_{\rm c}$, a core radius $r_{\rm c}$ and contain N stars, mass m^*. m_8 is the mass of the smaller black hole, in units of $10^8\ M_\odot$, presumed to be associated with the smaller galaxy. M is the mass of the larger black hole, assumed to be less than Nm^* (the mass of the core). $t_{\rm df}$ is generally longer than the core crossing time and so the merged cores should be fairly relaxed.

(3) When the black hole separation r shrinks to a value $r_{\rm B} \sim (M/Nm_*)^{1/3} r_{\rm c}$, they will become bound to each other with an orbital velocity that is initially smaller than the velocity dispersion of the stars by a factor $(M/Nm_*)^{1/3}$.

(4) The holes continue to spiral together under dynamical friction. As the binary becomes 'harder', the maximum impact parameter for effective energy transfer diminishes as $(r/r_{\rm B})^{3/2} r_{\rm c}$ because a binary cannot lose energy effectively to a field star during an encounter which lasts longer than one orbital period. For longer encounter times, the orbital energy is adiabatically invariant and the energy transfer diminishes exponentially[11]. This affects $t_{\rm df}$ only through the logarithm as long as the binding energy of the binary is small compared with the total kinetic energy of all the stars whose orbits pass sufficiently close to interact effectively.

(5) When $r \leqslant r_{\rm lc} = (m/M)^{1/4}(r_{\rm B}/r_{\rm c})^{9/4} r_{\rm c}$, this condition is violated and further stellar dynamical evolution is controlled by the rate at which stars whose orbits do not come close to the binary can diffuse into more radial 'loss cone' orbits[12] that pass within a radius $\sim r$. Two-body 'star–star' relaxation will repopulate the loss cone in a time ~(solid angle of loss cone) × (two-body relaxation time). The loss cone must be repopulated $(r_{\rm lc}/r)^4$ times to halve the binary orbit. The relevant binary evolution time is then:

$$t_{\rm lc} \sim t_{\rm df} \max\left[1, \left(\frac{m}{M}\right)^{7/4} N\left(\frac{r_{\rm B}}{r_{\rm c}}\right)^{27/4}\left(\frac{r_{\rm lc}}{r}\right)\right] \qquad (2)$$

Collective effects may, however, lead to a more rapid repopulation of the loss cone[13] and evolution on a time closer to $t_{\rm df}$.

(6) The binary becomes 'hard' when its orbital speed reaches $v_{\rm c}$ at a separation $r_{\rm h} \sim (r_{\rm B}/r_{\rm c})^3 r_{\rm c}$. The maximum impact parameter for dynamical friction is now $(rr_{\rm h})^{1/2}$. Each interacting star on average carries off a fraction $\sim m_* m/M^2$ of the binary's binding energy. The binary evolution time scale is now

$$t_{\rm h} \sim t_{\rm df} \max\left[\left(\frac{r_{\rm h}}{r}\right)\ln N, \left(\frac{M}{Nm^*}\right)^2 N\right] \qquad (3)$$

(7) When the binary becomes sufficiently tightly bound, gravitational radiation shrinks the orbit on a time scale $|r/\dot{r}|$ given by

$$t_{\rm GR} \sim 3\times 10^5 \left(\frac{m}{M}\right)^{-1} M_8^{-3} r_{16}^4 \quad {\rm yr} \qquad (4)$$

(8) The evolution now proceeds quite rapidly to coalescence (which takes a time $\sim M_8$ h). This may be accompanied by a powerful burst of electromagnetic radiation, depending on the local gas density and magnetic field strength, as well as a pulse of gravitational radiation[4,5]. Indeed, the final plunge will lead to the emission of net linear momentum and the recoil may be sufficient to eject the combined hole from the core and hence from the galaxy[5].

In addition to these stellar dynamical effects, infall of gas onto the binary can also lead to some orbital evolution. Gas may be flung out of the system, acquiring energy (and angular momentum) at the expense of the binary; alternatively, gas may accrete onto the larger hole, causing orbital contraction as the product Mr is adiabatically invariant. In either case, the evolution time scale is

$$t_{\rm gas} \sim 10^8 M_8 (\dot{M}/1 M_\odot\ {\rm yr}^{-1})^{-1} \quad {\rm yr} \qquad (5)$$

During phases of nuclear activity, gas infall rates $\dot{M}$ of 1–10 $M_\odot\ {\rm yr}^{-1}$ are required for times 10^7–10^8 yr. It is, therefore, quite likely that this process controls the binary evolution when r just exceeds $r_{\rm GR}$ and the stellar dynamical effects are weakest.

These time scales, $|r/\dot{r}|$, are given schematically in Fig. 1. It is clear that the longest evolutionary phase, and therefore the one containing most potentially observable binaries, is that with $r_{\rm h} \gtrsim r \gtrsim r_{\rm GR}$. During this phase a tight binary will persist in a quiescent state with almost constant r, except when it is undergoing fuelling and it becomes a conspicuous source of non-thermal power. The energy dissipated by the material flung out (at the expense of the binary orbital energy) is generally negligible at this time[14]. Slow secular contraction proceeds during active phases and pauses during intervals of quiescence. The details and statistics of observability depend on the time-dependence of $\dot{M}$ (is it intermittent or recurrent?, are the active phases as long as $M/\dot{M}$?). In conditions appropriate to galaxies like M87 ($r_{\rm c} \sim 100$ pc, $v_{\rm c} \sim 300\ {\rm km\ s^{-1}}$, $Nm^* \sim 3\times 10^9\ M_\odot$) it is

028-0836/80/390307—03$01.00

clear that the two-body evolution times given by equations (2) and (3) are much longer than $t_{\rm gas}$. (This may not be true for much less massive cores and small holes, $M \leqslant 10^6 M_\odot$.) If the binary gains mass at a constant rate, then the probability of observing a binary with separation greater than r will fall as r^{-1}. If $\dot{M} \propto M$, then binaries are distributed uniformly in log r. In any case, the separation $r_{\rm GR}$ at which gravitational radiation becomes dominant is insensitive to the values of $t_{\rm h}$ and $t_{\rm gas}$,

$$r_{\rm GR} = 5 \times 10^{16} \left(\frac{m}{M}\right)^{1/4} M_8^{3/4} \times \left[\frac{\min\,(t_{\rm h}, t_{\rm gas})}{10^8\ {\rm yr}}\right]^{1/4} {\rm cm} \tag{6}$$

For $r \leqslant r_{\rm GR}$ the orbital evolution is very rapid and the probability of observing a binary with separation smaller than r will decline as r^4. Most observed binaries will have $r_{\rm GR} \lesssim r_{\rm h}$.

The most direct evidence for a massive black hole binary would be some manifestation of the keplerian motion, which has a period

$$P_{\rm orb} \sim 1.6 r_{16}^{3/2} M_8^{-1/2} \quad {\rm yr} \tag{7}$$

Any eccentricity in the orbit will almost certainly be erased by the frictional drag and so the orbit is assumed to be circular. We generally expect the spin axes of the holes to be misaligned unless thay have both accreted a substantial amount of gas with a fixed angular momentum[15]. The spin axes will then undergo geodetic precession about the total angular momentum. For the more massive hole, the period is,

$$P_{\rm prec} \sim 600 r_{16}^{5/2} (M/m) M_8^{-3/2} \quad {\rm yr} \tag{8}$$

The spin angular momentum will be small compared with that in the binary provided that $(m/M) \geqslant (GM/rc^2)^{1/2}$ and so the spins precess in a cone with the orbital angular momentum as axis.

The beams of plasma which give rise to compact and extended radio structure in active galaxies may be collimated sufficiently near a massive black hole that the Lense–Thirring effect aligns them with the hole's axis[15], irrespective of the original momentum of the inflowing gas. (This requires the collimation scale to be much smaller than the binary separation r in the phases that concern us here.) The beams will then process with period $P_{\rm prec}$. It has been suggested that a scaled-down version of this mechanism causes a pair of jets to precess in SS433 (refs 16, 17).

As $(r_{\rm h}/r_{\rm GR})$ can be as large as 10^4, $P_{\rm orb}$ and $P_{\rm prec}$ can span many orders of magnitude and be made manifest in different ways. We outline below two examples that could correspond to different phases in the evolution of a binary. The observed activity is assumed to be only associated with the more massive component.

Wide binary ($r_{16} \sim 30$, $M_8 \sim 1$, $m_8 \sim 0.1$). In this case the precession time scale is $\sim 3 \times 10^7$ yr—comparable with the inferred lifetime of extended radio components. Precession of the beam axis would then result in an inversion symmetry in the source structure. Such precession has been inferred[3] on phenomenological grounds, but the massive binary seems to be the only way to set this in a dynamical context. (Jet alignment can occur, however, with a lone black hole[15].) Note that the morphology may differ from that associated with a ballistic trajectory, because of gas-dynamical effects, but should nevertheless have the same average symmetry (M.C.B., in preparation).

The orbital period (300 yr) would be too long to be detected directly. However, the broad emission lines may originate in a region around the more massive hole while the narrow lines would come from a much larger system enveloping the binary. The broad lines may then peak at a velocity up to $\sim 10{,}000\, r_{16}^{-1/2} M_8^{-1/2} m_8$ km s^{-1} different from that of the galaxy as determined by the narrow lines. Blue- and redshifts (relative to the narrow lines) should be about equally common.

Close binary ($r \sim r_{\rm GR}$, $t_{\rm gas} \sim 10^8$ yr). In this case $P_{\rm orb} \sim 18(m/M)^{3/8} M_8^{5/8}$ yr, $P_{\rm prec} \sim 3 \times 10^4 (M/m)^{3/8} M_8^{3/8}$ yr. Any extended radio structure associated with jets, built up over many precession periods, will be aligned with the orbital angular momentum; the precession related curvature will be discernible, however, on the scales probed by VLBI or the VLA.

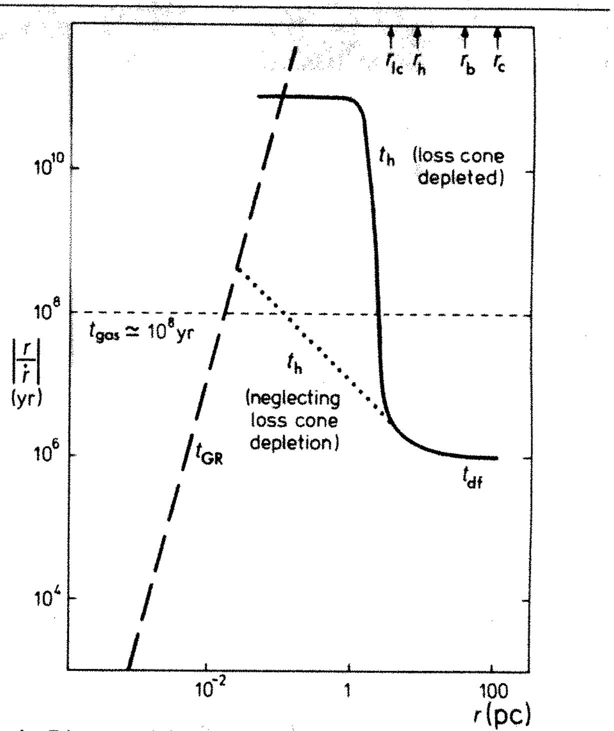

Fig. 1 Diagram of the time scales involved in the approach, and eventual coalescence, of a supermassive binary. The core parameters chosen are those that might be appropriate to a giant elliptical: $r_c \sim 100$ pc, $v_c \sim 300$ km s^{-1}, $N \sim 2 \times 10^9$ and $m_* \sim 1$. The members of the binary are taken to have masses $M_8 = 1$ and $m_8 = 0.3$. For this system, $t_{\rm df} \sim 10^6$ yr. Within $r_{\rm h}$ the evolution time scale would be $(r_{\rm h}/r)t_{\rm df}$ if loss cone depletion could be ignored; however, unless collective effects permit replenishment of the loss cone on much less than the ordinary stellar relaxation time, the evolution within $r_{\rm lc}$ proceeds on a very much longer time scale $\geqslant 10^{11}$ yr (compare equation (3)). Influx of gas into the system at a rate $\dot{M} \sim 1\, M_\odot\, {\rm yr}^{-1}$ would however yield a time scale $\sim 10^8$ yr. Gravitational radiation would take over as the dominant mechanism within $1.3 \times 10^{-2} (t_{\rm gas}/10^8\ {\rm yr})^{1/4}$ pc. The values of the various critical radii are indicated. (Note that in this particular example $r_{\rm lc}$ lies inside $r_{\rm h}$; for the case of two similar masses, as discussed in the text, this ordering is reversed.)

Suppose that the jets precess around a cone of semi-angle ϕ. If the jets were narrow with a non-relativistic speed $V \ll c$, a 'snapshot' would reveal the beam material tracing out a spiral pattern around the core: successive turns would be separated by a fixed distance $vP_{\rm prec}$, the pattern becoming more transverse at larger distances from the apex. However, in the 'superluminal' sources the jet velocity is believed to be relativistic with Lorentz factor $\gamma = (1 - v^2/c^2)^{-1/2}$ in the range 5–10 (ref. 2). What is actually observed from a precessing jet is modified by Doppler boosting and light travel time effects that depend on the observer's orientation. We can readily show that this geometry can account for a large bending and consequent misalignment between fast-moving VLBI features and any extended structure.

Let the observer's line of sight make an angle Ψ with the cone axis. The jet will be observed to be brightest when it makes an angle $\lesssim \gamma^{-1}$ with the line of sight. If $\phi \gtrsim \gamma^{-1}$, this implies that for the strongest sources, the observer direction must lie in the hollow cone, $\phi + \gamma^{-1} \gtrsim \Psi \gtrsim \phi - \gamma^{-1}$. Assuming that the emissivity of the jet decreases away from the apex, the source will again appear brightest when the central region points within an angle γ^{-1} at the observer direction, which it will do for a fraction $\sim (2\pi\gamma\phi)^{-1}$ of each precession period. When observed from this direction, a precessing jet will be brightest and appear to bend through an angle ~ 1 radian. Individual inhomogeneities will, however, appear to move rectilinearly. Superluminal expansion of inhomogeneities convected outwards by the jet with apparent speed $\sim\gamma c$ will occur. Curvature of this order has been reported in a number of superluminal radio sources[2]. For 3C273 and 3C345, continuous bending through an angle ~30° is visible on angular scales θ from ~5 to ~30 m arc s. If the distance of the source is d, we can infer the necessary precession period using the fact that the projected expansion speed is $\sim\gamma c$ to obtain,

$$P_{\text{prec}} \sim 2\pi\phi\theta d/c \qquad (9)$$

For 3C273, we substitute $\phi \sim 60°$, $\theta \sim 30$ m arc s, $d = 800$ *Mpc* to obtain $P_{\text{prec}} \sim 500$ yr. We could obtain this short precessional period if $r_{16} \sim 1.7$, $M_8 \sim m_8 \sim 1$, $t_{\text{GR}} \sim 3\times10^6$ yr. More distant sources require somewhat larger and more probable precessional periods. If, as we have assumed, $\phi \gg \gamma^{-1}$, then at large distance from the nucleus the jet will not be subject to large Doppler shifts.

Orbital motion at the source of a jet is another possible source of jet curvature[18]. However, the maximum transverse displacement in a single wavelength is of order the binary separation r, far too small to account for observed bent superluminal sources, though possibly relevant to small scale bends in sources like NGC6251 (ref. 18) which has a jet 1 pc long, misaligned by 3°. This would be expected from a binary with separation $r \sim 10^{17}$ cm.

We have argued that there are good reasons to expect binary black holes in galactic nuclei and that most observed examples will have separations in the range $10^{16}\text{ cm} \leq r \leq 10^{19}$ cm. Wide binaries may be responsible for inversion-symmetric features in large scale jets. Very close binaries may produce bending and misalignment in VLBI jets through the kinematic consequences of precession. Orbital motion may be reflected in the profiles of permitted emission lines; short orbital periods (~10 yr) may even be detectable photometrically using archival plate libraries.

If the binary hypothesis is correct, then we expect that jets that appear to be orbiting or precessing should be associated with cD or irregular galaxies in clusters or groups with large numbers of close companions. Furthermore, estimating the rate of merging and making an evolutionary correction we can compute the frequency of black hole coalescence events from objects at large redshifts to be in the range 10^{-3}–1 yr^{-1} (refs. 4, 5). These events (hypernovae) would be accompanied by detectable bursts of electromagnetic and gravitational radiation of powers that can, in principle, approach $c^5G^{-1} \sim 10^{59}\text{ erg s}^{-1}$ for a duration of ~1 h. However, as with a supernova, the actual peak electromagnetic power will be moderated by the amount of gas surrounding the explosions, and the strength of the gravitational radiation pulse by a fairly small efficiency factor[5].

Of course the evolutionary properties of binaries could be far richer than we have described. For example, drawing an analogy with stellar evolution, if one of the holes possessed a massive extended disk or envelope in which the inflow time is as long as $|r/\dot{r}|$ then mass transfer between the components could be important and may even account for much of the variability associated with quasars. Also, merging may occur more rapidly than evolution of the binary and three or more black holes may collect in the core. In this case a gravitational sling-shot[19] rather than coalescence will probably occur.

The detection of a stellar cusp around a central mass, as has been claimed for M 87 (ref. 20), implies that this mass is probably not a recently merged binary, because if black holes were brought together by dynamical friction they would have scoured out all the stars passing within r_h and there should actually be a deficit of stars in this region. The cusp may, however, be restored if a large mass of gas has subsequently been accreted thus repopulating the cusp.

We thank Juhan Frank for helpful comments. M.C.B. and R.D.B. thank the Institute of Astronomy, Cambridge for hospitality and acknowledge support under NSF grants AST77-23069 and AST78-05484 respectively.

Spectral broadening measurements of the ionospheres of Jupiter and Saturn

Richard Woo & J. W. Armstrong

Jet Propulsion Laboratory, California Institute of Technology,
Pasadena, California 91103

When Pioneers 10 and 11 flew by Jupiter, their 2.3-GHz monochromatic radio signals underwent substantial spectral broadening as they propagated through the planet's ionosphere[1,2]. Although spectral broadening has been observed during radio occultation by the solar corona[3,4], the Pioneer measurements of Jupiter represent the first time it has been observed during radio occultation by a planetary atmosphere. The Pioneer data are also unique in that r.f. spectral broadening, a scattering phenomenon normally associated with strong intensity scintillations ($\sigma_\chi^2 \sim 1$ where σ_χ^2 is the variance of the log-amplitude scintillations), occurred when the intensity scintillations were weak. This unusual opportunity makes it possible to compare the theory for spectral broadening with the more widely used weak intensity scintillation theory[5,6]. We report here that good agreement is found, and present the inferred characteristics of the electron density irregularities for the ionospheres of both Jupiter and Saturn. The Saturn results are based on measurements made during the 1979 Pioneer 11 encounter of Saturn.

The details of the Pioneer 10 radio occultation experiment have been discussed elsewhere[1,2,7]. Figure 1 shows the measured r.f. spectrogram at 2.3 GHz for the lower ionosphere (~200–500 km altitude region designated region C by Woo and Yang[7], where altitude is determined by reference[2] to the atmospheric level at which the neutral gas has a refractivity of 10), measured during exit occultation which took place at 26 °N latitude when the solar zenith angle was about 81°. The electron density irregularities in this region have been found to be isotropic[7]. The inherent linewidth over a comparable integration time as determined from measurements outside the ionosphere is less than 0.5 Hz, and can therefore be ignored when interpreting Fig. 1. The three-dimensional spatial wave number spectrum of the refractive index fluctuations corresponding to a power-law spectrum can be written as[6,7]

$$\Phi(x,\kappa) = \frac{\Gamma(p-1)}{4\pi^2}\sin\left[\frac{\pi(p-3)}{2}\right] c_{no}^2 \exp\left[\left(\frac{x-L}{a}\right)^2\right] \kappa^{-p} \qquad (1)$$

where Γ is the gamma function, κ is the spatial wave number, p is the spectral index, c_{no} is the structure constant of refractive index fluctuations, x is the wave propagation direction, L is the spacecraft to planetary limb distance, and a is the extent of the region of irregularities in the x direction.

Figure 2 shows a plot of the structure wave function $D(\tau)$ divided by 2 (refs 4–6). For the power-law density spectrum, a log–log plot of $D(\tau)$ against τ gives an estimate of the spectral index directly from the slope of a linear fit to the data. We have

0028–0836/80/390309—03$01.00

drawn the dashed line which corresponds to $p = 3.3$, and it can be seen that it represents a very good fit to the data. The power spectrum $W_\chi(f)$ of the log-amplitude scintillations over the same time interval has been studied previously[7] and is reproduced in Fig. 3 with the theoretical fit corresponding to $p = 3.3$. The relevant parameters for the theoretical fit are $v = 3.5 \times 10^4$ m s^{-1} (v is the transverse speed of the line-of-sight path), $a = 1.5 \times 10^7$ m and $L = 2.9 \times 10^8$ m. It is clear that the intensity scintillation and spectral broadening measurements are consistent in showing that the density spectrum is power-law with spectral index about 3.3. Comparison of the structure wave function with W_χ shows that the former is a more sensitive estimator of p. Thus, we conclude that p is 3.3 and not 11/3 (Kolmogorov) as obtained from earlier studies of intensity scintillations alone[7].

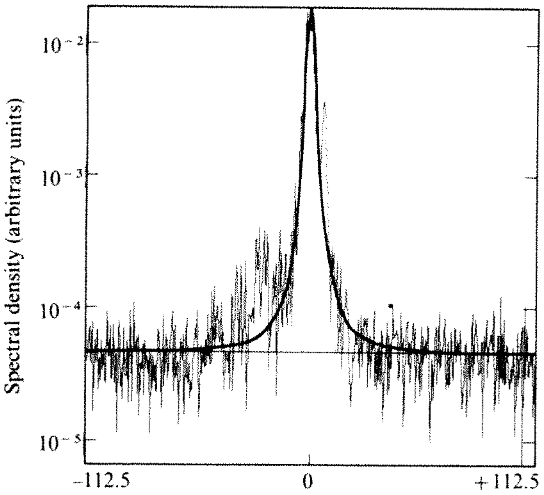

Fig. 1 R.f. spectrogram of Pioneer 10 2.3-GHz signal during Jupiter exit occultation (region C, see text). The heavy solid line is the $p = 3.3$ model discussed in the text, added to an estimate of the system noise (light horizontal line)

For the density spectrum given by equation (1), the variance σ_χ^2 of the log-amplitude scintillations can be obtained[8]

$$\sigma_\chi^2 = \frac{\Gamma(p-1)}{4} \sin\left[\frac{\pi(p-3)}{2}\right] c_{no}^2 \sqrt{\pi}\, a \Gamma\left(\frac{2-p}{2}\right) \cos\left[\left(\frac{2-p}{4}\right)\pi\right] k^{(2-p)/2} L^{(p-2)/2} \tag{2}$$

where k is the free space wave number and equation (2) is valid whenever $\sigma_\chi^2 < 1$. The bandwidth B, which represents the full width between frequencies enclosing half the area under the r.f. spectrum, is related to σ_χ^2 by[8]

$$B = \frac{Av}{2\pi} \sqrt{\frac{k}{L}} \left\{ \frac{4\sigma_\chi^2}{\cos\left[\left(\frac{2-p}{4}\right)\pi\right] \Gamma\left(\frac{p}{2}\right) 2^{p-1}} \right\}^{1/(p-2)} \tag{3}$$

where A is a constant having a value of about 1.95 for $4 \geqslant p \geqslant 3$. Using the measured noise-corrected σ_χ^2 of 0.27 and $p = 3.3$, equation (3) gives $B = 2.5$ Hz. We have superimposed on Fig. 1 the theoretical shape of the spectrum corresponding to these values. As can be seen, the agreement is very good.

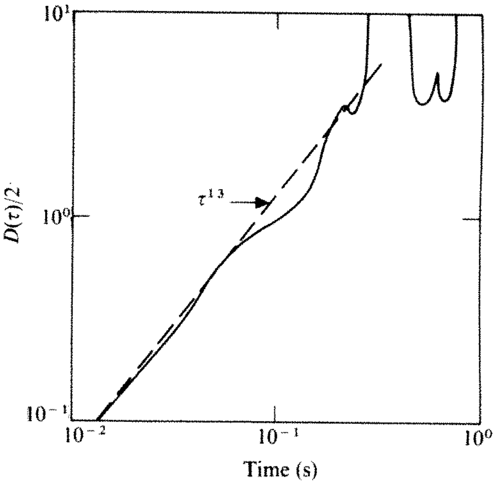

Fig. 2 Structure wave function divided by 2 for spectrum of Fig. 1. The linear fit (dashed line) corresponds to the $p = 3.3$ model.

It is significant that the spectral broadening and intensity scintillation measurements agree so well because this is the first time such a comparison could be made in weak scintillation conditions. When the scintillations become strong, as may be the case when L is large, intensity scintillations become difficult to interpret while the theory for spectral broadening remains valid[5,6]. In this case, spectral broadening becomes the more useful radio observation for measuring the density spectrum. In equation (1) we have assumed that the irregularities are isotropic as is the case for the region C data discussed here. In the upper ionosphere the irregularities are anisotropic because of alignment with the planetary magnetic field[7]. Theoretical results for interpreting spectral broadening measurements taking into account anisotropic irregularities and a general power-law density spectrum are available[9].

Note from equations (2) and (3) that although $\sigma_\chi^2 \sim L^{(p-2)/2}$, B is independent of L but is proportional to v. Thus, like multipath propagation[2], intensity scintillations become more severe when the distance between the planet and spacecraft is increased (as long as $\sigma_\chi^2 \leqslant 1$). On the other hand, the amount of spectral broadening is unchanged as long as v is unchanged. It is also clear from equation (3) that the substantial spectral broadening observed by Pioneers 10 and 11 was due to the very large fly-by velocities, rather than strong intensity scintillations.

The one-dimensional spectrum of the electron density fluctuations is of particular interest because it corresponds to the spectrum measured directly by spacecraft. For the case discussed above, we have $V_{ne}(\kappa) = 2.1 \times 10^{26} k^4 c_{no}^2 \kappa^{-1.3}$. Applying equations (2) and (3) to the results shown in Figs 1–3, we obtain $c_{no} = 8.3 \times 10^{-10}$ m$^{-0.15}$ so that $V_{ne}(\kappa) = 7.8 \times 10^{14} \kappa^{-1.3}$ (el/m^3)^2/m^{-1} for $5 \times 10^{-4} \leqslant \kappa \leqslant 2 \times 10^{-3}$ m^{-1}.

A radio occultation experiment of Saturn was carried out during the recent Pioneer 11 fly-by[10]. We have studied the intensity scintillation and spectral broadening measurements

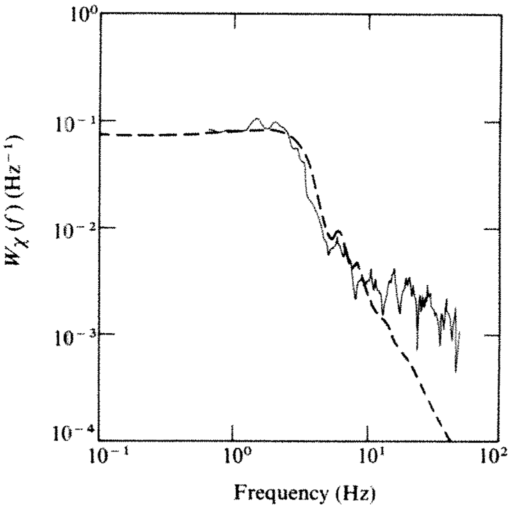

Fig. 3 Fluctuation power spectrum of the log-amplitude scintillations for region C data. Smooth dashed curve is the $p = 3.3$ model. System noise level is about 2.5×10^{-3} Hz^{-1}; the roll-off at high frequencies is due to digital filtering.

made by the ionosphere during exit occultation at latitude 9.5 °S and solar zenith angle 90.6°. Within the instrumental limits of the radio system, neither intensity scintillations nor spectral broadening was detected. Using the relevant parameters for the Saturn occultation ($v = 2.44\times10^4$ m s^{-1}, $L = 1.2\times10^8$ m and $a = 1.6\times10^7$ m) and assuming a density spectrum with $p = 3.3$, we deduce that $c_{no} \leqslant 3.4\times10^{-10}$ m$^{-0.15}$. The corresponding one-dimensional spectrum for the electron density fluctuations is then $V_{ne}(\kappa) \leqslant 1.3\times10^{14}\,\kappa^{-1.3}$ where $\kappa \geqslant 7.8\times10^{-4}$ m^{-1}. The Pioneer 11 measurements, therefore, show that the electron density fluctuations are smaller in the ionosphere of Jupiter. This may not be too surprising because the mean electron densities are higher in the ionosphere of Jupiter[2] than in Saturn[10]. Note that the Pioneer measurements of Jupiter and Saturn represent the observations of only a few locations and that globally these irregularities may vary substantially, as in the case of the Earth's ionosphere[11].

We thank A. Kliore for permitting us to analyse the Pioneer 11 Saturn radio occultation data and for useful discussions, H. Hsu and D. Cheng for help with software development and data analysis, and W. A. Coles for constructive criticism of an earlier version of this report. This report is Jet Propulsion Laboratory Atmospheres Publication 980-7 and presents the results of one phase of research carried out at the Jet Propulsion Laboratory, California Institute of Technology, under contract NAS 7-100, sponsored by the Planetary Atmospheres Program, Office of Space Science, NASA.

Galileo's observations of Neptune

Charles T. Kowal

Palomar Observatory, California Institute of Technology, Pasadena, California 91125

Stillman Drake

University of Toronto, Toronto, Ontario M5S 1A7, Canada

The planet Neptune was discovered in 1846. As its period of revolution is almost 165 years, Neptune has not yet completed one revolution since its discovery. Largely as a result of this, its orbit is not known with a precision comparable to that of the inner planets. A pre-discovery measurement of Neptune's position by Lalande in 1795 differs from the predicted position by 7 arc s. There is some debate about whether this discrepancy is real or an error of measurement[1]. Clearly, it would be worthwhile to find other pre-discovery observations of this planet. One possible way of finding such observations is to search for close approaches of Neptune to other objects which were frequently observed. Neptune was actually occulted by Jupiter in January 1613 and September 1702 (ref. 2). By 1702 the telescope was in widespread use, and examination of manuscripts of that period should reveal cases where Neptune was seen near Jupiter and mistaken for a star. The abundance of possible material, however, makes a search for such observations lengthy. We have found that Galileo observed the planet Neptune on 28 December 1612 and 28 January 1613. The latter observation may be of astrometric value, and differs by 1 arc min from the predicted position of Neptune. Galileo also detected the motion of Neptune.

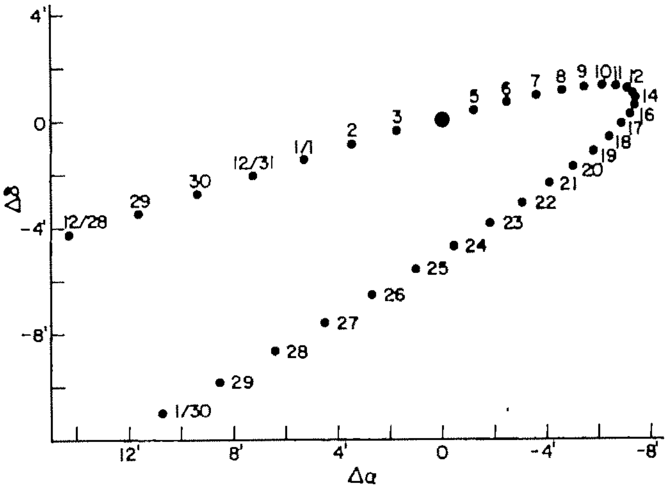

Fig. 1 The positions of Neptune with respect to Jupiter, 28 December 1612 to 30 January 1613. Black dots, Neptune; cross-hatched circle, Jupiter.

We began by examining Galileo's observations of 1612–13. Galileo observed Jupiter almost nightly at that time, and sometimes more than once on the same night. His notebooks have been published in several editions.

Figure 1 shows the ephemeris positions of Neptune with respect to Jupiter for 28 December 1612 to 30 January 1613. The field of view of Galileo's telescope was about 15 arc min, so both planets were within the same field for the entire interval. Jupiter became retrograde in mid-January, and so passed Neptune twice.

Figure 2 shows portions of a page of Galileo's notebooks which cover some of this time interval. In these drawings of Jupiter and its satellites, north is to the upper right, and east to the upper left. The first observation is dated: "1612 December, day 27, hour 15:46 a.m.". This corresponds to 28 December, 0346 a.m., local time. (Galileo considered each day to begin at noon.) A 'fixed star' is marked to the east of Jupiter on this date. The Palomar Sky Survey prints show no bright star in this position. There are, in fact, very few bright stars in that entire region of the sky in the constellation of Virgo. (Galileo was occasionally able to see stars of magnitude 9, but none fainter. Neptune is always brighter than magnitude 8. The galilean satellites have magnitudes of 5 to 6.) We have found that the direction of Galileo's 'star' from Jupiter is almost exactly the direction of Neptune on that night (Fig. 3). It would not have been possible to draw the distance of Neptune to scale, since the planet would have been off the edge of the page, so he put it at the edge of the page and indicated its direction with a dotted line.

Table 1 Mean positions of the objects for 28 January 1613, 2300 UT

Jupiter (from JPL DE 102)	$\alpha = 12$ h 04 min 59.54 s $\delta = +1°02'11.0''$	1950.0
SAO 119234 (includes proper motion)	$\alpha = 12$ h 05 min 27.02 s $\delta = +0°54'10.8''$	1950.0
Neptune (from JPL DE 102)	$\alpha = 12$ h 05 min 33.3 s $\delta = +0°52'24''$	1950.0
Galileo's position of Neptune	$\alpha = 12$ h 05 min 30.5 s $\delta = +0°53'11''$	1950.0

Galileo's position of Neptune with respect to the star is probably accurate to better than 10 arc s as judged from his accuracy in measuring the positions of the satellites. The accuracy of the position of the star itself depends on the accuracy of its proper motion, as listed in the SAO Star Catalog. We have used a total proper motion of 0.13 s in RA, and 11.5″ in declination.

0028–0836/80/390311—03$01 00

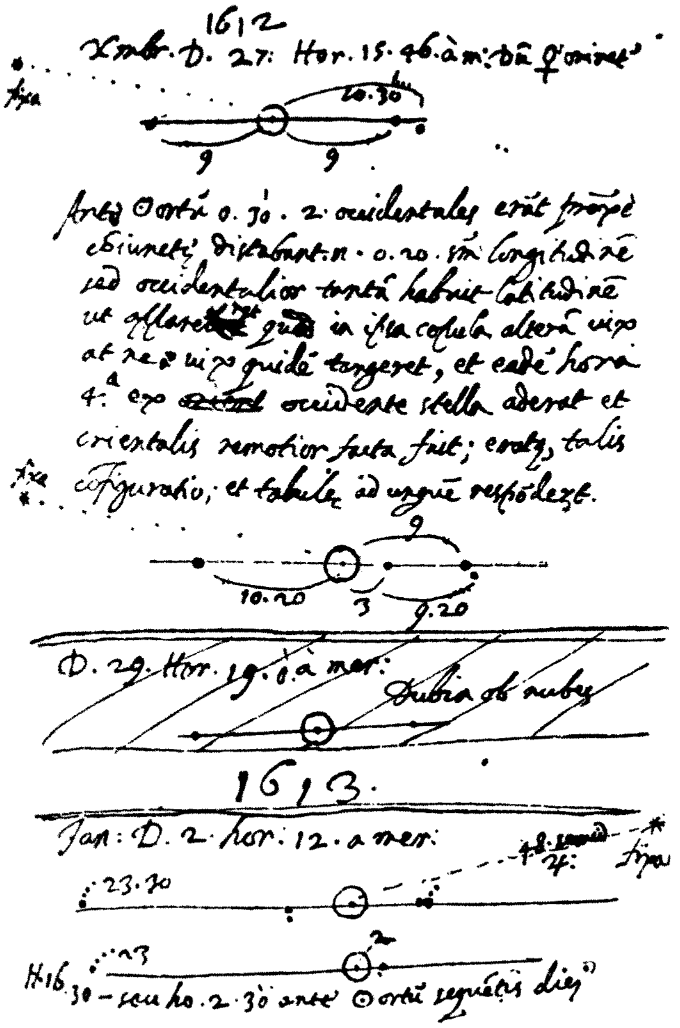

Fig. 2 Portions of a page from Galileo's notebooks, for 27/28 December 1612 to 2/3 January 1613 (ref. 3).

Figure 3 shows the ephemeris positions of the jovian satellites and Neptune for 0300 UT, 28 December 1612, together with the indicated position of Galileo's 'fixed star'. The exact correspondence of the directions and the absence of any bright stars in that area make us confident that Galileo actually saw Neptune on this night—234 yr before that planet was discovered.

Returning to Fig. 2, we see a star marked "48 jovian radii" to the north-west of Jupiter on "1613 January, day 2, hour 12 midnight". This star was easily identified as SAO 119234, visual magnitude 7.1. The star was actually 52 radii from Jupiter at the time. Again, this star would have been off the edge of his notebook paper, so Galileo drew it at the edge of the page.

Galileo must have seen Neptune during each of the following nights. It is puzzling that he did not show the planet in his drawings. Perhaps he did not want to clutter his drawings of the satellites with 'extraneous' objects near the satellite plane.

Figure 4 shows two observations from the end of January 1613. On "day 27" we again find SAO 119234, 20 jovian radii south-east of Jupiter. On the following night, two stars are shown in a separate drawing. The time of this latter observation is given as "day 28, 6 hours after sunset". This corresponds to about 2300 local time on 28 January. A plot of the ephemeris positions of Jupiter, Neptune and the star (Fig. 5), shows immediately that "star 'a'" is SAO 119234, while "star 'b'" is definitely Neptune. Galileo's note in the lower left quarter of this drawing may be translated as follows:

> Beyond fixed star "a", another followed in the same straight line, this is "b", which was also observed on the preceding night, but they (then) seemed farther apart from one another.

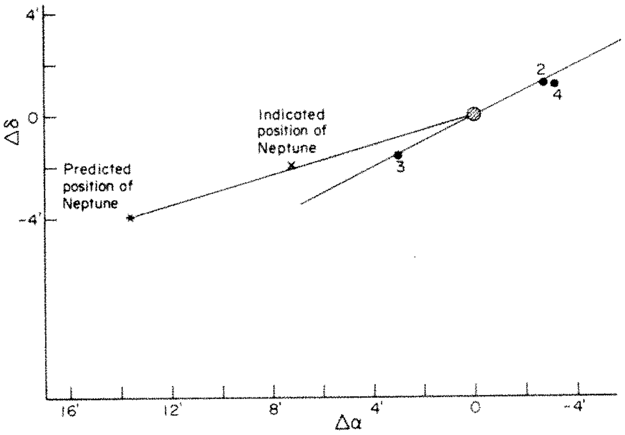

Fig. 3 The positions of Neptune and the jovian satellites, with respect to Jupiter, for 28 December 1612, 0300 UT. All of the positions in this paper are from Development Ephemeris 102, Jet Propulsion Laboratory, Pasadena, California.

b

Fig. 4 Galileo's notebook for 26/27 and 27/28 January 1613.

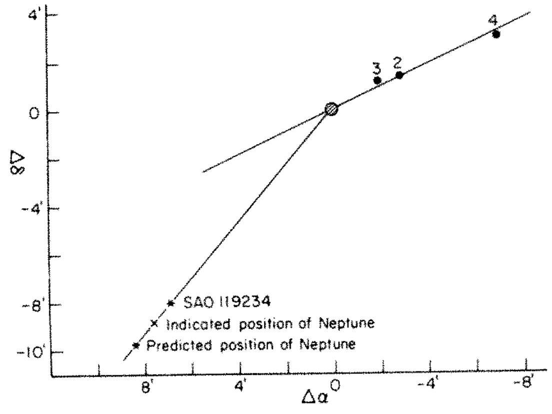

Fig. 5 The positions of Neptune, the jovian satellites and a star, for 28 January 1613, 2300 UT.

In other words, not only did Galileo see Neptune, he also noticed that it had moved with respect to a fixed star. Without an adequate telescope mounting it would have been impossible for him to follow up this observation after Jupiter had moved on, even if he had thought of doing so.

This observation of Neptune may be of astrometric value. Immediately below the drawing of Jupiter and its satellites is a linear scale showing 24 jovian radii. Below this scale is a drawing of the two 'stars'. The drawing indicates that Neptune was 3.75 radii, or just over 1 arc min, from star 'a'. The ephemeris shows that Neptune should have been 2 arc min from the star. It is therefore possible that the ephemeris is incorrect by about 1 arc min—a relatively large amount in celestial terms (see Table 1). We see no reason to doubt that Galileo drew the stars to the indicated scale, although it is surprising that the 'incorrect' ephemeris position still lies on the same straight line from Jupiter and the star. In principle, the error in the ephemeris could be in any arbitrary direction, most likely along the ecliptic, which is not parallel to the line from Jupiter.

We are left, then, with the strong possibility that the ephemeris of Neptune is in error by a significant amount, which would require a revision of the orbital elements of that planet, and suggests the existence of an unknown perturbation. [One of us (S.D.) believes that such revisions may disclose an occasion on which Galileo mistook Neptune for a satellite near Jupiter. Eclipse conditions and an ambiguity in timing one of his observations suggest this as a possibility, even if remote.]

The ephemeris of Neptune used in this work is from Development Ephemeris no. 102 of the Jet Propulsion Laboratory. Other ephemerides will give different results. We hope that this work will help decide which ephemeris is most accurate. It would be most interesting to try to fit the Galileo position and the Lalande positions into a new ephemeris of Neptune.

We thank Drs Jay Lieske and E. Miles Standish for supplying ephemerides of Jupiter, Neptune and the galilean satellites which made this work possible, and Dr Alexander Pogo for help and advice. C.T.K. is supported by grants from the National Aeronautics and Space Administration, and the NSF.

Imaging and focusing of neutrons by a zone plate

P. D. Kearney*, A. G. Klein*, G. I. Opat* & R Gähler†

*School of Physics, University of Melbourne, Parkville, Victoria, Australia 3052
†Institut Laue-Langevin, 38042 Grenoble Cedex, France

The use of refractive lenses for long-wavelength neutrons, although possible[1], is severely limited by the fact that the refractive index differs only very slightly from unity (for example, $n-1=2.3\times10^{-4}$ for quartz at $\lambda=20$ Å). However, the fact that only a relatively thin layer of material is needed to produce an optical path difference of half a wavelength (for example, 2.4 μm of Cu at $\lambda=20$ Å) led us to propose[2] previously that neutrons could be focused by diffraction from a phase grating of variable spacing; this is , in fact, a type of zone plate. Zone plates, first described by Soret[3], have been used satisfactorily over a large part of the electromagnetic spectrum[4-6]. We now report the successful focusing and imaging of a slow neutron beam by means of a Fresnel zone plate[8].

Conventional zone plates work by blocking out alternate zones. Constructive interference of the waves diffracted from the remaining zones occurs at specific points which are in an image relationship to their original source. Lord Rayleigh[7] pointed out that phase reversing, rather than absorbing alternate zones, would achieve a focus with greatly enhanced intensity. In the absorbing zone plate, only half the incident amplitude (leading to one-quarter the intensity) is focused; in addition, a 0 order beam of unfocused waves is present. This is not the case with the phase reversal zone plate in which the 0 order is absent and much more of the energy is focused. These facts were experimentally verified by Wood[5].

The geometric pattern of a Fresnel zone plate (see Fig. 1) is precisely that of the interference pattern of two spherical waves of differing radii of curvature. Thus, the zone plate may be regarded as the hologram of a point. This fact suggested our first approach to the construction of zone plates for long wavelength neutrons, along the lines previously used by others[6] in producing zone plates for soft X rays. However, we subsequently found that higher quality zone plates could be produced by the successive photographic reduction of a computer drawn pattern.

Our zone plates, which are of the phase reversal type, were produced in Melbourne by photolithographic techniques close to the limits of resolution used by the microelectronics industry. A thin layer of positive photoresist (Shipley AZ 1350 J) on a silicon wafer substrate was exposed to UV light through a mask carrying the zone plate pattern. After dissolving away the unexposed photopolymer, a layer of copper was electrolytically deposited on to the exposed surface. (Before coating with photoresist, a thin layer of chromium was deposited on the substrate to enhance the adhesion of the copper.) The thickness of the copper deposited was strictly controlled to be equal to $D(\lambda/2)=2.4$ μm, the thickness calculated to give a phase reversal to neutrons of 20 Å wavelength.

$$D(\lambda/2)=\tfrac{1}{2}\lambda/(n-1) \tag{1}$$

where

$$n=1-\lambda^2 Nb/2\pi \tag{2}$$

for a material having N scattering centres per unit volume, each with scattering length b.

The final zone plates produced in this way had the following characteristics: diameter $d=2$ mm, number of zones $\xi=200$, width of outermost zone $\delta=2.5$μm, focal length f (m) $=50/\lambda$ (Å) $=2.5$ m at $\lambda=20$ Å. Note that the width, δ, of the outermost zone, limited by the resolution of our plating technique, determines the quality of the lens in the sense that its F-number (f/d ratio) may be shown to be given by

$$F=\delta/\lambda \tag{3}$$

Thus, our lens has $F=1,250$, which is poor compared with lenses used with visible light but comparable with the performance of lenses used in electron optics. The reasons for this are most easily understood by reference to the holographic aspects of the problem. Regarding the zone plate as a hologram of a point, recorded with light of a given wavelength but reconstructed with waves of wavelength 250 times shorter, it is

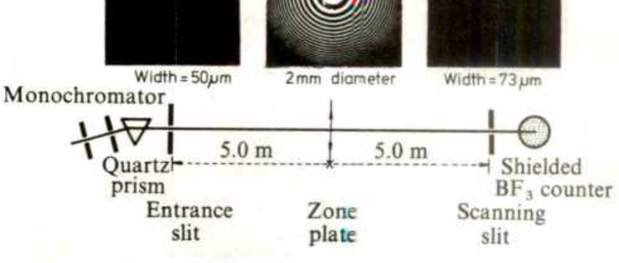

Fig. 1 Schematic layout of neutron focusing experiment.

0028-0836/80/390313—02$01.00

easily shown that the ultimate resolution is still that attainable with visible light. Therefore, better quality zone plate lenses can only be produced by methods avoiding the use of visible light, such as electron beam lithography.

We tested our zone plate on the long wavelength neutron beam, H18, at the High Flux Research Reactor of the Institut Laue-Langevin in Grenoble. The main features of the apparatus are shown in Fig. 1. The monochromator, consisting of a 120° quartz prism with entrance and exit slits, was used to select a 1-Å wide wavelength spread centred on 20 Å. The monochromator exit slit, set to 50 μm width, served as the object to be imaged by the zone plate at 1 : 1 magnification, that is, the object and image distances were both 5 m. The image was scanned in 20-μm steps by a 30-μm wide slit, placed in front of a shielded BF_3 proportional counter. A Polaroid camera with a lithium-loaded ZnS scintillator screen was also used to photograph the beam in the object and image positions, giving the results shown in Fig. 1.

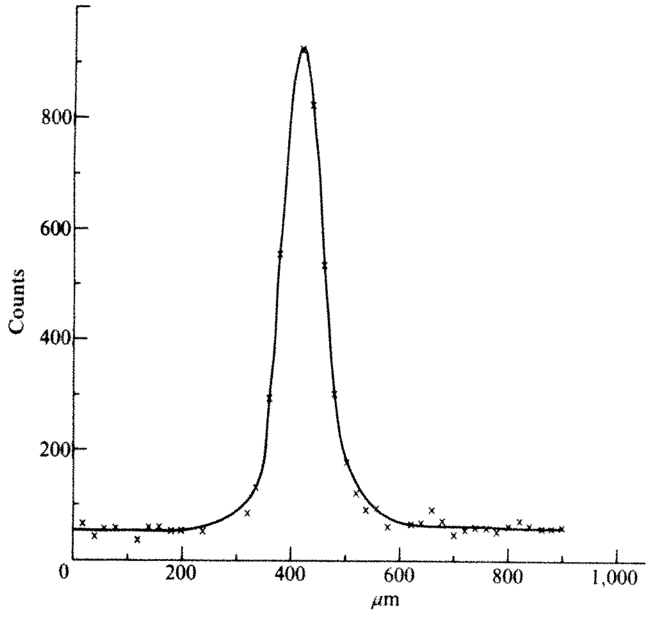

Fig. 2 Neutron intensity in the image plane.

Measurements of the beam detected in the image plane are shown in Fig. 2, and gave FWHM = 73 μm, a value consistent with the instrumental resolution, combined with the calculated chromatic aberration. Because object and image distances were fixed by the lengths of vacuum tanks taking up the flight paths, longitudinal scanning of the focus was not possible with this apparatus. We did, however, verify the calculated focal length by observing the width of the image as the wavelength was varied by rotating the monchromator prism. The image width showed a sharp minimum at 20 Å. An estimate of focusing efficiency (the fraction of neutrons going through the lens aperture that are focused into the image) was obtained by comparing counting rates at the image position with and without the lens. This gave 40 ± 10%, in agreement with theoretical expectations.

The applicability of the zone plate lenses described above is limited by the smallness of their aperture, their inherent chromatic aberrations and the low intensities of available long wavelength neutron beams. Nevertheless, there are several interesting possibilities in the field of neutron optics, some of which we have described previously[2].

We thank the directors and staff of the Institut Laue-Langevin for their hospitality and encouragement, the University of Melbourne for travel grants, Professor J. Kalus of the University of Bayreuth for allowing us the use of his apparatus, R. L. Shaw and P. Francis for their help with the production of holographic zone plates, and D. Sheridan, Siang Tjio and M. Crary for their help with photolithography. A.G.K. thanks the French government for a Senior Fellowship.

Electron irradiation induced vitrification at dislocations in quartz

D. Cherns, J. L. Hutchison*, M. L. Jenkins & P. B. Hirsch

Department of Metallurgy and Science of Materials,
University of Oxford, Parks Road, Oxford OX1 3PH

S. White

Department of Geology, Imperial College, London SW7 2AZ, UK

Recent observations using the 'weak beam' electron microscopy technique of split images of dislocations in quartz have been interpreted as arising either from dissociation of the dislocations into partials[1], or from a glassy (metamict) phase at the core[2], resulting from irradiation damage. In this letter we describe observations of lattice images of near end-on dislocations in quartz, which enable us to distinguish between these two models.

Quartz, the second most abundant crustal mineral, is important in the study of deformation within the Earth's crust. Plastically deformed quartz has therefore been the subject of numerous studies[3–5] from which two significant findings have emerged: (1) quartz deforms by dislocation creep mechanisms within the deeper crust and (2), trace amounts of lattice-bound OH cause a marked softening of quartz ('water weakening'). The causes of water weakening are not known with certainty but it is thought to arise from increased glide and/or climb velocities[6–9]. Any detailed model for this effect and for the interpretation of stress–strain curves requires a knowledge of the structures of the dislocation cores in quartz. Two different models have been proposed for the commonly encountered *a*-dislocations: Trepied and Doukhan[1] observed a splitting of weak beam images during irradiation in the microscope which they attributed to the movement of partial dislocations bounding a stacking fault composed of a complex twin structure; Cherns *et al.*[2] re-examined the image splitting and proposed an alternative model whereby irradiation damage led to the preferential formation of a metamict region in the vicinity of the dislocation core. The observed widening of the split weak beam images from about 6nm to several tens of nm was then attributed to additional radial displacements around the dislocation, generated by the expansion due to the crystalline–amorphous transition.

We have now attempted high-resolution lattice imaging of deformed quartz to obtain further information about core structures of essentially unirradiated dislocations, and to investigate in detail the development of any metamict phase. We used the naturally deformed quartz from the Cap de Creus shear zones in north-east Spain[10]; detailed textural and electron microscopic studies had been completed on this material, and

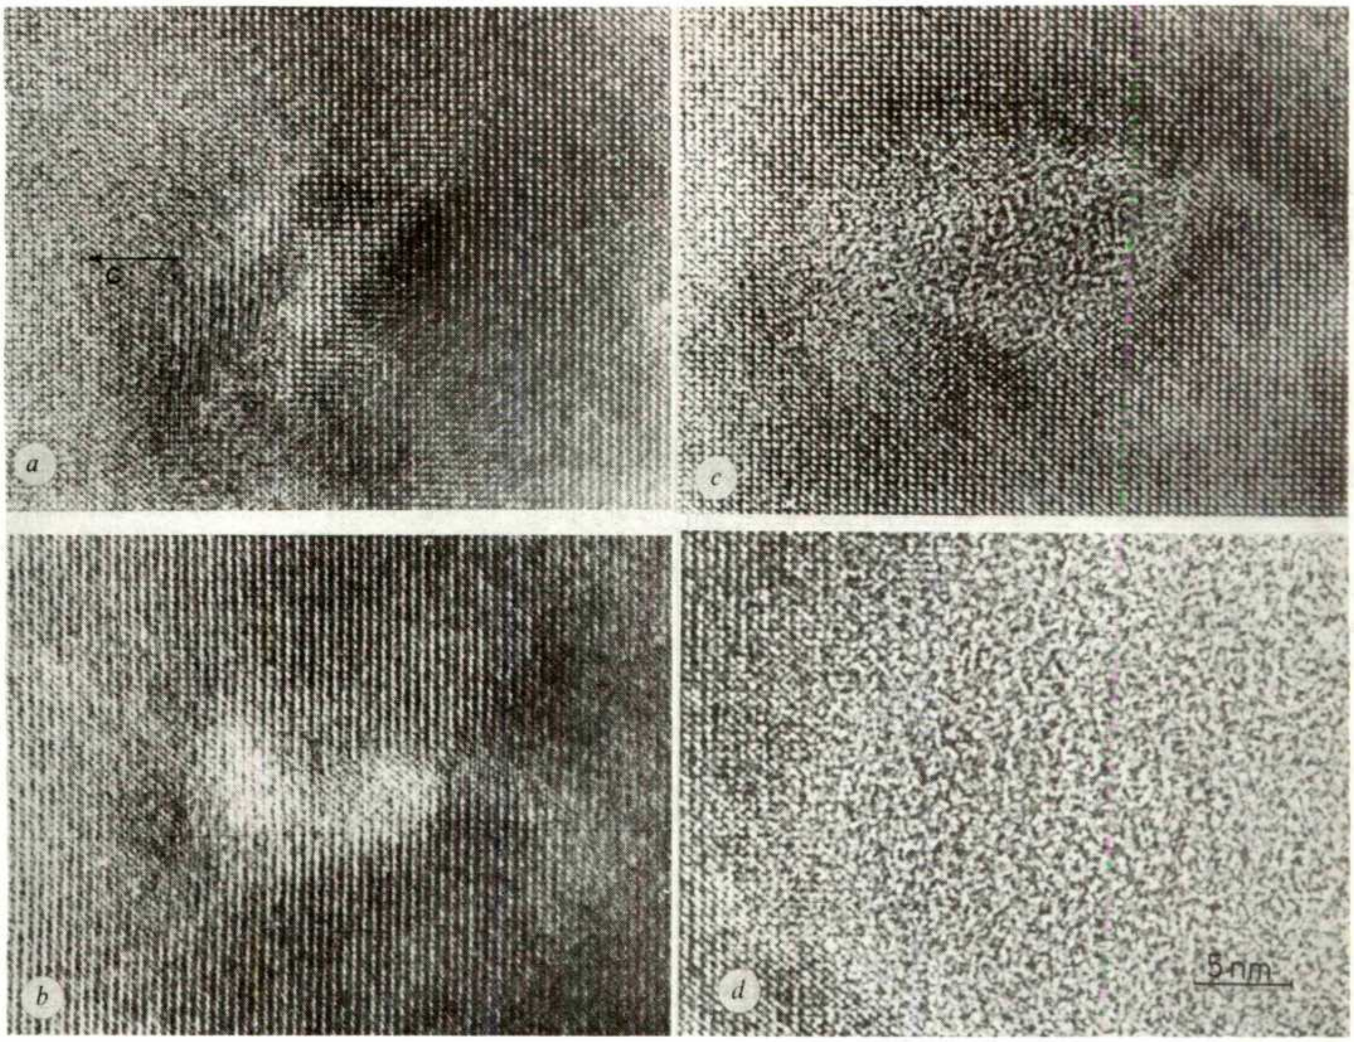

Fig. 1 *a*, $\langle 11\bar{2}0\rangle$ lattice image of a defective region in quartz, before electron beam damage becomes visible. *b*, The same region of crystal, after a further 10 s of exposure to the electron beam. *c*, After another 10 s in the beam a region of 'amorphous' contrast has appeared in the core region. *d*, After a total irradiation time of about 40 s most of the field of view has been replaced by the 'glassy phase'. Magnification, 3×10^6.

consequently it was known to contain *a*-type dislocations lying in the basal (0001) plane. Samples were cut normal to the basal plane and within a few degrees of a $[11\bar{2}0]$ pole. Dislocations of two of the three *a*-types, with Burgers vectors $\mathbf{b}=\frac{1}{3}a[1\bar{2}10]$ and $\frac{1}{3}a[\bar{2}110]$ and with line orientations close to 60°, preferred in these specimens, are close to end-on in a foil oriented at the $[11\bar{2}0]$ pole, if they exhibit dot contrast in diffraction contrast images. Specimens were ion-thinned and examined in a JEOL JEM 200CX electron microscope operating at 200 kV, with a high-coherence LaB_6 electron source and an objective lens with spherical aberration coefficient of 1.1 mm. A minimal exposure technique was used to reduce beam damage effects, photography being carried out on regions adjacent to those used for orientation, stigmation and focusing adjustments. $[11\bar{2}0]$ lattice images were recorded on Kodak 4463 film at a magnification of 4×10^5.

Figure 1 shows an irradiation sequence of an area containing a nearly end-on dislocation, as judged by the dot contrast criterion at lower magnification. The total irradiation time between Fig. 1*a* and *d* was rather less than 1 min. Figure 1*a* shows the earliest stages of the irradiation. In areas well away from the dislocation core the image reflects the quartz structure projected down $[11\bar{2}0]$.

By construction of a Burgers circuit in the undistorted region the presence of a dislocation was confirmed, the Burgers vector being consistent with one of the expected types. In the vicinity of the dislocation core, near the centre of the micrograph, the regular lattice is distorted; direct interpretation in this region is not possible because the dislocation geometry and diffracting conditions are not sufficiently well defined. A slightly later stage of the irradiation is shown in Fig. 1*a*. The strong diffraction contrast at the dislocation has almost disappeared, to be replaced by a lighter region diffracting less strongly than the surrounding area. Within this region the lattice image may still be discerned, but less clearly. In Fig. 1*c*, a central oval-shaped region has developed, displaying 'amorphous' contrast typical of a glass, whereas the regular lattice image is still clearly visible in surrounding regions. In Fig. 1*d* most of the field of view appears amorphous. The contrast between Fig. 1*c* and 1*d* is clearly indicative of a transition from crystalline to metamict quartz, and strongly supports the model proposed by Cherns *et al.*[2]. Vitrification of the dislocation core due to electron irradiation has also been suggested previously by Ardell *et al.*[11]. The metamict region grows with irradiation time in both [0001] and $[1\bar{1}00]$ directions, and is oval with its long axis in the *c* direction.

While the images show no evidence of any pronounced dissociation into partial dislocations on the basal plane, as envisaged by Trepied and Doukhan[1], to be accompanied on their model by displacements along $[1\bar{1}00]$ in the $[11\bar{2}0]$ projection, the possibility of dissociation over a width of less than 1 nm cannot be ruled out. The absence in Fig. 1*a* of evidence for an amorphous region suggests that the image splitting of about 6 nm reported by Cherns *et al.*[2] in the first micrograph of their irradiation sequence is due to the irradiation induced metamict phase. However, we cannot exclude the possibility of the presence of an amorphous region a few tenths of a nanometre in diameter ('colloidal cores' as postulated by Tsinzerling[12]). Finally, note that because of the additional displacements generated by the growth of the metamict phase, great care must be taken in the determination of Burgers vectors of dislocations in quartz.

Silica retards radial growth of spherulites in isotactic polystyrene

M. Kennedy, G. Turturro*, G. R. Brown & L. E. St-Pierre

Department of Chemistry, McGill University, Montreal,
Quebec, Canada H3A 2K6

We recently reported the retardation of the rate of crystallization, measured calorimetrically, in isotactic polystyrene (iPS) nucleated with silica (Cab-O-Sil) that had been treated with trimethylsilane[1]. The loading of the nucleant was 5 g per 100 g of polymer or two parts per hundred (p.p.h.) by volume, of polymer. From microscopic observations it was known that the number of nuclei present in the nucleated system was at least double that present in the pure polymer in identical cooling conditions[2]. The only rationale available for the retardation effect seemed to be that the nucleant was inhibiting the growth of the crystals and thus the overall rate of crystallization. However, previous workers have reported spherulitic growth rates to be unaffected by the presence of nucleants in systems with loadings up to 3 p.p.h. (refs 3–6). To clarify this apparent paradox the measurement of the radial growth rates of spherulites in the system iPS–silica by photomicrography was undertaken. Here we confirm that silica does retard the rate of growth of such spherulites.

A Zetopan Reichert research microscope equipped with crossed polarizers and a Nikon 35 mm camera were used in conjunction with a Mettler FP52 hot stage (controlled to ±1°C and calibrated using the melting points of benzoic acid, naphthalene and benzophenone). The samples were prepared by melting 0.1–0.2 mg of iPS between a precleaned microscope slide and a coverglass separated by Pt washers ~20 μm thick. Before observation the samples were premelted at 255 °C for 5 min. Subsequently, they were cooled to the desired crystallization temperature and the growth rates of spherulites was followed by photographing them at regular intervals. The diameters of 15 and 60 spherulites, respectively, for the un-nucleated and nucleated systems were measured at least five times for each photograph and a growth rate for each spherulite was determined, using a linear least squares program, for diameters in the range 15 to 45 μm. An average of the spherulitic growth rates was calculated by taking the average of the growth rates of individual nuclei at a given crystallization temperature.

Figure 1 shows the effect of temperature, in the range 150–200 °C, on the rate of radial growth of spherulites in un-nucleated iPS (viscosity molecular weight approximately 1 × 10^6, equilibrium melting point = 231 °C). The growth rates, G, can be described by a modified form of the Lauritzen–Hoffman equation[7]

$$\ln G = \ln G_0 - \left[\frac{C_1}{R(C_2 + T - T_g)}\right] - \frac{4b_0\sigma\sigma_e T_m^0}{k\Delta H T\Delta T} \qquad (1)$$

where G_0 is a pre-exponential factor which is independent of temperature. The effect of temperature of the rate of transport in a polymer melt is described by the term $[C_1/R(C_2 + T - T_g)]$ where R is the gas constant, C_1 and C_2 are the WLF constants describing viscous flow in polymers, T is the crystallization temperature, and T_g is the glass transition temperature. The remaining term in equation (1) relates to the nucleation energy which depends on the monomolecular thickness b_0, the side and end interfacial energies, σ and σ_e, respectively, the equilibrium melting point, T_m^0, the heat of fusion, ΔH, the Boltzmann constant, k, and ΔT, the supercooling. As shown in Fig. 1, an excellent 'fit' to the growth pattern in the un-nucleated system is obtained when:

$$C_1 = 1.72 \times 10^4 \ \ \text{J mol}^{-1}$$

$$C_2 = 75\ \text{K}$$

$$T_g = 365\ \text{K}$$

and

$$\frac{4b_0\sigma\sigma_e T_m}{k} = 9.25 \times 10^4\text{K}^2 \quad (T_m^0 = 503.8\ \text{K})$$

The addition of 0.8 vol. % fine particle silica (Cab-O-Sil M – 5) caused a decrease in the radial growth rate over the range 170 to 190 °C (Fig. 1). To obtain a fit to the data for this system, equation (1) was modified to include a contribution due to the adsorption of polymer segmers onto the silica with a heat of adsorption (ΔH_{ads}) known[8] to be 2.05 × 10^4 J mol^{-1}, to

$$\ln G = V_2 \ln G_0 - \frac{C_1 + \phi\Delta H_{ads}}{C_2' + T - T_g} - \frac{4b_0\sigma\sigma_e T_m^0}{k\Delta H T\Delta T} \qquad (2)$$

where V_2 is the volume fraction of polymer and ϕ is a constant. Again, an excellent fit is obtained to the data when

$$\phi = 8.27 \times 10^{-2}, \qquad C_2' = 107\ \text{K}$$

The observed increase in C_2 to C_2', that is 75 to 107 K, is in accordance with, but somewhat larger than, directly measured values for the change in T_g in the presence of added silica[9].

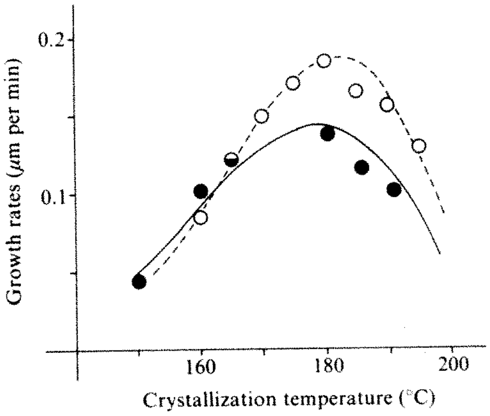

Fig. 1 Effect of crystallization temperature on the spherulite growth rates in un-nucleated (○) and nucleated (●) isotactic polystyrene [– – – – theoretical, equation (1); ——— theoretical, equation (2)].

Interestingly, as would be expected, a satisfactory account for the retardation in the rate of radial growth in iPS due to added silica can be achieved by considering only the transport term in equation (1).

These results demonstrate a decrease in the rate of radial growth of spherulites in nucleated polymer melts. This effect is probably general but has not been previously recognized because, despite the retardation in the rate of development of the spherulites, the overall crystallization rate will be retarded only in cases where the increase in the number of nuclei is small. The transport limitation has been demonstrated to result from the formation of quasi-crosslinks in the polymer melt as a result of the physisorption of the polymer segments on the nucleant[10].

We thank the Natural Sciences and Engineering Research Council for financial support and Drs Gray and Manley of McGill University for the use of their equipment.

Simulation of a lipid monolayer using molecular dynamics

A. J. Kox*, J. P. J. Michels† & F. W. Wiegel‡

*Institute of Theoretical Physics, University of Amsterdam, Amsterdam, The Netherlands
†Van der Waals Laboratory, University of Amsterdam, Amsterdam, The Netherlands
‡Department of Applied Physics, Twente University of Technology, Enschede, The Netherlands

Numerical simulation is often a useful tool for investigating the behaviour of complex systems with many degrees of freedom. Of the two major methods in this field, the Monte Carlo method and the molecular dynamics method, only the first has been applied to realistic models of lipid monolayers[1–5]. The term lipid monolayer is used here to describe a class of systems consisting of chain molecules on a liquid substrate, the characteristic properties of which can be summarized as follows. (1) The constituent molecules are amphipathic, that is they consist of a hydrophilic (polar) head group and one or more hydrophobic hydrocarbon chains. (2) Due to the amphipathic character of the molecules, the head groups are constrained to the plane of the substrate, whereas the tails are directed outwards from this plane. (3) The collective properties of the molecules are determined by their short-range repulsive and long-range attractive interactions and by the steric repulsion of the tails. We now present what we believe to be the first molecular dynamics simulation of a realistic model of a lipid monolayer. The model system, which has all three properties enumerated above, shows a first order phase transition from an ordered fluid-like state to a disordered, gas-like state.

Cotterill[6] and Toxvaerd[7] have performed numerical dynamics calculations on very rough models of monolayers. Both authors only consider models in which the individual molecules are reduced to purely two-dimensional objects which move in the plane of the monolayer. The influence of the steric interactions of the chains and of their large number of configurations is therefore neglected. Consequently, these calculations are at best a simulation of the crystalline state of a monolayer, with all lipid chains parallel and in the all-*trans* state. Also, the mechanism believed to be responsible for the main phase transition in lipid monolayers—the 'melting' of the tails—is absent in these models. These are rather severe limitations (see ref. 8 for a review of lipid monolayer theory and of some of the terminology used here). To improve this situation we have performed a molecular dynamics simulation of a realistic model of a lipid monolayer. The system consists of 90 chain molecules (lipids), each molecule consisting of seven repeating units (CH_2 groups). The first repeating unit of each chain (the head group) is constrained to move in a plane, thus simulating the interaction between the head groups and the molecules of the substrate. The head groups interact with a 12,6 Lennard-Jones interaction potential with cutoff 2.5σ

$$\begin{aligned} V(r) &= 4\,\varepsilon\{(\sigma/r)^{12}-(\sigma/r)^{6}\} \quad (r<2.5\,\sigma) \\ V(r) &= 0 \quad (r>2.5\,\sigma) \end{aligned} \tag{1}$$

where r denotes the distance between two head groups, and ε and σ are parameters. The geometry of the hydrocarbon chains is simulated in the following way. In each chain, the distance between two neighbouring repeating units is kept fixed, within small fluctuations, by a strong harmonic force, proportional to

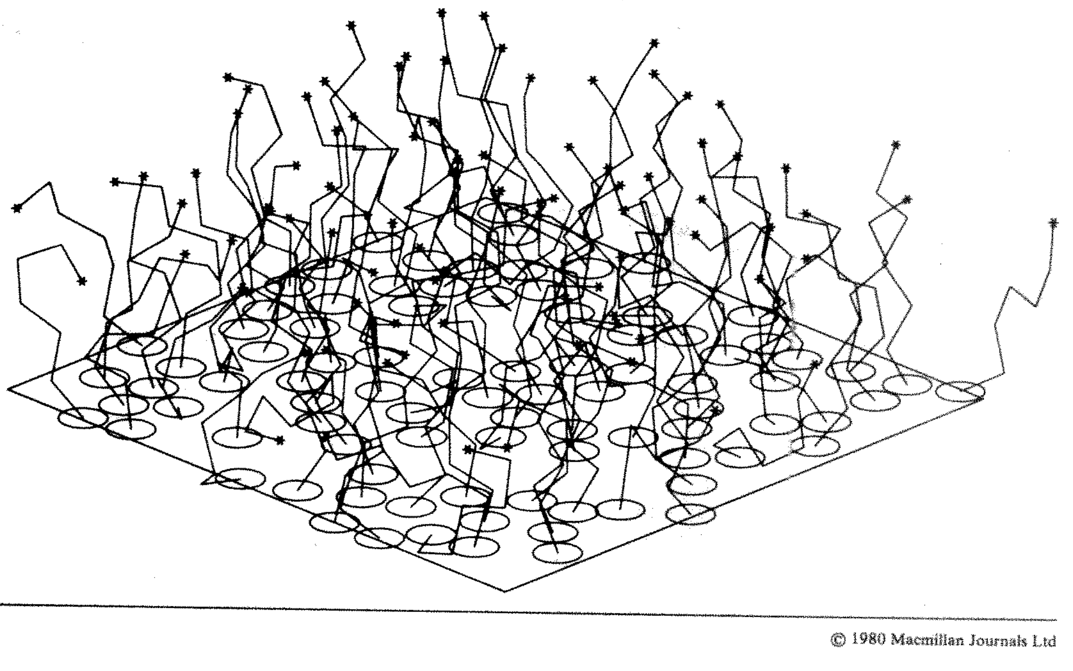

Fig. 1 A typical equilibrium configuration of a lipid monolayer for $T^* = 1$ and $\rho^* = 0.4$. T^* is the reduced temperature: $T^* \equiv kT/\varepsilon$; ρ^* is the reduced number-density: $\rho^* \equiv \rho/\rho_0$ with ρ_0 the close-packed density. The head group of each lipid is indicated by a circle of radius σ and the end of each lipid by an asterisk. Note the clustering of the head groups and the formation of small pores. These pores, which might play a part in membrane permeability, have also been found previously in an exactly solvable membrane model[12–14].

0028-0836/80/390317—03$01.00

$r-\sigma$, which acts to drive the two repeating units back to their equilibrium distance σ. In the same way, a strong harmonic force keeps the distance between any pair of next-nearest neighbours in a chain fixed at the value a. The value of a is chosen in such a way that any two successive C–C bonds in a chain define an angle of 109.5°, in agreement with the experimental value for hydrocarbon chains. With the exception of the head groups, all repeating units in different chains interact with a strong repulsive force proportional to $(\sigma/r)^{20}-1$, with a cutoff σ. The plane to which the head groups of the lipids are constrained acts as a reflecting plane for all other repeating units, through a strong repulsive force.

Clearly, therefore, our model incorporates most of the features quoted in the first paragraph. However there are three exceptions. (1) The attractive part of the interaction between a pair of chains is concentrated in the head groups instead of being distributed over the whole length of the chains. (2) Although the polar forces between the head groups and the molecules of the substrate have been accounted for, the polar interactions between the head groups themselves are neglected. (3) The energy difference of about 0.35×10^{-13} erg between a *trans* and a *gauche* configuration of a C–C bond has not been taken into account, implying that there is no difference between the liquid expanded and liquid condensed phases.

The properties of this system were determined by numerical integration of the equations of motion of the 630 repeating units, using Verlet's algorithm[9]. The calculations were done on the CDC Cyber 73/28 and CDC Cyber 173/8 of SARA in Amsterdam. We used two-dimensional periodic boundary conditions. The initial configuration, for which the all-*trans* state was chosen, tends to equilibrium after a sufficient number of collisions. We used an adjustment procedure[10] to guide the sytem to thermodynamic equilibrium at one particular temperature T. A typical equilibrium configuration is depicted in Fig. 1.

Once the system is in thermodynamic equilibrium, the lateral pressure Π can be calculated from the virial theorem[11].

$$\frac{\Pi A}{NkT} = 1-(2N\langle \mathbf{v}^2\rangle)^{-1}\sum_{i\neq j}(\mathbf{r}_{i,j}\cdot\mathbf{a}_{i,j}). \qquad (2)$$

Here A denotes the area, N the number of repeating units, k is Boltzmann's constant, $\mathbf{r}_{i,j}\equiv\mathbf{r}_i-\mathbf{r}_j$ is the difference between the projections onto the plane of the head groups of the position vectors $\mathbf{r}_i$ and $\mathbf{r}_j$ of two repeating units i and j, $\mathbf{a}_{i,j}$ their relative acceleration in the plane of the head groups and $\langle\mathbf{v}^2\rangle$ the average of the squares of the projected velocities. The time step used in the integration procedure was chosen as $0.005\times\sigma(m/kT)^{1/2}$, with m the mass of a repeating unit. Averages were taken over 24,000 time steps. In this time a repeating unit covered a mean distance of approximately 200 σ. Figure 2 shows a number of points belonging to two isotherms. The isotherm corresponding to the lower temperature shows the characteristic part of the Van der Waals loop which indicates the coexistence region of a system with a first order phase transition. The occurrence of this loop is interpreted to mean that the isotherms of the lipid monolayer are flat in the coexistence region. As this phase transition takes place at rather low densities, it corresponds to the transition between the liquid expanded and gaseous states of the monolayer.

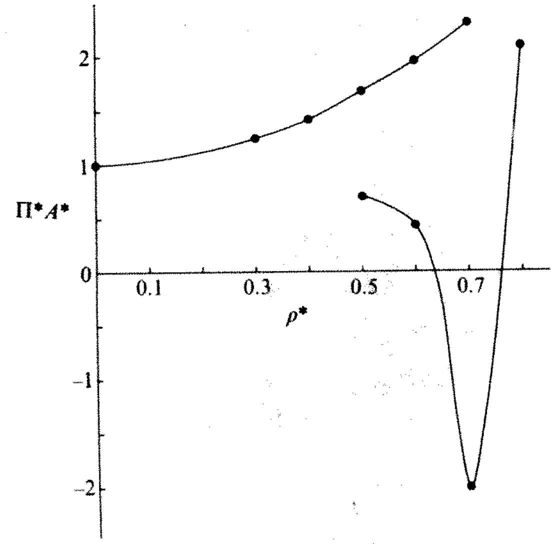

Fig. 2 Lipid monolayer isotherms at temperatures above and below the critical temperature. The upper curve corresponds to $T^*=1$, the lower one to $T^*=1/15$. The product Π^*A^* equals the left hand side of equation (2).

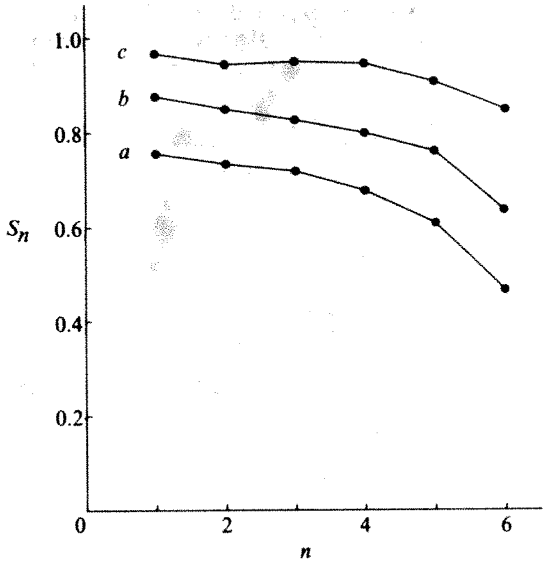

Fig. 3 Lipid monolayer order parameters at $T^*=1$ and $\rho^*=0.3$, 0.5 and 0.7 (curves *a*, *b* and *c*, respectively).

Figure 3 shows the density dependence of a set of important parameters—the order parameters S_n which measure the degree of order in the conformation of a chain. These quantities are defined by the relationship

$$S_n\equiv\frac{3}{2}\langle\cos^2\theta_n\rangle-\tfrac{1}{2} \qquad (3)$$

in which the brackets denote an average over all chains and θ_n the azimuth angle of the nth bond, minus its value in the all-*trans* state, measured with respect to the chain axis in this particular state (see discussion in ref. 8). Both the way in which the order parameters depend on the density and their numerical values agree with the results of Scott[2], who used the Monte Carlo method. Knowledge of the order parameters is important in mean field theories for lipid monolayers of the type discussed by Marcelja[5].

The system discussed here could quite easily be treated numerically. This justifies the expectation that the model can be extended in several ways. We suggest the following possibilities. (1) Extending the number of chains and increasing the number of repeating units per chain. (2) Incorporating the energy difference between a *trans* and a *gauche* configuration, so that it will be possible to study the main phase transition of the monolayer, which separates the liquid-condensed and liquid-expanded states. (3) Adding one or more proteins to the monolayer.

The quasi 2-day wave in the Southern Hemisphere mesosphere

R. L. Craig*, R. A. Vincent*, G. J. Fraser† & M. J. Smith†

*Department of Physics, University of Adelaide, Adelaide,
South Australia 5001
†Department of Physics, University of Canterbury, Christchurch,
New Zealand

We report here preliminary results of a coordinated series of observations made in January and February 1980 to observe the quasi 2-day wave in winds in the Southern Hemisphere mesosphere. The observations were made with the aim of measuring both the vertical and horizontal structure of the wave whose presence has previously been observed at several meteor wind stations in the Northern Hemisphere and at one station (Adelaide) in the Southern Hemisphere[1–3]. Rocket observations also indicate the possible existence of a 2-day wave in the winds near the equatorial stratopause[4]. The observations suggest that the wave is a late summer phenomenon, peaking in late July/early August in the Northern Hemisphere and in late January/early February in the Southern Hemisphere.

Quasi 2-day waves with amplitudes of the order of 10–20 m s^{-1} appear to be typical of both meridional (NS) and zonal (EW) winds in the mid to high latitudes in the Northern Hemisphere[5], although amplitudes nearer 30 m s^{-1} have been quoted for NS oscillations near the Equator[6]. However, an examination of a decade (1966–75) of Adelaide meteor wind data shows amplitudes as large as 50 m s^{-1} in the NS wind component. Further investigations are therefore required to see if the differences in amplitude are due to hemispheric or latitudinal differences or both. Furthermore, more precise measurements of the wave period are required if the source of the wave is to be determined, because many of the previous investigations were for durations of the order of 5 days. Periods in the range 48 ± 6 h have been quoted from the Northern Hemisphere results but a period near 51 h seems favoured[1,7].

Our observations were made from three stations—Townsville (19°40′S, 146°50′E) and Adelaide (34°35′S, 138°30′E) situated in northern and southern Australia, respectively, and Christchurch, New Zealand (43°40′S, 172°40′E). The observations were made using the partial reflection drift technique which enabled both the NS and EW winds to be measured over the 65–100 km height range at either 2 or 2.5 km height intervals (depending on the station) with a time resolution of less than 1 h (refs 8, 9). For the results reported here, hourly mean values were used and only the 80–100 km region is considered because over this height range data are available for both day and night, enabling the tidal wind components to be easily extracted. Observations were made at Christchurch for the whole of January and February, at Adelaide for the period 10 January–12 February and at Townsville for the period 15–31 January. All the data were continuous except for a few occasions when data were lost due to power failures.

Figure 1 shows the hourly mean meridional winds at an altitude of 88 km slightly smoothed by a 3-h running mean, as observed at Adelaide and Townsville. It is apparent that a strong oscillation with about a 2-day period had begun by 10 January at Adelaide, but it did not reach full amplitude at Christchurch (not shown) until 12 January. The oscillation was at its most stable between 10 January and 6 February, and seemed to die out completely by 12 February. At all three stations the NS component of the oscillation was 2–3 times larger in amplitude than the EW component, and maximum amplitudes of up to 50 m s^{-1} occurred in late January. These observations agree well with the previous results from the Adelaide radio meteor winds[3].

As may be seen from Fig. 1, strong 24- and 12-h tidal components were superimposed on the quasi 2-day wave, as expected in view of previous observations at Adelaide. Because of the presence of these strong tidal components the data for each height were analysed with a least squares fitting process to find the mean amplitude and phase of the quasi 2-day wave as well as the period which best fitted the observations. The zonal (u) and meridional (v) wind components were separately represented as a function of time (t) by

$$u(t),\, v(t) = a_0 + \sum_{i=1}^{3} a_i \sin\left(\frac{2\pi}{T_i} t + \phi_i\right)$$

where a_0 is the prevailing wind and a_i and ϕ_i give the mean amplitude and phase for the 12 h ($i = 1$), 24 h ($i = 2$) and the wave of period T_3 which was varied systematically between 46 and 52 h. We found that the best fit occurred for a wave period of 49 ± 1 h.

The amplitude of the 2-day wave seemed to vary with latitude. At Townsville and Adelaide the amplitudes of the meridional component had mean values of 30–35 m s^{-1} in the 85–90 km region and decayed above 90 km. At Christchurch the amplitude was about 18 m s^{-1} at 88 km and increased slowly with height to reach a value of about 25 m s^{-1} at 98 km. The zonal wind components decayed with height at all three stations. The 2-day wave amplitudes were significantly larger than the tidal amplitudes. For example, at Adelaide the mean amplitudes were about 15–20 m s^{-1} in the EW and NS components for both the 24- and 12-h tides. The prevailing winds were typical of a late summer circulation, that is, eastward at heights above 80 km and with a weak equatorward flow.

The time of maximum eastward and northward winds occurred at earlier times at the higher altitudes, implying a downward

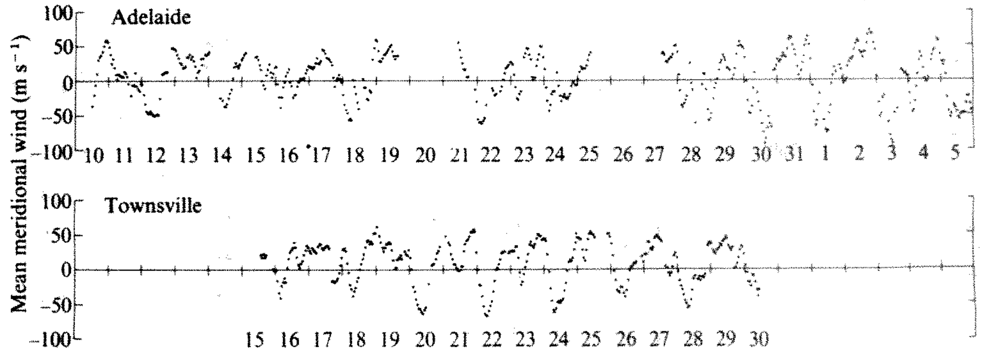

Fig. 1 Hourly mean meridional winds at 88 km observed at Adelaide (35° S) and Townsville (20° S) from 10 January to 5 February 1980, showing the 2-day wave. The values have been smoothed with a 3-h running mean.

0028–0836/80/390319—02$01.00

phase and upward energy propagation. For the meridional component the implied vertical wavelengths were 50 ± 10 km at Townsville and 100 ± 10 km at both Adelaide and Christchurch. The phase of the EW oscillations seemed to lead the NS by 6–12 h. The NS oscillations at Adelaide and Christchurch showed a consistent 15 ± 1 h phase difference, with Christchurch leading. Assuming the phase difference to be due solely to the difference (34°) in longitude, these results are not inconsistent with a westward-propagating planetary wave of zonal wave number 3.

The 2-day wave observed here seemed to persist for ~13–15 cycles, longer than any previous 2-day wave observed at Adelaide. The period was closer to 48 h than the 51–52 h suggested by the Northern Hemisphere results. The amplitude variations with latitude suggest that the meridional velocity amplitude maximizes at low latitudes. It is still not clear whether the wave is larger in the Southern Hemisphere than in the Northern Hemisphere, although the amplitudes at Christchurch do seem to be slightly larger than the results reported from mid to high northern latitudes[5]. However, the inferred zonal wave number agrees with the values found in the Northern Hemisphere[5,10]. Finally, we note that although the phase variations with height indicated that energy was propagating vertically, the little or no growth in amplitude with height indicates that this energy was being dissipated.

We acknowledge the help of A. Didenko and W. K. Hocking in taking the data at Townsville. This research was supported by grants from the Australian Research Grants Committee and the New Zealand Universities Research Committee.

Radiocarbon variations with the 11-year solar cycle during the last century

A. A. Burchuladze*, S. V. Pagava*, P. Povinec†, G. I. Togonidze* & S. Usačev†

*Department of Nuclear Physics, Tbilisi State University, Tbilisi, USSR
†Department of Nuclear Physics and Institute of Physics and Biophysics, Comenius University, 81631 Bratislava, Czechoslovakia

As ^{14}C is produced in the atmosphere by interactions between neutrons and nitrogen atoms, changes in the cosmic ray flux associated with the 11-yr solar cycle will produce variations in ^{14}C production with the same period[1]. These variations are difficult to observe because the atmosphere acts as a low-pass filter, greatly attenuating their amplitude[2]. Previous investigations on short-term ^{14}C variations in tree rings either reported no correlation with the 11-yr solar cycle[3–5] or found a correlation with an average amplitude of 1.5 to 3‰ (refs 6–10). However, Baxter *et al.* reported an average amplitude of about 10‰ in tree rings[11,12] and in samples of whiskies, wines and plant seeds[13], and Lavrukhina *et al.*[14] found a 10‰ correlation amplitude in wood samples. However, very precise ^{14}C tree-ring measurements reported more recently[15–17] show only minor short-term ^{14}C variations. A comparison of results obtained by Stuiver[15] and Baxter *et al.*[11] suggests that the larger ^{14}C fluctuations found by the latter group may be due to a lower precision of their ^{14}C measurements. Here we have dated wines from the period 1909–52 and our results show ^{14}C variations with an average amplitude of 4.3±1.1‰ during the 11-yr solar cycle.

Georgian wine samples of known origin (~38° N, ~45° E, altitude ~300 m above sea level), obtained from the Tbilisi Wine Museum, were used for ^{14}C measurements. The ^{14}C concentration of the alcohol fraction of wine should be closely related to the ^{14}C concentration of the grapes from which it was made, and thus to the atmospheric ^{14}C concentration. Our previous investigation of wines from the period 1950–75 showed a very good correlation between ^{14}C levels in the atmosphere and those in wine samples[18]. The use of wines allows an independent determination of the ^{14}C level. Because there is uncertainty regarding possible radial transport of ^{14}C between individual tree rings, the use of wines is preferable for investigating short-term ^{14}C variations during the last century. We also tried to use brandy samples, but found that these were unsuitable because of the special methods used in their preparation.

The methodology of alcohol extraction from wines as well as the method of acetylene and benzene preparation and counting have been described elsewhere[18]. The results are listed in Table 1 and plotted in Fig. 1 as Δ^{14}C values, defined by[19]

$$\Delta^{14}\mathrm{C} = \delta^{14}\mathrm{C} - (2\delta^{13}\mathrm{C} + 50)\left(1 + \frac{\delta^{14}\mathrm{C}}{1{,}000}\right)\text{‰}$$

$$\delta^{14}\mathrm{C} = \frac{A - A_{\mathrm{STD}}}{A_{\mathrm{STD}}} \times 1{,}000\text{‰}$$

where A_{STD} is equal to the product of 0.95 and the activity of NBS oxalic acid, corrected for age to 1950, and A is the activity of the sample, also age corrected to the year of growth. A ^{14}C half life of 5,730 yr has been used in these corrections. Unfortunately, we were unable to carry out mass spectrometric measurements on these samples. However, our previous results[20], obtained with 15 samples of modern wines, showed that δ^{13}C values did not differ by more than ± 1‰ from the mean value of −23.4‰ (1σ error of a single determination was 0.3‰). The results given in Table 1 were corrected for isotopic fractionation using the assumed δ^{13}C value of −23.4‰. The standard deviations quoted (1 σ error) describe only uncertainties associated with the sample, standard and background determinations.

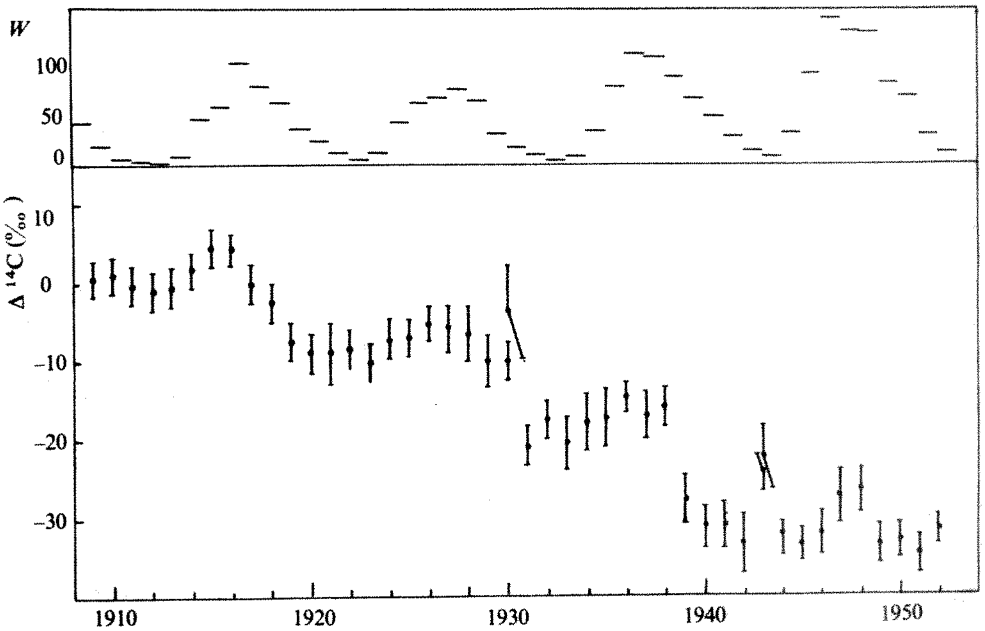
The cyclic trend in the ^{14}C data shown in Fig. 1 is very clear. The gradual decrease in ^{14}C concentration is due to the Suess effect. Our results, when compared with ^{14}C measurements in tree rings for the same period[10,16], are higher by about 5‰. This is perhaps due to the remoteness of the wine growing area from industry and hence a less marked Suess effect.

For a better evaluation of short-term ^{14}C variations, we performed a spectral analysis of our ^{14}C values and compared our results with those of a spectral analysis of sunspot numbers

Table 1 Radiocarbon content of wines calculated with a half life of 5,730 yr

Year of growth	Δ^{14}C in wines (‰)	Year of growth	Δ^{14}C in wines (‰)
1909	+0.4 ± 2.4	1931	−21.1 ± 1.6
1910	+1.0 ± 2.3	1932	−17.3 ± 2.7
1911	−0.1 ± 2.5	1933	−20.5 ± 3.6
1912	−0.9 ± 2.6	1934	−18.0 ± 3.8
1913	−0.4 ± 2.6	1935	−17.3 ± 4.0
1914	+1.8 ± 2.3	1936	−14.6 ± 1.9
1915	+4.6 ± 2.5	1937	−16.9 ± 3.0
1916	+4.3 ± 2.1	1938	−15.9 ± 2.6
1917	−0.3 ± 2.4	1939	−27.9 ± 3.2
1918	−2.5 ± 2.6	1940	−31.1 ± 2.4
1919	−7.6 ± 2.6	1941	−31.1 ± 3.1
1920	−8.7 ± 2.5	1942	−33.3 ± 3.8
1921	−8.8 ± 4.2	1943	−22.5 ± 4.1
1922	−8.5 ± 2.4	1943	−24.3 ± 2.3
1923	−10.1 ± 2.4	1944	−32.4 ± 2.2
1924	−7.3 ± 2.7	1945	−33.3 ± 2.0
1925	−6.8 ± 2.7	1946	−32.2 ± 2.9
1926	−5.2 ± 2.2	1947	−27.3 ± 3.7
1927	−5.5 ± 3.0	1948	−26.5 ± 2.9
1928	−6.5 ± 3.4	1949	−31.0 ± 2.6
1929	−9.7 ± 3.6	1950	−30.5 ± 2.3
1930	−3.6 ± 6.3	1951	−34.8 ± 2.4
1930	−11.1 ± 2.4	1952	−31.8 ± 2.0

Fig. 1 Radiocarbon data of Georgian wine samples (~38° N, ~45° E) for the period 1909–52. The sunspot record has also been included for comparison.



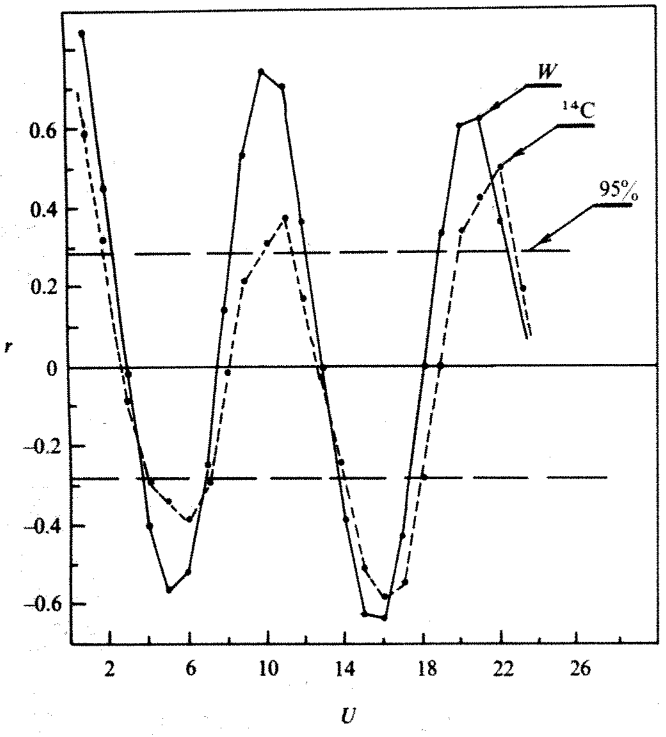


Fig. 2 Autocorrelation functions $r(U)$ of stationary time rows $\Delta^{14}\text{C}(t)$ and $W(t)$ for argument values $U_{^{14}\text{C}} = 11 \pm 1$ yr and $U_W = 10 \pm 1$ yr.

W (Fig. 2). It can be seen that the autocorrelation functions $r(U)$ of stationary time rows $\Delta^{14}\text{C}(t)$ and $W(t)$, for argument values $U_{^{14}\text{C}} = 11 \pm 1$ yr and $U_W = 10 \pm 1$ yr have a quasiperiodical behaviour, with the period of 11-yr at the 95% confidence interval. The 11-yr solar cycle spectra are in both cases very sharp and have a similar shape. The basic power of the spectra is concentrated on the frequency 2.9×10^{-9} Hz, corresponding to a period of 11 yr.

Further, we calculated correlation coefficients for various phase shifts for the different solar cycles. The required phase shifts varied from 3 to 7 yr, with a mean of 4 yr for four solar cycles. The correlation coefficients for optimal phase shifts were 0.67–0.86 for the various solar cycles, and the mean correlation coefficient for the phase shift of 4 yr was −0.58.

As spectral analysis of the ^{14}C data has shown the periodicity of the $\Delta^{14}\text{C}(t)$ row, we also carried out harmonic analysis of $\Delta^{14}\text{C}(t)$ and $W(t)$ rows. Figure 3 shows the first harmonics of $\Delta^{14}\text{C}(t)$ and $W(t)$ rows for different solar cycles. The amplitude of Δ^{14}C variations ranged from 3.3‰ to 5.6‰ for different solar cycles, and the average ^{14}C variation for the investigated time interval was 4.3 ± 1.1‰. The calculated time shift between W and Δ^{14}C maxima was 1–2 yr, and 3.5–5 yr between W maxima and Δ^{14}C minima for the different solar cycles. The harmonic analysis confirms the correlation analysis, especially that ^{14}C values lag behind Wolf sunspot numbers.

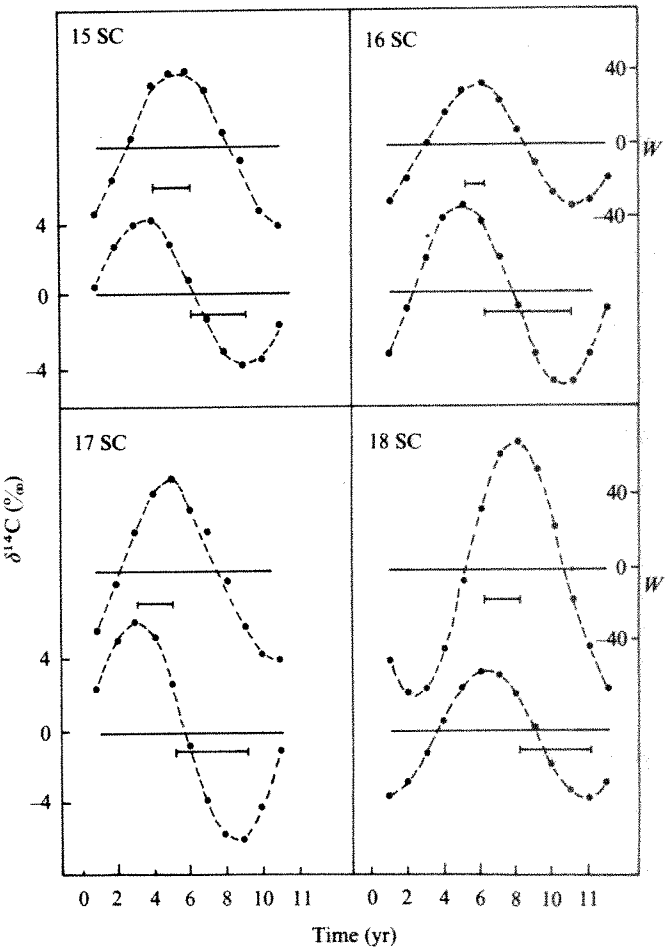

Fig. 3 The first harmonics of $\Delta^{14}C(t)$ and $W(t)$ for the 15th, 16th, 17th and 18th solar cycles (SC).

The amplitude of ^{14}C variations obtained in the present study is about a factor of 2 higher than the results of Damon *et al.*[8] for the 18th solar cycle (3.3 ± 1.1‰ compared with 1.5‰), and 50% higher than our previous results for the 17th and 18th solar cycles[10]. Time shifts in the anticorrelation dependence of Δ^{14}C on W are comparable. The present results only partly cover the time interval investigated by Alekseev *et al.* (1890–1916)[9], but except for the positive correlation, are similar for the years 1890–1900 (3‰ compared with our mean value of 4.3 ± 1.1‰). However, for the time interval 1900–16 the average amplitude obtained by these authors[9,14] is about 10‰ compared with our value of 4.0 ± 1.1‰ for the 15th solar cycle. The reasons for the extreme cycles of 10‰ amplitude found in tree rings by Baxter *et al.*[11] and Lavrukhina *et al.*[14] are poorly understood. Lavrukhina *et al.*[14] found a sharp decrease of 3‰ per yr for the period 1909–16. This decrease may have been caused by an above average fossil fuel contribution.

More precise ^{14}C measurements in tree rings reported recently show only minor ^{14}C fluctuations during the 11-yr solar cycle[15–17]. Furthermore, extensive ^{14}C series of single-year Douglas fir measurements[15] have not shown statistically significant 11-yr periodicity between 1820 and 1950.

Thus, the present investigation has shown the existence of 11-yr ^{14}C variations in wine samples with a mean amplitude of 4.3 ± 1.1‰ over four solar cycles covering the period 1909–52. A comparison of our ^{14}C variations with those of previous investigations has revealed discrepancies which may be due to local variations of stratospheric inputs and the time lag between input and growing season. The observed ^{14}C variations may thus increase dating errors of short-lived samples used for archaeological research.

We thank Dr M. Alaniya for helpful discussions.

Santorini tephra from Rhodes

C. Doumas & L. Papazoglou

Department of Antiquities, National Archaeological Museum,
Tositsa 1, Athens, Greece

The large eruption of the Santorini (Thera) volcano, in ~1500 BC, inspired Marinatos to attribute the decline of the Minoan civilization to this eruption[1]. It is still, however, being debated[2,3] whether tsunamis were actually generated by the eruption of the volcano and whether the ash fall over eastern Crete was sufficient to cause its archaeologically attested desolation. Moreover, the problem of chronology remains unsolved. For, although there is no evidence that the eruption occurred after 1500 BC, the desolation of Crete is accepted as having taken place during the late Minoan IB period, at ~1450 BC (ref. 4). We describe here recent excavations at Ialysos (Trianda) on Rhodes which have produced further evidence of the south-easterly distribution of the Thera tephra. Although a considerable amount of this tephra has been found there, this does not seem to have affected the continuity of life at the settlement, corroborating the view that the ash fall over Crete would have had little, if any, effect.

Confirming the wide distribution of tephra from the late Bronze Age eruption of the Santorini volcano in the south-east Aegean Keller has stated that: "still wanted for our problems is the distinct tephra layer in well defined late Minoan I stratified position"[5]. This tephra layer has now been located in Rhodes near the old Italian excavation at Trianda (Ialysos). We started an excavation on land in May 1978, to examine the possibility of building a new house there. The proximity of this land to the area which Monaco had excavated in 1935 and 1936[6,7], as well as some technical problems, meant that additional care had to be taken causing slow progress and delaying the start of the work. The pottery evidence (Fig. 2) made assigning the first architectural remains (Fig. 1) to the late Minoan settlement an easy task. These remains, at a depth of 1.5 m below the present surface, required careful excavation so that we could study the stratigraphy and thus help to solve the problems already posed by the excavation of the late Bronze Age city of Akrotiri on Thera[8]. As work progressed, to a depth of 1.80 m below the present soil surface, a layer of whitish powdery substance 10 cm thick was

Table 1 Mineralogical analyses* of samples from Rhodes

* Analyses performed by J. Keller, Albert-Ludwig Universität, Freiburg.

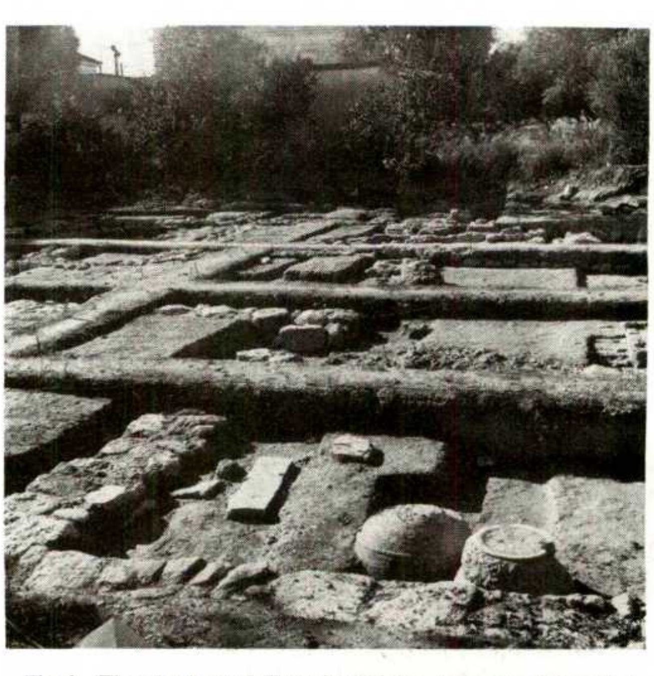

Fig. 1 Theocharis' land, Trianda, Rhodes. A general view of the excavation.

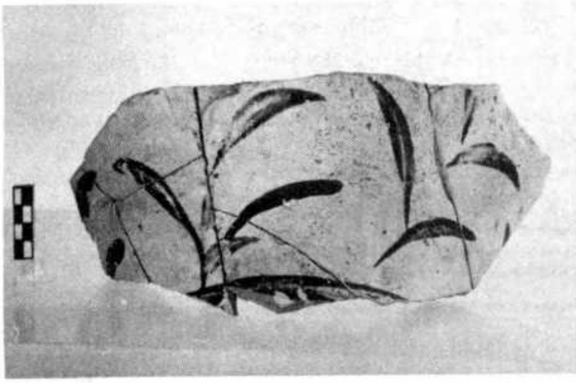

Fig. 2 Pottery fragments from above the tephra layer.

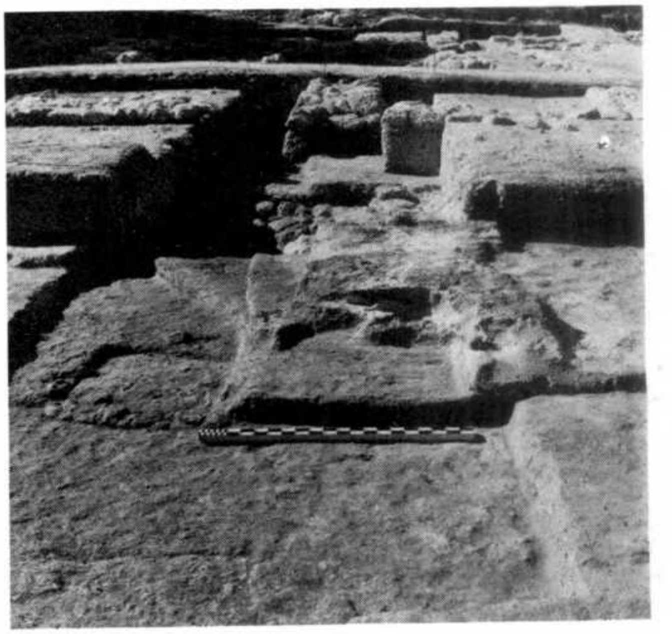

Fig. 3 The tephra layer in square B3.

observed in squares B3–B4 (Fig. 3). The uncontaminated layer of this whitish substance covered ~15 m^2, whereas almost the entire excavated area (~90 m^2) showed patches of this material mixed with earth. The first sample collected was sent to Indiana University, Bloomington, for determination of the refractive index. This material was identified as tephra from Thera on 20 October 1978. Eight more samples were later collected from almost all the excavated area (squares B3–B4: three samples; from just left of square A5 and from squares A6, B5, Γ6 and E3 one sample) and sent to Albert-Ludwig Universität, Freiburg, for mineralogical analysis. These results are shown in Table 1.

Having identified the tephra from Rhodes, it only remained to elucidate when this tephra came to the island. The only pottery evidence from beneath the clear tephra layer consists of sherds belonging to the same vase (Fig. 4). It has been difficult to look for more pottery underneath the pure tephra layer without destroying it. Thus this investigation has been postponed until all problems relating to the tephra layer have been solved. The style and decoration of the above vase place it in the late Minoan I A period[9,10]. All the pottery fragments collected from above the clear tephra layer are mixed, dating from late Minoan I A to late Helladic II B (Fig. 2). Although there is little pottery evidence from under the tephra stratum, note that all the later pottery comes from above the tephra. This location of the later pottery mixed with late Minoan I A suggests that the tephra fall did not cause any significant break in the life of the settlement. This is of paramount importance as far as the eruption of the Santorini volcano and its consequences are concerned. Because if the tephra at Trianda had been airborne, as is suggested by its fine quality and the purity of the layer, then:

(1) A considerable amount of tephra must have fallen over the south-east Aegean region and, anyway, more than that which fell on the eastern part of Crete, where it is estimated to have formed a layer ~1–5 cm thick[11].

(2) It is confirmed that northwesterly winds prevailing during the eruption sent the tephra south-east[11].

(3) It is also confirmed that Rhodes and the south coast of Turkey "have suffered severe tephra-fall"[11].

(4) Despite its thickness, the tephra which fell on Rhodes seems to have had very little if any, influence, on the settlement of Ialysos. This implies that the effect of the tephra fall on Crete was even less. Therefore, the problem of the cause of the desolation of eastern Crete[12–14] remains unsolved, and the disruptive influence of the volcanic eruption of Thera on the development of Aegean civilization more doubtful[15,16].

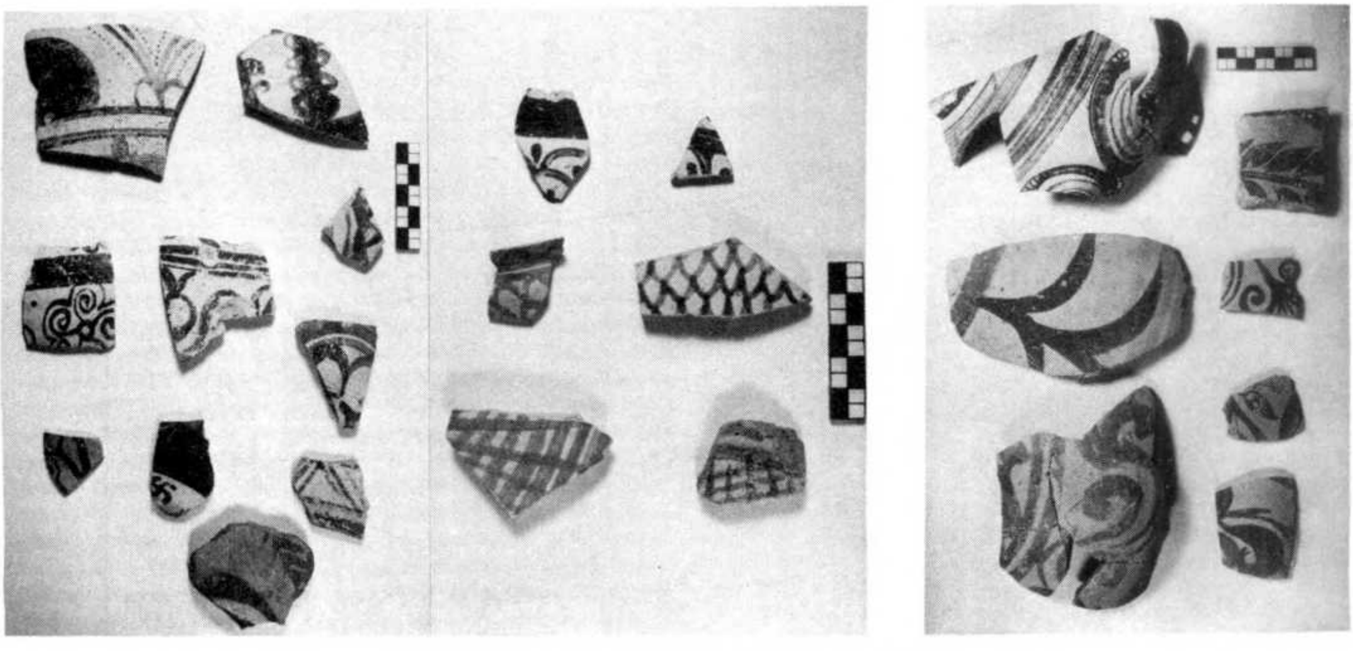

Fig. 4 Pottery fragments from underneath the tephra layer.

We dedicate this paper to the memory of the land owner Mr John Theocharis who died suddenly in the summer of 1979. We thank Professor C. Renfrew and Professor J. Luce for taking care of the first sample when they visited the excavation. We also thank Professor Charles, Dr Dorothy Vitaliano and Professor J. Keller for the examination and analyses of the samples.

Pollen analytical evidence for early forest clearance in North Sumatra

B. K. Maloney

Department of Ethnography, British Museum, London W1X 2EX, UK

Pollen analysis of sediments from the Toba Highlands of North Sumatra, Indonesia reported here suggests strongly that forest clearance by man began ~7,500 yr BP. Less convincing evidence suggests that man may have been disturbing the vegetation perhaps from ~17,800 yr BP, but climate has also changed and isolation of causal factors is, therefore, difficult. No Sumatran archaeological sites have yet been scientifically excavated, nor are ^{14}C dates available[1]. However, megaliths possibly 2,000 yr old occur in the study area[2] and Hindu-Buddhist remains occur further south[2]. Lowland shell-middens may be much older[1,3]. Forest clearance may have begun by 11,000 yr BP on Taiwan[4] and agriculture between 14,000 and 8,000 yr BP in Thailand[5,6] but these conclusions have been disputed[7,9]. Archaeological evidence for agriculture dating from ~9,000 yr BP onwards has been found in Papua New Guinea[10,11] while rice may have been cultivated in Sulawesi[12] by 6,000 yr BP.

Little palynology has been undertaken in Indonesia[13–15]. A 9.76-m long core from Pea Sim-sim swamp (Fig. 1) has yielded a basal ^{14}C date of 18,496 ± 95 (SSR 472). The site is at an altitude of 1,450 m on a plateau (mainly deforested) about 30 km west of an escarpment which falls sharply to Lake Toba at 900 m. Mountains rising above 2,000 m occur 40 km to the north-west, east and south-east. Swamp and limnic sediments have infilled a basin ~100 m in diameter, probably volcanic in origin. Volcanic sediment is absent from the site stratigraphy but the plateau itself is covered with rhyolitic ash at least 75,000 yr old[16] from which the soils are derived.

Climatic data are not available from the immediate locality but readings from Siborongborong[17] nearby indicate a mean annual rainfall of 2,000–2,100 mm for the region. The occurrence of lower montane forest in places demonstrates that the plateau is capable of supporting well developed vegetation in existing conditions. Much of the Toba Highlands, including the area studied, is under wet or dry rice cultivation but millets and, less frequently, taro and sweet potato are also grown.

0028–0836/80/390324—03$01.00

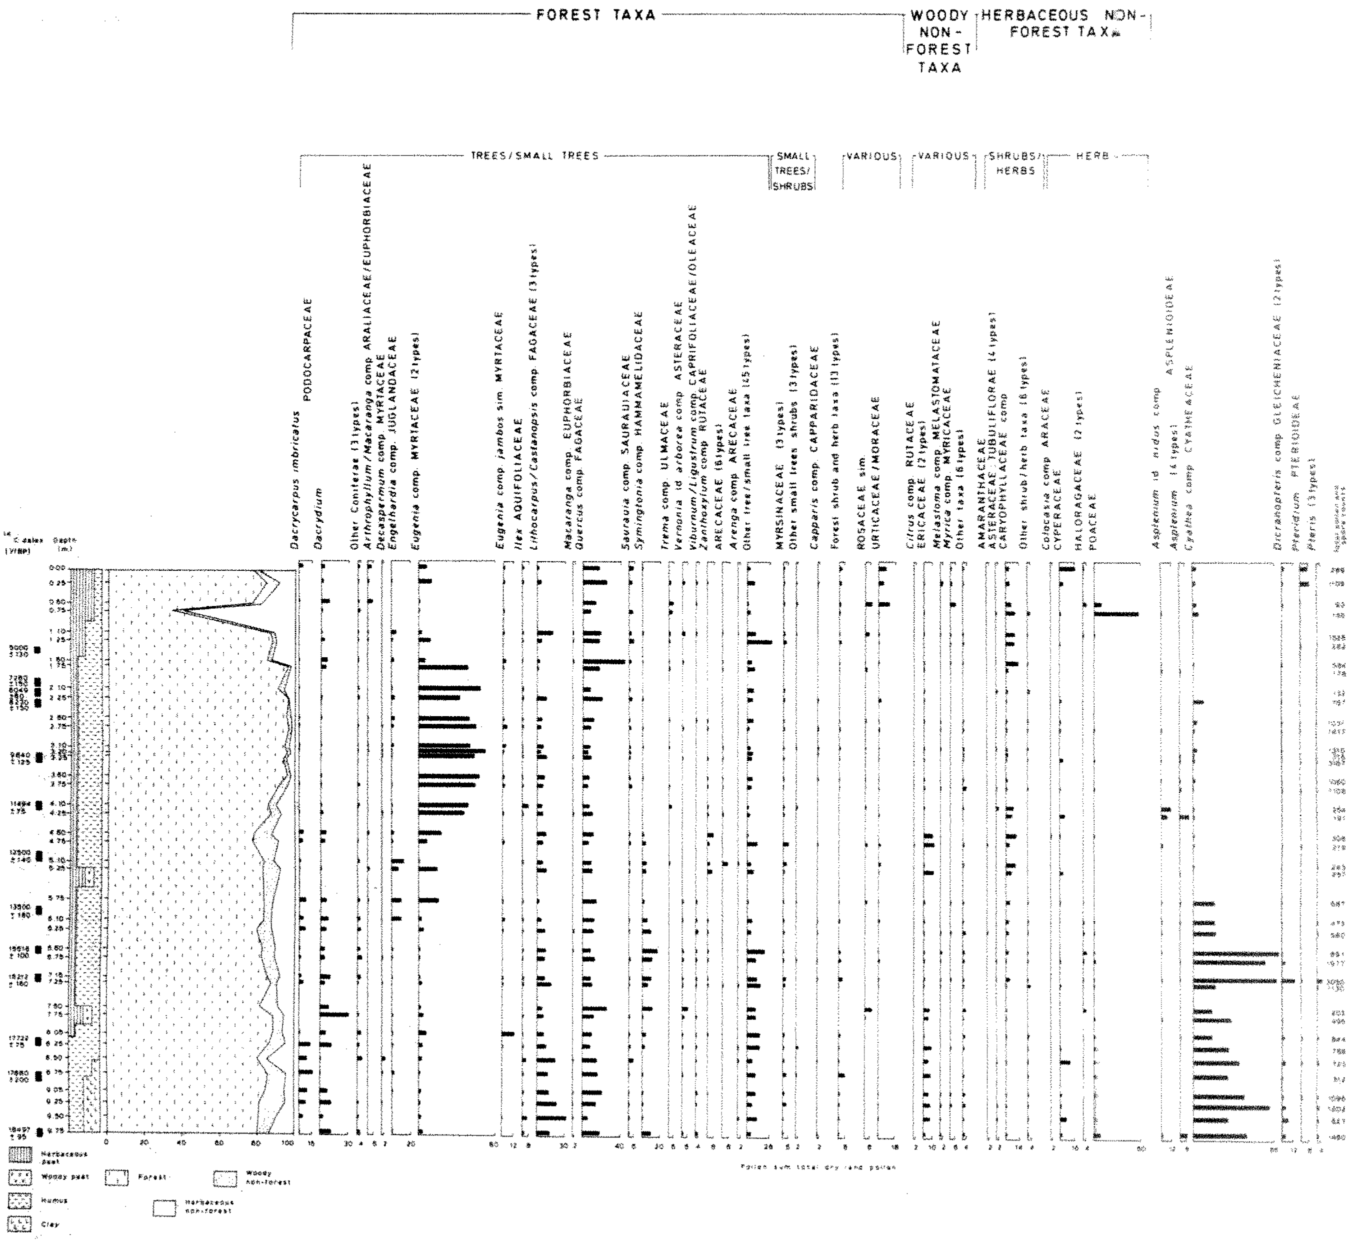

Fig. 2 Pollen diagram and site stratigraphy of the Pea Sim-sim site.

The core analysed was extracted from near the swamp centre. Unfortunately the bottom of the deposit could not be reached. Figure 2 shows a pollen diagram based on an ecological grouping of those pollen taxa which were determined and selected indicator pollens. Radiocarbon dates have been obtained for levels where the biostratigraphy shows important changes and the pollen diagram has been interpreted using spectra from surface sediments, an ecological survey and reference to literature on South-east Asian botany[18–25].

Figure 2 can be divided into four sections. The lowest part, dating between ~18,500 yr BP and an estimated 16,500 yr BP, is dominated by Coniferae and Fagaceae although *Symingtonia* is important in the basal sample. Comparison with the surface sample from the core suggests that forest pollen is over-represented. Indicators of open conditions occur but definite alpine taxa are absent. *Lithocarpus/Castanopsis* pollen is generally deposited within or near the forest but *Quercus* and, particularly, Coniferae pollen seems to be much more widely dispersed. Most of the forest pollen may have been transported in from lower altitudes, however, a mosaic of alpine and upper montane forest vegetation could have been present on the plateau. A brief decline in forest pollen around 17,800 yr BP may relate to climatic deterioration, man's influence, or both: the occurrence of a high percentage of *Cyathea* spores in the lower part of Fig. 2 could be attributed to disturbance by fire while the rapidity of sedimentation supports the view that open conditions existed.

Lithocarpus/Castanopsis or Fagaceae (with *Quercus*)–*Symingtonia* forest became established at ~16,500 yr BP. This persisted until around 12,000 yr BP and may indicate climatic amelioration. *Symingtonia* can grow between 1,000 and 3,600 m above sea level. It is commoner above 1,700 m in Central Sumatra now but its natural lower limit in North Sumatra is not known. Fairly high percentages of taxa which can be significant in secondary forest and swamp forest in addition to primary forest are present and Caryophyllaceae have some of their highest percentages in the core. More ecological data are needed to clarify whether man may have been disrupting the vegetation.

The third part of Fig. 2 dates between ~12,000 and 7,500 yr BP (estimated). *Eugenia* attains large values in many levels. *Lithocarpus/Castanopsis* is quite important but Coniferae and

Symingtonia decline. The change could be attributed to altering climate, with upper montane forest giving way to lower montane forest, but *Eugenia* is often a component of swamp forest and the site stratigraphy indicates that swamp forest probably did exist in the past. As no swamp forest remains in the region it has not been possible to assess the efficiency of the formation in filtering the atmospheric pollen rain. The probability that *Eugenia* pollen especially is over-represented has to be borne in mind while the likelihood that the taxon was growing on dry land and the swamp complicates the interpretation. A *Lithocarpus/Castanopsis–Eugenia* forest may have been present on dry land.

Pollen of well dispersed taxa (*Dacrydium*, *Quercus* and Urticaceae/Moraceae) increases in the top section of the core while *Symingtonia* and *Lithocarpus/Castanopsis* pollen decreases. This suggests an opening out of the forest. *Eugenia* declines abruptly to fairly constant low levels after ~6,500 yr BP; possible disturbance indicators such as *Arthrophyllum/Macaranga* and *Trema* are commoner and the herbaceous non-forest component becomes especially significant. The suddenness of the change suggests that man was probably responsible. Perhaps the swamp forest was the major remaining source of wood? Had swamp forest not been so prominent, earlier dry land forest clearances might have been more strongly shown in the pollen stratigraphy.

Cereals may have been cultivated throughout much of this phase but work on the grass pollens proved to be inconclusive. However, the early literature[26–28] describes a land largely deforested and planted with rice, much as it is now.

Pollen of other possible cultivars (particularly of fruit trees) occurs in numerous samples but the level of pollen identification and statistical considerations make any definite pronouncements unwise.

These findings suggest that agriculture might have been practised in Sumatra for much longer than was previously suspected, but further palaeoenvironmental research is desirable for verification, elaboration and assessment of possible regional interactions.

I thank the NERC and Hull University for funding, the NERC and the University of Zimbabwe for radiocarbon dating, Lembaga Biologi Nasional, Indonesia, for sponsorship and Dr J. R. Flenley for advice and encouragement.

Periodical cicada nymphs impose periodical oak tree wood accumulation

Richard Karban

Biology Department, University of Pennsylvania, Philadelphia, Pennsylvania 19104

All deciduous woody tree species of the eastern United States serve as hosts for large numbers of root parasitizing cicada nymphs (*Magicicada* spp.)[1–4]. Periodical cicadas spend their larval lives 6–24 inches underground, feeding on xylem fluid from rootlets and roots[5]. They emerge every seventeenth year in the north or every thirteenth year in the south. Densities of cicadas underground are very great—Dybas and Davis report emergence densities of over 300 nymphs per square yard or about 1,500,000 per acre. This represents the highest reported biomass values of any naturally occurring terrestrial animal[6]. During the adult stage, which lasts 3–4 weeks, cicadas mate and females lay their eggs in twigs of deciduous trees. When the eggs hatch the first instar nymphs fall to the ground to begin their 17-yr development. The damaging effects to twigs by ovipositing adult cicadas is well established[7–13] but the major effect of cicadas may be due to the feeding of nymphs: nymphs are implicated in a reduction in productivity of orchard trees[14–16]. However, no studies have compared growth of parasitized and unparasitized trees in the same environment. I report here that feeding cicada nymphs can reduce tree growth, as measured by growth rings, by as much as 30%.

Fifty scrub oak trees (*Quercus ilicifolia*) were selected randomly on a flat plain of sandy soil, 3 km east of Ridge, New York[17]. Mature periodical cicadas, *Magicicada septendecim* (Brood XIV) had emerged there in 1974 (refs 17–19). All the trees were about 1.5 m tall and grew in a nearly monospecific stand. To minimize environmental variability, trees were selected which did not border trails or roads and were not near runoff channels in the soil. The stems were cut one inch above the ground and annual wood accumulation was measured with a dissecting microscope and ocular micrometer for each year from 1978 to 1971. Although the trees are older than this, 1971 was as far back as it was possible to measure accurately radial wood increment. When cicada eggs hatch the first instars fall into the ground below the egg nest. As cicada nymphs do not travel far during their tenure underground, oviposition scars provide a reliable indicator of the number of nymphs in that immediate vicinity[18,20]. Of the 50 trees selected, 20 had three or more egg nests (oviposition of one set of eggs by one female, mean = 7.20 ± 0.76 nests per plant), 15 had one or two egg nests and 15 had none. A mean of 19 eggs successfully hatch from each nest[21]. Infested and uninfested trees were in a random mixture on the site, precluding the possibility of an environmental cause for differential growth. Infested trees at this site support fewer cicadas than trees at other sites[6]. However, the dwarf oaks at this site are extremely small, are rooted in poor sandy soil and are very slow growing (Table 1).

For each of the three years before the emergence, no significant (0.05 level, Wilcoxon two-sample rank-sum test) difference was found between the trees with three or more egg nests and those with none (Table 1). During the emergence year and each of the four years following it, radial increment of the trees with no cicada eggs was significantly greater ($P<0.05$) than trees with three or more egg nests. Trees with one or two egg

*The emergence year.

nests were not significantly different than those without nests during any of the years and grew significantly more than trees with three or more nests during 1975 and 1977 only. In this analysis the three years preceding the emergence serve as a control. The fact that there was no difference in growth between the treatments for each of the three years preceding the emergence is evidence that microenvironmental factors, independent of cicadas, are not responsible for the observed growth effect during the years including and following the emergence.

It is difficult to interpret the reduction in growth of trees with egg nests during the emergence year. Cicadas emerge in May and June. The eggs hatch at least six to eight weeks after the emergence so that first instars do not enter the ground until July. It is expected that a large proportion of the annual wood increment would have already been added by this time. However, Phipps presents data showing that seasonal stem enlargement for *Quercus alba* varies considerably from year to year. A substantial fraction of growth may occasionally occur during July and August[22]. Current season wilting, death of branches, epinasty due to differential growth and short, weak shoots caused by oviposition wounds have been noted for *Quercus phellos* and *Quercus palustris*[23]. Thus, oviposition damage or the large energetic demands made by last instar nymphs on their host plant before emergence, rather than feeding nymphs, could reduce radial growth during the emergence year. The data reported here do not allow testing of these hypotheses.

The previous analysis considered differences between trees of the three cicada treatments within each year. Next I examined differences within each treatment and preceding and following the emergence. Total radial increment was summed for the four years following the emergence (1975–78) and for the four years preceding and including the emergence (1971–74) for each tree. Those trees with three of more egg nests grew 43% more during the four years preceding the emergence than during the four years following it ($\chi^2 = 7.20$, $n = 20$, d.f. $= 1$, $P < 0.01$ using Friedman's method for randomized blocks)[24]. No difference was found for the trees without egg nests ($\chi^2 = 0.70$, $n = 15$, d.f. $= 1$) nor for trees with one or two egg nests ($\chi^2 = 0.0$, $n = 14$, d.f. $= 1$). This result is unchanged if the data are analysed without the emergence year, 1974. This analysis shows an inverse relationship between a large number of cicada egg nests and radial incremental growth of *Q. ilicifolia* individuals following the emergence. In this analysis the trees without egg nests serve as controls. The fact that only those trees with three or more cicada egg nests in their canopies show a reduction in wood accumulation and those without cicadas show no effect is further evidence that climatic or other environmental factors are not responsible for the observed reduction in growth of trees with cicadas during the years following the emergence.

The result that cicada nymphs affect tree growth more in years including and following the emergence is in keeping with recent field observations. Periodical cicadas undergo five instars while growing underground. Earlier instars feed on smaller rootlets[25]. Younger nymphs live in short tunnels rather than the more permanent ellipsoidal cells inhabited by older nymphs[25,26]. Young nymphs presumably change feeding sites each time the rootlet they are currently using dies[25]. Older nymphs feeding on larger roots apparently do not kill their host root, resulting in relatively less damage to the tree by older nymphs[5,25].

The greater impact of feeding cicada nymphs in the years immediately following the emergence compared to the years immediately preceding the emergence may also be, in part, the result of a demographic reduction in cicada nymph density. Mortality factors such as predation by moles[27], direct competition[27,28] and starvation[25] reduce the population of cicada nymphs. A schedule of survivorship for developing nymphs is needed.

Periodical cicadas occur in great numbers feeding on all species of deciduous trees in eastern North America. If the growth effect documented here is a general one, cicada nymphs are a serious pest. Feeding cicada nymphs are capable of reducing tree growth by as much as 30%. Because feeding nymphs decrease tree growth more during the years following an emergence than during the years preceding an emergence, they may be inducing a periodical pattern of tree growth.

I thank Timothy Brown for help in preparing and counting growth rings, Chris Simon for logistical help during the study and showing me this forest, Daniel Janzen, James Quinn, Chris Simon, Alan Smith, Truman Young and an anonymous reviewer for comments on the manuscript. I also thank Monte Lloyd and JoAnn White for numerous suggestions and discussions.

Sexual dimorphism in early anthropoids

John G. Fleagle[*], Richard F. Kay[†] & Elwyn L. Simons[‡]

[†] Department of Anatomy, Duke University Medical Center, Durham, North Carolina 27710
[‡] Duke University Center for the Study of Primate Biology and History, 3705 Erwin Road, Durham, North Carolina 27705

Sexual dimorphism in canine/premolar tooth size and in body size is found among many species of living primates and has been shown to be correlated with social organization. Among extant higher primate species that normally live in nuclear families consisting of a mated pair with their offspring, adult males and females are similar in body size and in the size of canine and anterior premolar teeth. In contrast, higher primate species living in more 'complex' polygynous groups (either single-male harems or multi-male groups) are characterized by sexual dimorphism in the size of canine/premolar teeth and frequently by body size dimorphism as well[1–4]. We provide here the first evidence for sexual dimorphism in three species of primates from the Oligocene of Egypt—*Aegyptopithecus zeuxis*, *Propliopithecus chirobates*, and *Apidium phiomense*. This is the earliest record of sexual dimorphism among higher primates and suggests, by analogy with living species, that the earliest known fossil Old World anthropoids lived in polygynous (either single-male harems or multi-male groups) rather than monogamous social groups.

Four higher primate species have been recovered from the Upper Fossil Wood zone of the Jebel el Qatrani Formation in the Fayum Province of Egypt: two hominoids—*A. zeuxis*[5,6] and *Pr. chirobates*[5–8] and two parapithecids—*Apidium phiomense*[8] and *Parapithecus grangeri*[8]. Until recently, most of these taxa were known from relatively few specimens preserving mainly molar teeth. However, recent cooperative expeditions by the Geological Survey of Egypt and Duke University have recovered more complete dental and cranial remains, as well as additional skeletal material of these early anthropoids[9,10]. Thus, for the first time, there are numerous jaws preserving the lower canines and premolars (Fig. 1)—the teeth that are critical for identifying sexual dimorphism in higher primates[11,12].

The largest species from the Egyptian Oligocene is the early ape, *A. zeuxis*. The molar teeth of specimens assigned to this species are uniform in size; however there is a distinct bimodal distribution in the size of lower canines and premolars similar to that found in sexually dimorphic living species, with the larger canines and premolars presumably belonging to males and the smaller ones to females (Fig. 2*a*,*b*). In both sexes of *A. zeuxis*, the lower canine is a projecting subconical tooth and the anterior lower premolar is sectorial, with a large wear facet on the anterolateral surface where it occludes with the upper canine (Fig. 1*a*, *b*). The lower canines (Fig. 2*a*) and anterior lower premolars (Fig. 2*b*) of presumed females, however, are about 25% smaller than those of presumed males (Fig. 2*a*, *b*).

Propliopithecus chirobates is a smaller ape closely related to *A. zeuxis*. Although this species is known from fewer specimens than *A. zeuxis*, it shows a similar bimodal distribution of canine/premolar dimensions in conjunction with low metric variability in molar dimensions (Fig. 2*a*, *b*). As in *A. zeuxis*, these teeth are very similar in morphology in the two sexes (Fig. 1*c*, *d*), but differ in size.

In *A. phiomense*, a small parapithecid, the canine is not so

Table 1 Mandibular depth, body mass ratio of adult males to adult females and social structure of anthropoidea

Species (*N*)		c.v. of mandible depth	Male mass / Female mass	Social structure
Cebus apella	(20)	19.5	1.30^{13}	MM†
Alouatta seniculus	(20)	19.4	1.41^{13}	S or MM†
Nasalis larvatus	(18)	18.3	1.37^{2}	MM^{15}
**Aegyptopithecus zeuxis*	(10)	16.3	*	*
**Apidium phiomense*	(22)	13.6	*	*
Macaca fascicularis	(12)	12.6	1.16^{2}	MM†
Gorilla gorilla	(40)	12.2	1.28^{2}	S or MM^{15}
Pan troglodytes	(26)	9.2	1.04^{2}	MM^{15}
Presbytis rubicunda	(12)	8.3	$1\ 03^{2}$	S^{17}
Hylobates lar	(12)	8.2	1.03^{2}	Mo‡
Saimiri sciureus	(18)	7.5	1.10^{14}	MM†
Pithecia pithecia	(17)	7.4	1.0^{9}	Mo†
Aotus trivirgatus	(17)	7.0	1.04^{2}	Mo^{16}
Hylobates hoolock	(16)	6.9	1.02^{2}	Mo^{18}
Symphalangus syndactylus	(10)	5.9	1.03^{2}	Mo^{16}

Mandibular depth was measured under M_1, sample sizes are to the right of the species. Social structures are categorized as follows: MM, groups with several adult females and several adult males; S, groups usually with one adult male and several adult females; MO, monogamous groups with one adult male and one adult female. All groups with offspring.

† Personal observation.

projecting and the shearing between the upper canine and anterior lower premolar (P_2) is not as well developed as in the hominoids (Fig. 1*e*, *f*). There is, nevertheless, dimorphism in the size of the lower canine relative to molar dimensions (Fig. 2*a*). At present, too little is known of the dental morphology of *Parapithecus grangeri* to determine the extent of sexual dimorphism in this parapithecid.

In addition to dental dimorphism, *A. phiomense* and *A. zeuxis* also show evidence of dimorphism in the depth of the mandibular corpus. (There are not enough jaws of *Propliopithecus chirobates* or *Parapithecus grangeri* to allow statistical comparison of mandibular dimensions.) Among extant higher primates showing sexual dimorphism in body size, the smaller females have relatively shallow mandibles and the larger males have relatively deep mandibles. In species with little sexual dimorphism in body weight, there is no dimorphism in mandible depth. The coefficient of variation ($100\,\mathrm{s.d.}/\bar{x}$) provides an estimate of variability within a species that can be related to dimorphism, but does not require prior identification of the sex of a specimen[11]. There is a very high positive correlation ($r = 0.940$) between the degree of sexual dimorphism in body weight ($\bar{x}$ female mass/$\bar{x}$ male mass) and the coefficient of variation of mandible depth below the first molar (Table 1). *Aegyptopithecus zeuxis* and *Apidium phiomense* show high coefficients of variation for mandible depth suggesting considerable dimorphism in body size.

The correlation of social organization with canine/premolar dimorphism and body size dimorphism among living primates appears to be mainly the result of differences in intra-sexual competition and possibly also predator defense[1–4]. In monogamous species, adults of both sexes appear to be equally active in repulsing same-sex intruders into the group and are often equally active in defense; thus there is little sexual dimorphism. In polygynous species, there is usually much more overt male–male competition for access to females and males often appear to play a greater role in troop defense; therefore males have large canines and anterior premolars and often greater size than females. The canine/premolar dimorphism and mandibular variation exhibited by *A. zeuxis*, *Propliopithecus chirobates* and *Apidium phiomense* are considerably greater than that found among any living monogamous higher primates and suggest that all three extinct species were probably living in polygnous groups characterized by male–male competition.

Among living higher primates, nuclear families and associated sexual monomorphism are found among many of the more primitive New World monkeys and among the lesser apes, suggesting that a monogomous social structure is phylogenetically very old and is possibly the primitive condition for all higher primates[19–21]. The evidence of considerable sexual dimorphism in Oligocene hominoids and parapithecids presented here, however, indicates that more complex, presumably polygynous social structures are definitely very old, probably represent the primitive condition for Old World higher primates, and may well be primitive for all anthropoids.

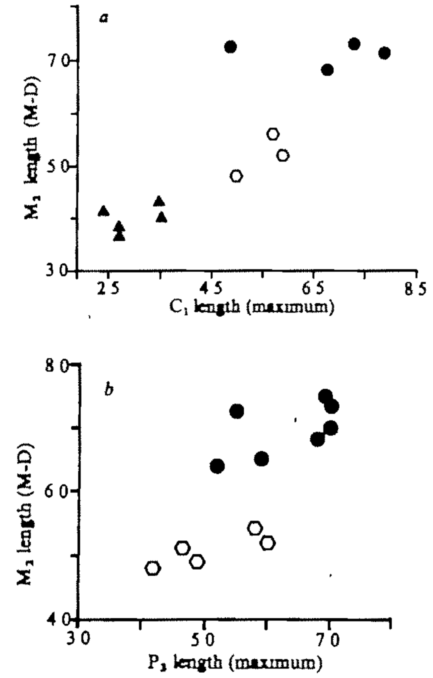

Fig. 2 *a*, Bivariate plot of length of C_1 versus M_2 for *Aegyptopithecus zeuxis* (●), *Propliopithecus chirobates* (○), and *Apidium phiomense* (▲) *b*, Bivariate plot of length of P_3 versus M_2 for *A. zeuxis* (●) and *Propliopithecus. chirobates* (○).

Finally, the finding that sexual dimorphism is typical among Fayum apes has important implications for interpreting the phylogenetic status of *Propliopithecus haekeli*. Since its initial description in the early years of this century[22], the type and sole specimen of this species has been put forth by many scientists as an early human ancestor because of its small canines[23–26]. To the contrary, the similarities between *P. haekeli* and females of *P. chirobates* indicate that *P. haekeli* is not hominid-like but rather is the female of a sexually dimorphic species[5,27]. This invalidates the available evidence for an Oligocene divergence of humans and apes.

We are grateful to the Geological Survey of Egypt for the assistance they provided in all aspects of our field work. This work was supported in part by NSF grants BNS 7683114, BNS 7724921, BNS 7720104 and BNS 79-24149, and Smithsonian Foreign Currency Grant FC 70869600.

Oxygen-linked CO_2 binding independent of *p*H in cephalopod blood

Gunnar Lykkeboe, Ole Brix & Kjell Johansen

Department of Zoophysiology, University of Aarhus,
DK-8000 Aarhus C, Denmark

The oxygen affinity of the haemocyanin-containing blood of some cephalopods is very dependent on the *p*H of the blood[1,2]. The effect of *p*H on the oxygen affinity is expressed quantitatively as the slope of the function between log P_{50} and *p*H, where P_{50} denotes the oxygen tension at an oxygen saturation fraction of 0.5. This Bohr coefficient, $\Delta \log P_{50}/\Delta pH$, is about −1.8 in the case of *Loligo pealei*[1] and about −1.5 for *Sepia officinalis*[2]. These pronounced Bohr effects are physiologically significant as they should allow the metabolically produced CO_2 in the tissues to promote the dissociation of oxyhaemocyanin and thus facilitate the unloading of oxygen to the tissues. However, the Bohr effect is tantamount to an oxygen-linked hydrogen ion binding to the respiratory pigment and the quantitative parameter of this Haldane effect is the change in the concentration of haemocyanin-bound hydrogen ion ($\Delta cHcH$) accompanying a change in the concentration of haemocyanin-bound oxygen ($\Delta cHcO_2$) at a constant *p*H. According to the linkage equation[3], the Bohr coefficient and the Haldane coefficient are identical: $\Delta \log P_{50}/\Delta pH = (\Delta cHcH/\Delta cHcO_2)_{pH}$. This implies that in a homogeneous system, such as in cephalopod blood, the amount of protons bound to the haemocyanin upon deoxygenation from the fully oxygenated state, at constant *p*H, equals the negative value of the Bohr coefficient times the oxygen capacity. Thus, a Bohr coefficient of <-1 implies that more than 1 mmol of protons will be bound to the pigment per mmol of O_2 unloaded. Since the CO_2 produced in the tissues can maximally yield 1 mmol of protons per mmol of oxygen consumed, at a respiratory exchange ratio of unity, we reinvestigated the reciprocal effects of O_2 and CO_2 on the respiratory properties of cephalopod blood to see whether blood *p*H can decrease during O_2 unloading when CO_2 is the only 'proton source' and the Bohr coefficient is <-1.

A spectrophotometric determination[4] of the oxygen affinity of the blood from *Sepia latimanus* at 25 °C gives the expression log $P_{50} = -1.37 \times pH + 11.83$ in the *p*H range 7.3–7.7 and the Bohr coefficient of −1.37 means that this blood is suitable for our investigation.

The relationship between the CO_2 tension, *p*H and the total content of CO_2 in oxygenated and deoxygenated blood was determined by measuring both *p*H and the CO_2 content[5,6] of blood brought into equilibrium with the appropriate gas mixtures in a tonometer kept at a constant temperature of 25 °C.

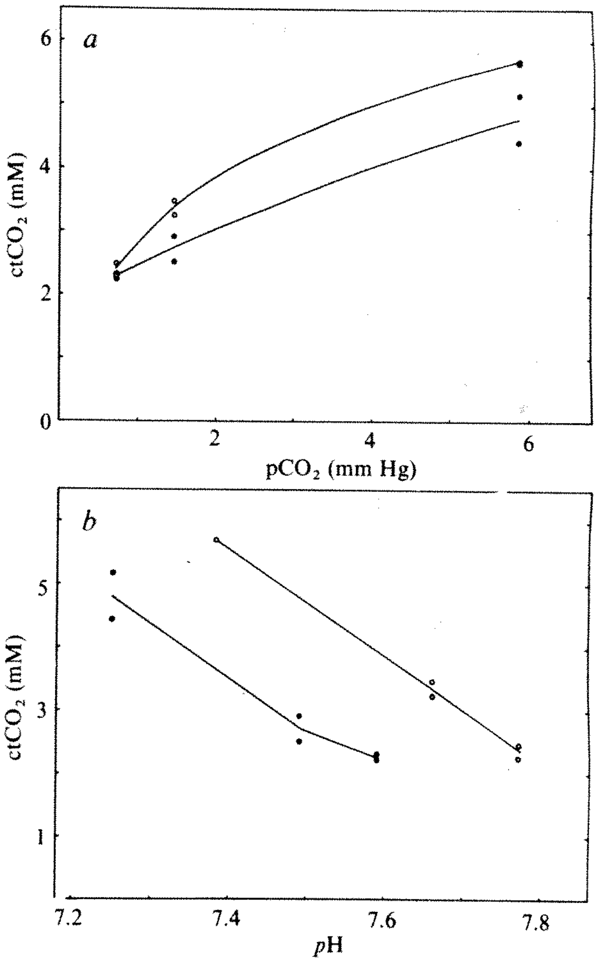

Fig. 1 *a*, CO_2 equilibrium curves of oxygenated and deoxygenated blood. $ctCO_2$ is the total CO_2 content. *b*, The data for total CO_2 content from *a* plotted against the corresponding measured *p*H values. Oxygen capacity = 1.86 mM. ●, Oxygenated; ○, deoxygenated.

Figure 1*a* shows that the deoxygenated blood contains more CO_2 at a given CO_2 tension than the oxygenated blood, except at the lowest CO_2 tension applied where the two curves coincide. As the blood has the same total CO_2 content ($ctCO_2$) at a CO_2 tension of about 0.7 mm Hg, irrespective of the state of oxygenation, one should expect the *p*H to be the same for oxygenated and deoxygenated blood. Figure 1*b* shows that this is not the case, as replotting the values for $ctCO_2$ from Fig. 1*a* against the corresponding *p*H of the blood reveals that a great *p*H difference exists between oxygenated ($pH = 7.59$) and deoxygenated ($pH = 7.77$) blood.

This *p*H difference at a constant CO_2 tension tells us that, as the total CO_2 is nearly unchanged, some of the CO_2 present in the oxygenated blood must have disappeared upon deoxygenation and that it has been replaced by an almost equal amount of bicarbonate.

To investigate this CO_2 component in oxygenated blood, CO_2 washout experiments were performed on oxygenated and deoxygenated blood. Blood tonometered to equilibrium at the lowest CO_2 tension was subjected to a CO_2 pressure of zero. Blood *p*H and $ctCO_2$ were measured repeatedly for about an hour and the results presented in Fig. 2.

The total content of about 2.3 mmol of CO_2 per l is in both cases washed out after 1 h, but both the time course and the total change in *p*H are different. The oxygenated blood shows a change in *p*H from 7.59 to nearly 7.74 and the change is almost fully established after 30 min when the system still contains about 1 mmol of CO_2 per l. By contrast, the deoxygenated blood exhibits a total change in *p*H from 7.77 to 7.99 and this change is complete after 70 min, when the CO_2 content of the blood is

0028–0836/80/390330—02$01.00

reduced to nearly zero. The much smaller *p*H increase in the oxygenated sample compared with the deoxygenated sample and the time course of this change indicate that the CO_2 pool in the oxygenated blood contains a component of CO_2 that is liberated without a simultaneous call for protons, and that the size of this part of the total CO_2 is close to 1 mmol per 1 of blood.

We suggest that this CO_2 component is present in the form of molecular CO_2 bound to the oxygenated haemocyanin and that this CO_2 fraction is oxygen linked such that it is liberated when the oxygen is given off from the haemocyanin.

The size of the oxygen-linked CO_2 component can also be estimated if one assumes that the $ctCO_2$ of the deoxygenated blood, at the two highest CO_2 tensions applied, is composed solely of physically dissolved CO_2 ($cdCO_2$) and bicarbonate. The *p*K′ values of the carbonic acid-bicarbonate system were calculated according to the equation:

$$pK' = pH - \log \frac{ctCO_2 - cdCO_2}{cdCO_2}$$

With the relationship between *p*K′ and *p*H established, *p*K′ values corresponding to the other measured values of *p*H for oxygenated and deoxygenated blood were determined and thereafter the apparent bicarbonate concentrations were calculated. The results of this procedure are represented in Fig. 3.

This plot shows that the calculated amount of apparent bicarbonate plus the physically dissolved CO_2 for oxygenated blood is between 0.7 and 1 mmol less than the measured values for total CO_2. Furthermore, it is now possible to test the identity between the values for the Bohr and Haldane effects. With an oxygen capacity of 1.86 mM (determined as half of the copper content of the blood) and a Bohr coefficient of −1.37, the total ΔcHcH at constant blood *p*H should be about 2.5 mmol per l of blood. When this value is compared with the increase in apparent bicarbonate at constant *p*H—2.7 mM at *p*H 7.38 decreasing to 2.5 mM at *p*H 7.59—a striking resemblance with the predicted value above is apparent. The correspondence of these numbers adds validity to the procedure used concerning the calculation of the apparent bicarbonate concentration and to the estimate concerning the size of the oxygen-linked CO_2 component.

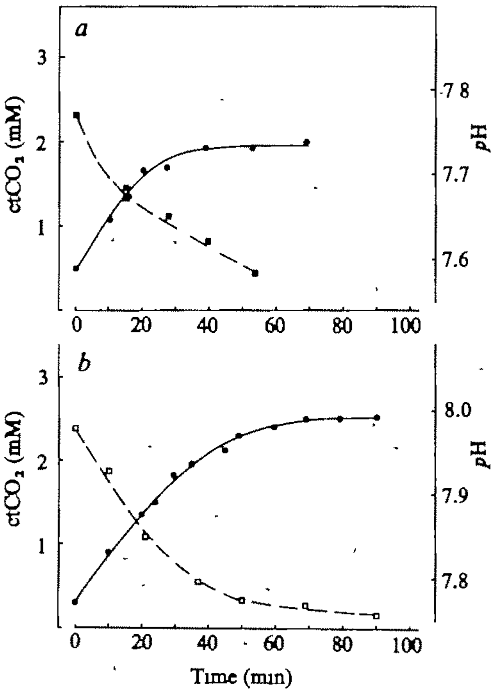

Fig. 2 CO_2 washout curves for *a*, oxygenated and *b*, deoxygenated blood. Squares, $ctCO_2$; circles, *p*H.

The effect of the oxygen-linked CO_2 component is a transformation of the Haldane coefficient to what could be called the functional Haldane coefficient, the latter expressed by the CO_2 binding potential of the system at constant *p*H. The size of this functional Haldane coefficient, in mM CO_2/mM O_2, ranges in *S. latimanus* from about 0.9 at *p*H 7.59 to about 1.1 at *p*H 7.38. This implies that no substantial decrease of the *in vivo* blood *p*H should occur when blood passes the tissue capillaries; on the contrary, small increases in blood *p*H should be more frequent, even at a respiratory exchange ratio of unity.

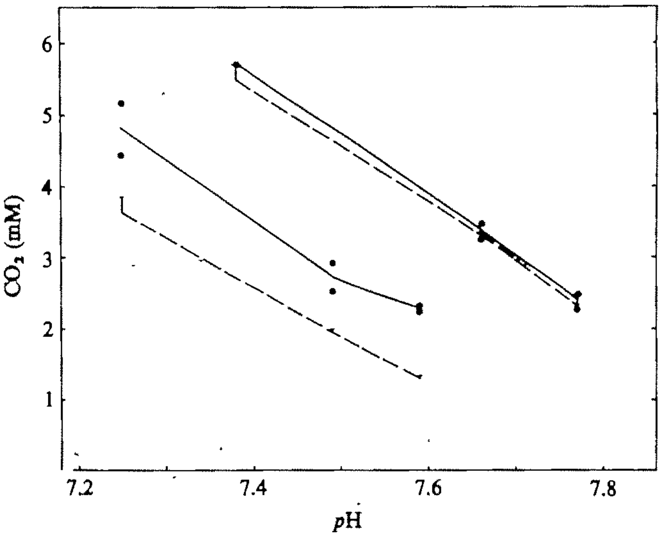

Fig. 3 This shows the same data as Fig. 1*b*, together with the corresponding calculated values for apparent bicarbonate concentration (broken line). Vertical bars (T) indicate the amount of physically dissolved CO_2 (solubility coefficient 0.039 mM l^{-1} $mmHg^{-1}$). Oxygen capacity = 1.86 mM. ●, Oxygenated; ○, deoxygenated; — $ctCO_2$.

The question of whether *p*H can actually decrease during O_2 unloading may be answered affirmatively. A requisite for this answer must, however, be the presence of an oxygen-linked CO_2 component large enough to generate a functional Haldane coefficient: mM CO_2/mM O_2 at constant *p*H, well below unity. This condition is likely to be species dependent and related to metabolic rate and metabolic scope. In *S. latimanus*, a moderately active cephalopod, the condition is marginally present, but in the case of *L. pealei*, a far more active species, it is likely to be more developed.

This study was done on *S. latimanus* blood brought back from the 1979 Alpha Helix expedition supported by NSF grant PCM 77-16269 and the Danish Natural SRC.

Isolation of human haematopoietic progenitor cells using monoclonal antibodies

P. C. L. Beverley*, D. Linch † & D. Delia‡

Studies of the differentiation of human haematopoietic cells have been greatly advanced by the use of *in vitro* cloning techniques to enumerate the myeloid and erythroid progenitor cells which form colonies in semi-solid medium[1-3]. The granulocytic/monocytic colony-forming cells (CFU-GM) and erythroid burst-forming cells (BFU-E) are thought to be mononuclear cells, similar in size to medium size lymphocytes, but their ontogenetic relationship to other progenitor cells and the putative pluripotential stem cell remains obscure[4,5]. This is partly because elucidation of parent-progeny relationships requires the isolation of precursor cells before they acquire mature phenotypic characters. Physical methods have failed to separate CFU-GM cleanly from other cells because of their heterogeneity, and immunologically specific markers for human progenitor cells have not been reported[6,7]. We report here that a fraction containing all the granulocytic/monocytic and erythroid progenitor cells, as well as cells which may be lymphoid progenitors, can be isolated from bone marrow using a combination of monoclonal antibodies.

The anti-leukocyte antibody (anti-HLe-1) was prepared by hyperimmunization of BALB/c mice with human peripheral blood mononuclear cells. The immune spleen cells were fused using polyethylene glycol to NS-1 myeloma[8] and the anti-HLe-1 clone was isolated by limiting dilution. By indirect immunofluorescence the antibody stains brightly all peripheral thymus-derived (T) and bone marrow-derived (B) lymphocytes and the majority of thymocytes. Peripheral blood monocytes and granulocytes and some bone marrow cells are weakly positive, whereas all other cell types tested, including mature erythrocytes and platelets, are negative[9,10].

The anti-myeloid antibody (TG-1) was derived, by limiting dilution cloning, from a fusion for which BALB/c mice were immunized with a glycoprotein fraction of thymocyte membranes (P.C.L.B. and A. Sullivan, unpublished observations). This antibody recognizes an antigen present on peripheral blood polymorphs and eosinophils but not on T and B lymphocytes and erythrocytes or the surface membrane of thymocytes. In bone marrow it labels predominantly cells of the granulocytic lineage. We do not know why we were able to derive an antibody reacting with granulocytic cells from a mouse immunized with thymocyte glycoproteins.

Samples of human marrow stained by indirect immunofluorescence with anti-HLe-1 were analysed and sorted on a FACS-1. Figure 1*a* shows the cell sorter profile obtained from such an experiment. Three major populations are separable by combinations of light scattering (cell size) and fluorescence intensity. Table 1 shows the cytological characteristics of the three sorted fractions. The unstained cells (fraction 1) are the recognizable precursors of the erythroid lineage. Fraction 2 contains the cells of the granulocytic lineage and fraction 3 contains mainly small and medium lymphocytes whose staining by indirect fluorescence is similar to that of peripheral blood lymphocytes. Table 1 also gives the colony-forming assay data (CFU-GM) for the various fractions and control unsorted marrow. The results show unequivocally that the CFU-GM are in fraction 2, but as this fraction contains approximately 50% of the cells isolated from bone marrow by Ficoll–Hypaque separation, this does not represent a significant enrichment of progenitor activity. However, this result does show that the granulocytic/monocytic progenitors appear on FACS analysis in a zone of cells labelled only weakly with anti-HLe-1 in which there are very few lymphocytes. It was therefore possible to identify the correct zone on the cell sorter profile for isolation of the progenitor cells after removing most granulocytic series cells with anti-myeloid antibody and complement.

Table 1 Differential counts and colony forming cells (CFU-GM) of bone marrow fractions

	Unseparated	Fraction 1	Fraction 2	Fraction 3
Erythrocyte precursors %	13	92	4	0
Blasts and promyelocytes %	0	0	2	0
Myelocytes %	27	4	29	1
Metamyelocytes %	44	3	61	2
Polymorphs %	1	0	3	2
Monocytes %	5	0	0	6
Lymphocytes %	10	1	1	89
CFU-GM per 10^5 cells	39	1.2	89.2	0.6
% Of total nucleated cells	100	17	52	10
% Of total CFU-GM	100	1	117	1

Bone marrow fractions were cytocentrifuged and stained by May–Grünwald Giemsa for differential counting. At least 200 cells were counted in each fraction. Granulocytic and monocytic colonies were grown in semi-solid agar bilayers containing α medium and 25% pre-screened fetal calf serum (FCS)[1]. The feeder layer contained 20% placental conditioned medium as a source of colony stimulating activity[13]. The cultures were incubated for 14 days at 37 °C in 5% CO_2 in humidified air and cell aggregates greater than 40 cells were scored as colonies. Values given are the means of three replicate cultures. This experiment has been repeated many times and the above is a representative sample of the results.

Table 2 Effect of TG-1 and complement on differential count and CFU-GM

	F/H marrow	TG-1+C
Promyelocytes %	1	0
Myelocytes %	10	1
Metamyelocytes %	20	0
Granulocytes %	5.5	0
Lymphocytes %	13	23
Plasma cells %	1	1.5
Monocytes %	5	10*
Erythroid precursors %	35.5	64.5
CFU-GM per 10^5 cells	80	142

* Many of these cells with cartwheel nuclei and ragged cytoplasm are probably degenerating myelocytes and metamyelocytes damaged by the antibody and complement.

In a second series of experiments, therefore, bone marrow cells obtained by Ficoll–Hypaque isolation were treated with TG-1 antibody and complement before staining with anti-HLe-1. The TG-1 antibody kills a significant proportion of bone marrow cells of the granulocytic lineage but spares the CFU-GM (Table 2). The cell sorter profile obtained after this sequential treatment is shown in Fig. 1*b*. Although the erythroid and lymphocyte fractions (fractions 1 and 3) are present, the granulocytic fraction (fraction 2) has been largely removed by the TG-1 treatment. It is still possible, however, to collect the

0028-0836/80/390332—02$01.00

surviving progenitor cells which fall in the band of cells staining weakly with anti-HLe-1. In the experiment detailed in Fig. 1 and Table 3, two different size fractions of this weakly staining population were collected and these represent somewhat different, though overlapping, progenitor cell populations. The majority of the CFU-GM and the more mature GM clusters and CFU-E are found in the large cell fraction. Both fractions, however, contain large numbers of BFU-E, and as BFU-E are thought to be more primitive than CFU-E or CFU-GM[11], it is probable that the smaller cell fraction includes the pluripotential stem cells.

Both fractions contain significant numbers of terminal deoxynucleotidyl transferase (TdT)-positive cells (from 3–15% in different experiments) whereas other sorted fractions do not. The TdT-positive cells in bone marrow are largely Ia (HLA-D) positive and are thought to be lymphoid progenitor cells[12] so that it seems probable that all the bone marrow progenitor cells are included in the weakly HLe-1 stained fraction.

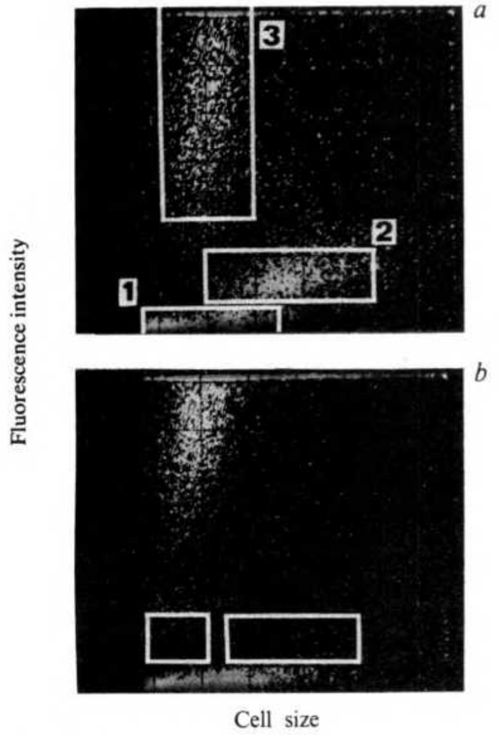

Fig. 1 Bone marrow aspirates were obtained from normal volunteers. The aspirated cells were separated on Ficoll–Hypaque to remove red cells and mature granulocytes and washed in HEPES-buffered RPMI-1640 medium with 5% added fetal calf serum (RPMI-FCS). For analysis or cell sorting, cells were incubated with anti-HLe-1 culture supernatant for 30 min on ice, washed twice with RPMI-FCS and then incubated (30 min on ice) with immunoabsorbent-purified fluorescein-conjugated $F(ab')_2$ sheep anti-mouse immunoglobulin antiserum (100 $\mu g\ ml^{-1}$ in RPMI-FCS), followed by a further two washes. In some experiments both first and second layers were diluted in 10% normal sheep serum to compete for Fc receptors, a procedure which very effectively prevents Fc binding of mouse immunoglobulin by peripheral blood monocytes (P.C.L.B., unpublished observations). This did not significantly change the FACS profile. For removal of mature cells of the granulocytic lineage, aliquots of bone marrow cells were incubated with TG-1 culture supernatant (2×10^7 bone marrow cells per ml) on ice, washed once and incubated at 37 °C for 45 min with undiluted autologous serum as a source of complement (4×10^7 cells per ml). Surviving cells were washed three times by centrifugation through FCS. This procedure killed approximately 50% of the nucleated cells in the Ficoll–Hypaque-isolated bone marrow. Samples were examined for fluorescence and light scattering on a FACS-1. A typical profile of normal bone marrow stained with anti-HLe-1 is illustrated in *a* and windows for collection of unstained erythroid (1), weakly stained myeloid (2) and brightly stained lymphoid fractions (3) are also shown. *b* Shows the effect of treatment of the marrow with TG-1 and complement before staining with anti-HLe-1. The granulocytic fraction is eliminated but cells can still be collected in the windows illustrated.

Table 3 Differential counts and colony forming data of antibody + complement treated and sorted marrow

		F/H marrow	Fraction 1 (small dim)	Fraction 2 (large dim)
Proerythroblasts %		1	5	14
Normoblasts %		16	6	25
Lymphocytes %		25	37	3
Monocytes %		2	1	0
Plasma cells %		1	1	19
Progenitor cells %		1	47	36
Maturing granulocytic cells %		54	3	3
Clusters-GM	per 10^5 cells	169	1,100	8,450
CFU-GM		56	700	2,800
CFU-E		292	3,780	17,130
BFU-E		34	3,333	2,777

Granulocytic/monocytic clusters and colonies were grown as detailed for Table 1. Clusters are smaller cell aggregates (<40 cells) scored at day 7. Erythroid colonies and bursts were grown in 1.8% methylcellulose containing supplemented α medium, 30% pre-screened FCS and 1% deionized bovine serum albumin[14]. Erythroid colonies were grown in the presence of 1 unit ml^{-1} of human urinary erythropoietin, and were scored at day 7 as benzidine-positive aggregates greater than eight cells. Erythroid bursts were grown in the presence of 3 units ml^{-1} of erythropoietin and scored at day 14 as haemoglobin-containing aggregates greater than 64 cells. As BFU-E require addition of feeder cells[15], 5×10^4 Ficoll–Hypaque-separated cells were added to each dish for the assays of fractions 1 and 2. The numbers are therefore derived by subtracting the number of bursts produced by 5×10^4 Ficoll–Hypaque cells from the total in each dish. Similar enrichment of erythroid progenitors has been obtained in two other experiments and of granulocytic monocytic progenitors in four. Progenitor cells are mononuclear cells with a high nuclear/cytoplasmic ratio, immature chromatin, with frequent nucleoli and basophilic cytoplasm. No attempt has been made to classify these as myeloblasts, lymphoblasts or undifferentiated blasts.

In these experiments we have isolated a small fraction of bone marrow (2% of nucleated cells) which contains all the myeloid and erythroid as well as presumptive lymphoid progenitors. The isolation of such a pure population of progenitors should allow detailed investigation of the regulation of progenitors by other cells, will allow a more exact cytological and antigenic phenotype to be assigned to the progenitor cells and may allow identification of pluripotential stem cells. The study also illustrates the usefulness of combinations of monoclonal antibodies in studies of normal differentiation.

We thank Mr W. Verbi for carrying out TdT staining. D. L. is a Wellcome Research Fellow.

Mitotic EBNA-positive lymphocytes in peripheral blood during infectious mononucleosis

James Robinson, Douglas Smith & James Niederman

Departments of Pediatrics and Epidemiology and Public Health,
Yale University School of Medicine, New Haven, Connecticut 06510

Infectious mononucleosis (IM) is usually a benign lymphoproliferative disease caused by Epstein–Barr virus (EBV)[1]. Although EBV induces a state of continuous proliferation in infected B lymphocytes *in vitro*[2,3], the most prominent lymphoproliferation during IM is of activated, or atypical, T lymphocytes presumably responding to the virus or virus-infected cells[4]. However, EBV genome-carrying cells are known to be circulating during IM, as cultured peripheral blood leukocytes from patients with the disease give rise to continuous lymphoblastoid cell lines, each cell of which contains the EBV genome and expresses the EBV determined nuclear antigen (EBNA)[5,6]. The proposal that EBV-infected cells in IM blood are not endowed with enhanced growth potential but are merely latently infected[7] is supported by demonstrations that cells infected *in vivo* enter a viral replicative cycle when placed *in vitro* and that most cell lines derived from cultured lymphocytes of IM patients are infected by virus released *in vitro*[8]. However the cells could also be capable of proliferation *in vivo*, since virus production and transformation are not mutually exclusive properties of EBV-transformed cells[9]. Recently, EBNA has been detected in a very small fraction of peripheral blood lymphocytes of IM patients after T cells were first removed[10,11] and this has been interpreted to indicate that cell transformation occurs *in vivo* during IM. The isolation of colonies of EBNA-positive cells from IM blood leukocytes cultures in soft agar suggests that at least some infected cells are capable of direct outgrowth into transformed cells[12]. We report here direct evidence that circulating EBV-infected cells exhibit increased growth properties during IM.

As EBNA is expressed by EBV genome-carrying lymphocytes in IM blood, and this antigen is physically associated with metaphase chromosomes in dividing transformed cells[6], we initially determined whether EBNA-positive cells were capable of entering the mitotic cycle after being placed in culture. When cells were incubated for 18 h after separation and then treated with colcemid, as many as 5% of the EBNA-positive cells were in mitosis (Table 1, Fig. 1*a*). To identify cells which had already entered the mitotic cycle *in vivo* at the time the blood was drawn, cells were treated with colcemid immediately after cell separation was completed. In two patients (Table 1), a small fraction (0.5%) of the EBNA-positive cells were in mitosis (Fig. 1*b*). Cells from one of the patients were examined again for EBNA-positive mitoses after 18 h in culture when there was a six-fold increase in the proportion of EBNA-positive cells arrested in metaphase.

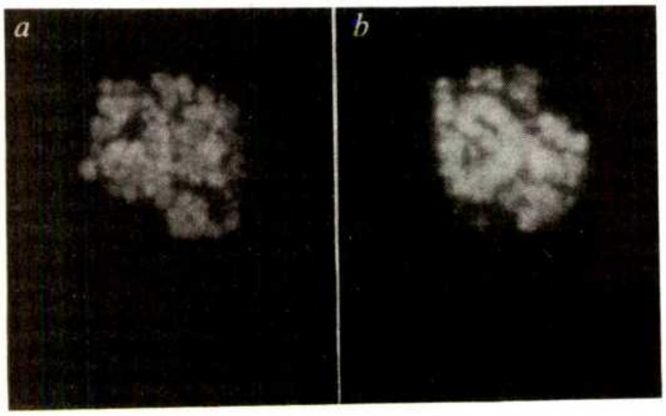

Fig. 1 *a*, EBNA-positive cell in mitosis. T-cell-depleted lymphocytes exposed to colcemid for 2 h after being cultured for 18 h. ×630. *b*, EBNA-positive mitotic cell after 2 h exposure to colcemid beginning immediately after cell separation completed. ×630.

Table 1 Identification of EBNA-positive metaphases in T-cell depleted lymphocytes from patients with IM

Patient	Days of illness	Time (h) cells* in culture	% EBNA	% Of EBNA -positive cells† in mitosis
1	6	18	6.5	5
2	6	18	18	1.0
3	7	2	10	0.5
		18	10	3
4	7	2	12	0.5

Mononuclear leukocytes were isolated on Ficoll–Hypaque gradients[16] from heparinized blood of patients acutely ill with IM. Adherent cells were removed by incubating washed leukocytes in plastic tissue culture flasks for 1 h at 37°C. A population of cells depleted of T lymphocytes and enriched for B lymphocytes was then isolated by separating cells which formed rosettes with neuraminidase-treated sheep erythrocytes (E_N) from non-rosetting cells on a second Ficoll–Hypaque gradient as previously described[3]. The non-T-cell fraction contained less than 4% E_N rosette-forming cells. $0.5\text{–}1 \times 10^6$ cells in 0.4 ml RPMI with 20% fetal calf serum were treated for 2 h at 37°C with $0.1\ \mu g\ ml^{-1}$ of colcemid, either immediately following cell separation, or after the separated cells had been cultured overnight (~18 h) at 37°C. Colcemid-treated cells were swollen in 4 volumes of 1% sodium citrate containing 1 mM $MgCl_2$ and $CaCl_2$ for 10 min at 37°C. Cell smears were then made on a cytocentrifuge, air dried, fixed for 5 min in acetone/methanol (2:1) and stored at −70°C. EBNA-positive cells in the smears were identified by a modification of the anti-complement immunofluorescence test of Reedman and Klein[6]. Gelatin-veronal buffer (GVB)[17] was used as diluent for sera and for washing slides. Smears were incubated with a human serum containing antibodies to EBNA (RM) or a serum lacking EBV antibodies (LH) which had been diluted 1:8 and heat inactivated. After 30 min at 37°C, the sera were aspirated and the smears were immediately covered with a 1:10 dilution of human EBNA-negative serum as a source of complement. The slides were washed three times in GVB and stained for 30 min at 37°C with a 1:30 dilution of rhodamine-conjugated goat anti-human C3 antibodies (Atlantic Antibodies). After three washes in GVB, the slides were mounted in glycerol-PBS, *p*H 9.5, and examined in a Zeiss Universal fluorescence microscope equipped with a Ploem type incident illuminator.

*After cell separation completed.

†100–300 EBNA-positive cells counted.

We detected EBNA in up to 18% of B-cell-enriched IM blood lymphocytes, although other investigators have identified these cells in only 0.1–2% of cells in similar populations[10,11]. However, our patients had been symptomatic for 7 days or less whereas the patients studied in earlier reports were usually in their second or third week of illness. We found that the number of EBNA-positive cells decreased rapidly during the second week of illness to levels comparable to those in earlier reports (data not shown). The low numbers of EBNA-positive cells late in disease precluded the detection of mitotic EBNA-positive cells in these specimens.

Rickinson *et al.*[8] have shown that EBV-neutralizing antibody drastically reduces the outgrowth of transformed cell lines from cultured lymphocytes of IM patients. The antibody presumably acts to neutralize virus released from cells which had been infected *in vivo* but which entered a productive viral cycle *in vitro*. To exclude the possibility that the dividing antigen-positive cells that we detected after 18 h in culture had not been infected by this two-step mechanism, we determined when virus release occurs. We incubated a patient's cells in medium containing EBV-neutralizing antibody at various times after the beginning of culture. As shown in Table 2, EBV-neutralizing antibody did not reduce the frequency of transformation in a quantitive culture assay if it was present only during the first 24 or 48 h. Antibody did reduce the rate of transformation markedly if it was maintained in the cultures for the duration of

0028-0836/80/390334—02$01.00

the experiment or during the second and third day of culture. Thus, virus production and release do not occur during the first 2 days of culture. Even if normal cells could be infected at the time cells were placed *in vitro*, proliferation does not begin immediately. As shown in Table 3, cell division in normal B lymphocytes inoculated with EBV *in vitro* does not begin until 34–46 h after exposure to virus. Thus, our results show that a proportion of cells infected by EBV *in vivo* are capable of cell division after being placed in culture and that some of the antigen-positive cells have already traversed the cell cycle while still in the peripheral blood.

The capacity of the dividing EBNA-positive cells to grow into continuous cell lines is unknown. They may be the same as the cells which form EBNA-positive colonies in soft agar[12]. However, the ability to grow directly into cell lines is not a prerequisite for establishing that transformation occurs *in vivo*. We recently studied a 4-year-old girl who developed a poorly differentiated lymphoplasmacytic malignancy during IM. The tumour cells and the majority of peripheral blood leukocytes contained both EBNA and cytoplasmic immunoglobulins of all heavy and light chain classes[13]. Although in this patient there was unequivocal evidence of viral transformation *in vivo*, her cells either entered a lytic viral cycle or failed to grow in culture; only a few ultimately formed cell lines in soft agar.

During IM, the host immune response to EBV infection, which is usually already evident at the time of diagnosis[14,15], is probably responsible for restricting EBV-induced proliferation to the relatively low levels that we observed *in vivo*. Were it possible to study IM patients before symptoms develop, much higher numbers of dividing EBNA-positive cells might be seen.

Table 2 Time of effectiveness of EBV-neutralizing antibody in reducing the transformation frequency of cultured B-lymphocytes from IM blood

Time period antibody present in cultures				Transformation frequency*
0–24 h	24–48 h	48–72 h	8 weeks	
–	–	–	–	23/24
+	+	+	+	10/24
+	–	–	–	21/42
+	+	–	–	24/24
+	+	+	–	15/24
–	+	+	+	7/24

T-cell-depleted lymphocytes were isolated from a patient with IM on the 6th day of illness as described in Table 1. Replicate cultures of cells containing 5×10^5 cells were incubated at 37 °C for 24-h periods in medium RPMI 1640 supplemented with 15% fetal calf serum and 5% human serum from either an EBV-seropositive (EBV neutralization titre = 1:80) or seronegative individual. Each group of cells was washed three times in RPMI after 24, 48 and 72 h in culture and then resuspended in 0.5 ml of medium with or without antibody. At 72 h, the cells in each treatment group were plated at 10^4 cells per well in microtitre tissue culture plates previously seeded with human placental fibroblast feeder layers as previously described[3]. Cultures were fed weekly by removing half of the medium and replacing it with medium with and without antibody. Cultures were observed for approximately 8 weeks and the number of wells showing transformation in each treatment group were scored. +, Antibody present; –, antibody absent.

*No. of transformed wells/no. of wells plated.

Table 3 Time course of EBV-induced proliferation in B-lymphocytes inoculated with EBV *in vitro*

Time after inoculation (h)	% EBNA	EBNA-positive mitoses per 1,000 cells
10	7	0
22	44	0
34	51	≤1
46	55	16
58	56	94

Lymphocytes depleted of T cells as in Table 1 were isolated from a normal individual and incubated with concentrated EBV (B95-8 strain; multiplicity of infection = 500 physical particles per cell) or medium at 4 °C for 2 h. After three washes, the cells were resuspended in medium at 1.5×10^6 cells ml^{-1}. Aliquots (0.4 ml) of these cells were cultured in 13 × 100 mm stoppered tubes at 37 °C in an atmosphere of 5% CO_2. Beginning 10 h after the cultures were initiated, infected and uninfected cells were treated with 0.1 $\mu\text{g ml}^{-1}$ colcemid at 12-h intervals; smears for EBNA and EBNA-positive mitoses were prepared as described in Table 1.

The increase in the proportion of EBNA-positive cells in mitosis 18 h after being placed in culture suggests a release from the influence of an inhibitory environment. Since no mitotic cells were seen in Giemsa-stained slides prepared from 18-h cultures of T-cell-depleted lymphocytes from four normal individuals, it is more likely that the increased mitotic activity is due to the presence of the EBV genome in the cells than to a nonspecific stimulation of the cells resulting from the absence of T cells or other factors. If adequate host control mechanisms fail to develop *in vivo* during IM, as was likely in our fatal case[13], the EBV-infected cells have the potential for causing a malignant lymphoproliferation.

Isoelectric focusing of IgG eluted from multiple sclerosis and subacute sclerosing panencephalitis brains

**David H. Mattson, Raymond P. Roos*
& Barry G. W. Arnason**

The University of Chicago, Chicago, Illinois 60637

Elevated IgG distributed in oligoclonal bands is characteristically observed in the cerebrospinal fluid (CSF) of patients with multiple sclerosis (MS) or subacute sclerosing panencephalitis (SSPE)[1–6]. Similarly, IgG in bands has been detected in neutral saline (NS) and acid eluates of brain material from these two diseases[7–21]. We have now used isoelectric focusing (IEF) to compare IgG eluted from control brain, three plaques and a white matter pool of an MS brain, and three regions of an SSPE brain. A direct peroxidase-conjugated anti-human IgG staining technique was used to stain IgG exclusively and to visualize the minute amounts of IgG obtained from individual MS plaques. Eluates from individual MS plaques have distinct IgG patterns; in contrast, those from separate SSPE brain areas have essentially identical IgG patterns. The identical IgG patterns in three areas of SSPE brain suggest a common response to the same antigen. The different IgG patterns among MS plaques suggest: (1) variable response to the same 'MS antigen' in each plaque, (2) response to different MS antigens in different plaques, (3) synthesis of 'nonsense' antibodies irrelevant to the pathogenesis of MS in each plaque, or (4) some combination of the above.

IgG was eluted by modifications of the techniques of Gilden[21,22] and Weil[14,15] from: the white matter pool (WMP) and three plaques of an MS patient, three discrete brain areas of an SSPE patient, and a WMP of an individual without neurological disease. Although seven NS washes reduced recoverable IgG to nearly zero in all material, subsequent acid elution recovered significant additional IgG (Table 1). The IgG eluted from these tissues, along with serum and CSF from the SSPE case, was then examined by IEF.

NS and acid eluates from each MS plaque had unique overall patterns of IgG bands on IEF despite many shared bands (Fig. 1). The WMP acid eluate contained all the IgG bands found in the acid eluates from the individual plaques plus additional bands. NS eluates had more anodal and fewer cathodal bands than acid eluates. The difference in pattern between acid and NS eluates could not be accounted for by acid exposure because treatment of NS-eluted IgG with acid did not change the IEF pattern. Analysis of three discrete 0.6–1.2 g white matter regions from a second MS case (age 36 yr, with a 13-yr history of chronic progressive MS) has given comparable differences in banding patterns.

The oligoclonal IgG patterns of the NS eluates of all three SSPE brain regions were identical, and similar to the pattern of the CSF. The serum had several bands, identical with bands in the CSF. Acid eluates of the three SSPE brain regions had virtually identical oligoclonal IgG patterns (Fig. 2). When compared with NS eluates and CSF, acid eluates had an additional major cathodal band and other minor differences. A second case of SSPE (age 14 yr, with an 8-month duration of disease and a history of primary measles at age 4 yr) has given similar results.

NS and acid eluates from control WMP showed indistinct bands very different from the sharp bands observed in MS and SSPE eluates (Fig. 3). These bands were more readily discerned in the NS than in the acid eluate. Diffusely distributed cathodal IgG was more evident in the acid than in the NS eluate.

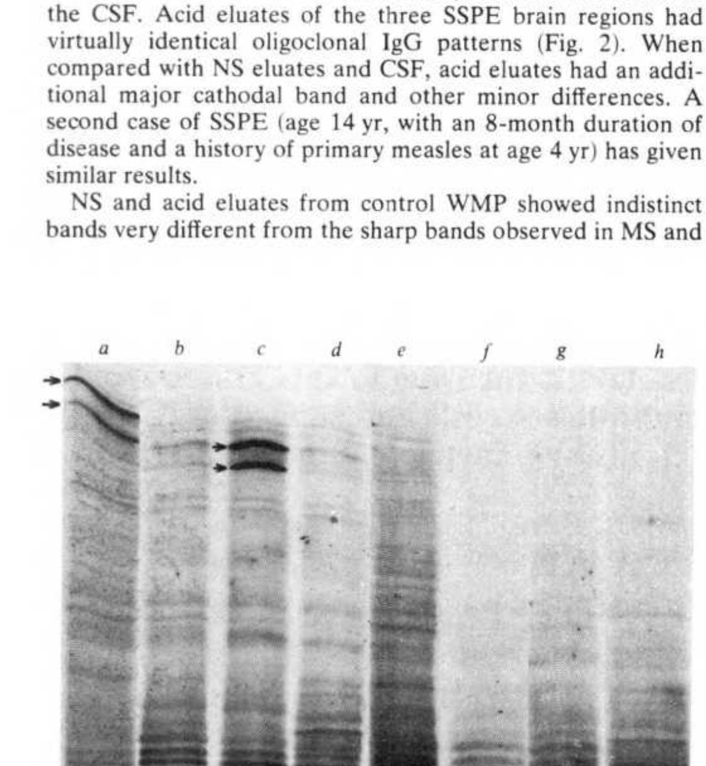

Fig. 1 IEF of MS brain material. *a*, WMP 1st + 2nd NS eluates; *b*, plaque 1 1st + 2nd NS eluates; *c*, plaque 2 1st + 2nd NS eluates; *d*, plaque 3 1st + 2nd NS eluates; *e*, WMP 1st + 2nd acid eluates; *f*, plaque 1 1st + 2nd acid eluates; *g*, plaque 2 1st + 2nd acid eluates; *h*, plaque 3 1st + 2nd acid eluates. The top of the gel is *p*H 7.0 and the bottom is *p*H 9.0. Arrows indicate haemoglobin which stains brown with our peroxidase substrate and is present especially in the 1st + 2nd NS eluates. IEF was carried out using LKB Ampholine PAGplate gels, *p*H 3.5–9.5, on an LKB 2117 Multiphor with an LKB 2103 power supply. The anode solution was 1 M H_3PO_4; the cathode solution 1 M NaOH. Samples containing 2 μg of IgG were applied to the middle of the gel in 5 × 10 mm pieces of filter paper and focused for 2 h at 4 °C and 30 W constant power. Immediately after focusing, gels were fixed for 1 h with trichloroacetic acid (TCA) and sulphosalicylic acid (SSA) (57.5 g TCA and 17.25 g SSA in 150 ml methanol and 350 ml water), and rinsed for 48 h in Tris buffer (0.1 M Tris–HCl, 0.85 M NaCl, *p*H 7.6). A cellulose acetate strip soaked with undiluted peroxidase-conjugated rabbit anti-human IgG (Dako), 40 μl per sample lane, was placed on the gel for 1 h at room temperature in a moist environment. Gels were rinsed with Tris buffer in the dark for 96 h, and developed for 1 h in 30 mg% 3, 3′-diaminobenzidine tetrahydrochloride (Sigma) and 0.06% hydrogen peroxide (in Tris buffer).

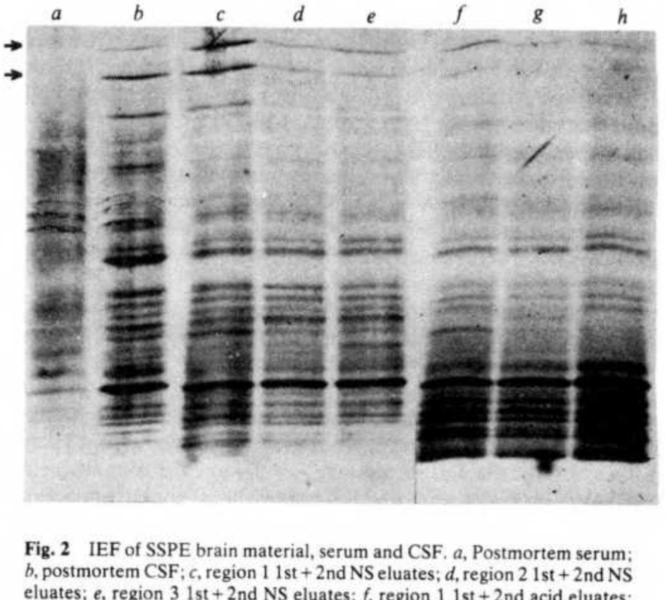

Fig. 2 IEF of SSPE brain material, serum and CSF. *a*, Postmortem serum; *b*, postmortem CSF; *c*, region 1 1st + 2nd NS eluates; *d*, region 2 1st + 2nd NS eluates; *e*, region 3 1st + 2nd NS eluates; *f*, region 1 1st + 2nd acid eluates; *g*, region 2 1st + 2nd eluates; *h*, region 3 1st + 2nd acid eluates. IEF as in Fig. 1.

IgG obtained after acid treatment of normal brain may be nonspecifically bound (through Fc receptors[23,24] or charge affinities), or released from fractured plasma cells. The oligoclonal pattern of this IgG, an observation made previously in NS eluates using agar gel electrophoresis (AGE)[19], may reflect sequestration of certain lymphoid cell clones in normal brain.

Acid elution of SSPE brain is thought to dissociate complexes of anti-measles oligoclonal IgG from measles antigen[14,15,18,20]; NS eluted IgG probably represents antibody in excess of antigen. This view is supported by the observation that most acid- and NS-eluted IgG bands, as well as CSF IgG bands, are absorbable by measles virus[13,17,18]. All three SSPE brain regions we examined had almost identical banding patterns, suggesting a restricted antibody response to the same antigen in each area. CSF and NS eluates, however, contained several IgG bands not apparent in acid eluates of brain. These bands may not be anti-measles antibodies but may instead be the product of nonspecific clones recruited to the brain. SSPE CSF oligoclonal IgG bands not absorbable with measles virus have been reported[13,17,18].

The three MS plaque acid eluates analysed had several bands in common, but each had a unique overall pattern. The acid eluate of MS WMP contained all bands present in the acid eluates of the three plaques plus additional bands, as if patterns from many plaques had been summed. Although some differences in band patterns may be quantitative rather than qualitative, the variation in band pattern from plaque to plaque indicates that different antibody-synthesizing clones are present (or expanded) in different areas of MS brain.

Several explanations for this observation can be advanced. If oligoclonal IgG eluted with acid from MS brain is antibody specifically bound to an MS antigen(s), plasma cell clones producing antibody directed against MS antigen(s) may appear, decline and disappear in different plaques over time. Old, chronic or inactive plaques might then be expected to contain different clones from more recent, active plaques. IgG bands (in serum) are known to change over time in animals chronically stimulated with a well defined antigen[25,26]. Our failure to find any changes in different regions of the brain in SSPE perhaps argues against this interpretation. Although the SSPE cases studied were less than 1 yr in duration, one would have thought that this was sufficient (especially considering an 'incubation period' of at least 10 yr from initial measles infection) for changes to have taken place.

Another explanation, which again would require that all acid-eluted antibody is specifically bound, would be that a different antigen is present in each MS plaque and for this reason antibody-synthesizing clones differ in each plaque. This seems improbable; however, a single agent can undergo antigenic shifts leading to different antibody responses over time. Antigenic shifts have been observed with visna virus in infected sheep brains[27].

A third possibility is that those bands common to all plaques are specific antibody directed against an MS antigen(s), whereas those bands unique to individual plaques are nonsense antibody irrelevant to the pathogenesis of MS. Such nonsense antibody would be the product of plasma cell clones that become localized in the plaque but are not stimulated by any antigen present there. This irrelevant IgG would be released by acid treatment through breakage of nonspecific bonds or rupture of plasma cells. Antibodies to several viruses, such as measles and rubella, are elevated in MS CSF and are oligoclonal in distribution[28]. Although these antibodies do not correspond to the CSF oligoclonal IgG bands seen by AGE, they could appear as bands when CSF or brain eluates are analysed by the more sensitive IEF technique. Of relevance is the observation that mice immunized with several antigens and boosted in a lymph node with one, show recruitment to the node not only of plasma cells specific to the stimulating antigen, but also of lymphoid clones directed against the other antigens[29]. Thus, there is a precedent for the notion that irrelevant plasma cell clones can be recruited in the face of specific antigenic challenge.

Finally, all IgG in MS plaques could be nonspecifically bound, irrelevant to any pathogenic antigen, and represent the product of B-cell clones sequestered randomly during attacks of MS. Bands common to eluates of all plaques would then represent the product of clones constantly maintained by repeated or continuous antigenic exposure whereas bands unique to a plaque would be the product of clones responding to antigens encountered shortly before activation of a plaque by an MS attack.

We believe that resolution of the questions raised by these findings may prove crucial for an understanding of the pathogenesis of MS.

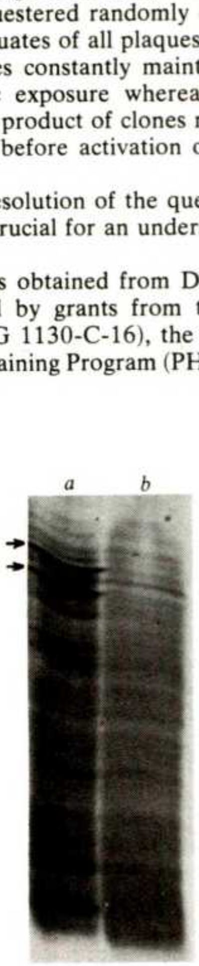

Fig. 3 IEF of control brain material. *a*, WMP 1st + 2nd NS eluates; *b*, WMP 1st + 2nd acid eluates. IEF as in Fig. 1.

Table 1 IgG recovered from MS, SSPE and control brain material on neutral saline and acid elution

	IgG recovered at various elution steps (μg)		
Material (weight)	1st + 2nd NS	7th NS	1st + 2nd acid
MS white matter pool* (6.0 g)	851 (0.142)§	7.7	390 (0.065)§
MS plaque 1* (0.1 g)	57 (0.574)	0	8.9 (0.089)
MS plaque 2* (0.4 g)	113 (0.283)	0.1	18 (0.045)
MS plaque 3* (0.4 g)	131 (0.328)	0.5	20 (0.050)
SSPE cortex region 1† (2.3 g)	1,222 (0.531)	4.1	97 (0.042)
SSPE cortex region 2† (1.8 g)	1,407 (0.782)	0.9	66 (0.037)

Sections 8 μm thick were cut on a cryostat and homogenized with 10 strokes of a Dounce homogenizer in a small amount of Dulbecco's phosphate-buffered saline (DPBS) containing 0.02% sodium azide. Each homogenate was rinsed seven times with at least 7 volumes of DPBS containing 0.02% sodium azide at 4 °C, with centrifugations at 100,000*g* for 1 h at 4 °C. Homogenates were then rinsed twice with similar volumes of 0.1 M glycine–HCl buffer at *p*H 2.5 (containing 0.1% bovine serum albumin, 0.005 M ε-aminocaproic acid and 2.8 μg ml^{-1} pepstatin), each time for 1 h at 4 °C with end over end shaking, followed by centrifugations at 100,000*g* for 1 h at 4 °C. Immediately after centrifugation, supernatants from each acid elution were brought to *p*H 7.0 by addition of 1 M Tris(hydroxymethyl)aminomethane (Sigma). The pooled first plus second neutral saline rinses, the seventh neutral saline rinse and the pooled first plus second neutralized acid eluates were concentrated using vacuum ultrafiltration with 25,000 molecular weight cutoff collodion bags (Schleicher and Schuell) against several changes of a 1:10 dilution of DPBS. IgG was quantified in the concentrated eluates by electroimmunodiffusion (Antibodies Incorporated).

* Periventricular white matter and three brain plaques were dissected at autopsy 13 h after death and stored at −70 °C for 2 yr. The patient was a 51-yr-old female with a 9-yr history of chronic progressive MS.

† Three separate areas of cortical white (with adjoining grey) matter were dissected at autopsy 6 h after death and stored at −70 °C for 1 week. Postmortem CSF and serum were also obtained. The patient was a 17-yr-old male with a 10-month history of SSPE. He had a primary measles infection at age 6 yr.

‡ White matter was dissected at autopsy 20 h after death and stored at −70 °C for 2 months. The patient was a 47-yr-old male with lung carcinoma.

§ Values in parentheses are μg per mg IgG recovered from starting material.

SSPE material was obtained from Dr J. H. Webster. This work was supported by grants from the National Multiple Sclerosis Society (RG 1130-C-16), the Kroc Foundation, the Medical Scientists Training Program (PHS 2 T32 GM07281) to D.H.M., by a Basil O'Connor Starter Research grant from the National Foundation March of Dimes (5-162) and a Schweppe Foundation Career Development Award (to R.P.R.).

Limitations in the use of actomyosin threads as model contractile systems

John D. Altringham, Paul H. Yancey & Ian A. Johnston
Department of Physiology, University of St Andrews, St Andrews, Fife KY16 9TS, UK

Recent studies have suggested that actomyosin threads may provide a useful model for studying the properties of contractile systems[1-3]. The development of highly sensitive positional feedback transducers has enabled the properties of these threads to be measured reproducibly[1]. Potential applications include such systems as ventricle, smooth muscle and non-muscle preparations, from which it is difficult to obtain suitable fibres for mechanical studies. In addition, studies with chemically modified myosins may provide new insights into the relationships between the biochemical and mechanical events in the cross-bridge cycle. However, there are indications that the mechanical properties of actomyosin threads differ from those of intact fibres in several important respects. For example, contraction velocity is proportional to isometric tension in threads[2], but is independent of filament density in intact fibres[4]. We have now determined the force–velocity characteristics of actomyosin threads prepared from muscles with known differences in their physiological contraction velocities. No direct relationships could be found between the velocity characteristics of the threads and those of intact muscle. We conclude that the measured velocities of threads reflect properties of the actomyosins other than cross-bridge cycling times, thus severely limiting the usefulness of this technique for comparative purposes.

Natural actomyosins were isolated from the ventricle and back (fast skeletal) muscles of rabbit, and from the red (slow) and white (fast) myotomal muscles of the dogfish *Scyliorhinus canicula*[5]. Purified actin[6], myosin[7] and tropomyosin–troponins[6] were also prepared from rabbit back muscle. Threads were formed using the method described by Crooks and Cooke[1], involving the extrusion of actomyosin at high ionic strength from a syringe needle moving through a solution of low ionic strength. Isometric contraction was initiated by the addition of ATP or $CaCl_2$ (Fig. 1). Calcium sensitivity (as defined by Lehman and Szent-Györgyi[5]) in the threads was difficult to achieve, even though ATPase activities of the actomyosins were typically >80% calcium sensitive and gel electrophoresis showed the presence of calcium regulatory proteins in the threads. Isotonic contraction velocities were measured in maximally activated threads by release against a series of electronically present loads. The force–velocity curves obtained in this manner are shown in Figs 2 and 3, and the unloaded contraction velocities (V_{max}) and maximal tensions (P_0) are listed in Table 1, together with ATPase activities for the actomyosins.

The data reveal several unphysiological characteristics. First, the velocities are all less than 0.012 lengths s^{-1}, two to three orders of magnitude lower than those of intact muscle fibres. For example, V_{max} values for *Tilapia* adductor operculi white and red fibres are 2.6 and 1.5 lengths s^{-1} at 18 °C (ref. 8); Lännergren reports values of 6.3 and 1.1 lengths s^{-1} for *Xenopus* fast and slow fibres (22.5 °C), and Close gives values of 14.5 and 6.3 lengths s^{-1} for whole extensor digitorum longus and soleus muscles of the rat (35 °C)[10].

Second, the relative velocities of the different thread types do not reflect those of the corresponding muscles (Figs 2, 3, Table 1). Barany[11] has shown a positive correlation between the actomyosin ATPase activity and the contraction velocity of a muscle. However, the velocities of the threads from both animals show a complete reversal of the results predicted from both the ATPase levels and the studies noted above on single fibres and whole muscles from different muscle types. It therefore seems that the measured contraction velocities of actomyosin threads reflect factors other than cross-bridge cycling times. The most important of these is probably related to the geometry and packing of filaments within the threads. Threads lack the polarity and native organization of myofilaments found in intact muscle[12]. As noted above, Cooke and Franks[2] found velocity to be proportional to isometric tension (which is determined by protein concentration) in threads, whereas it is independent of myofibrillar density in intact muscle[4].

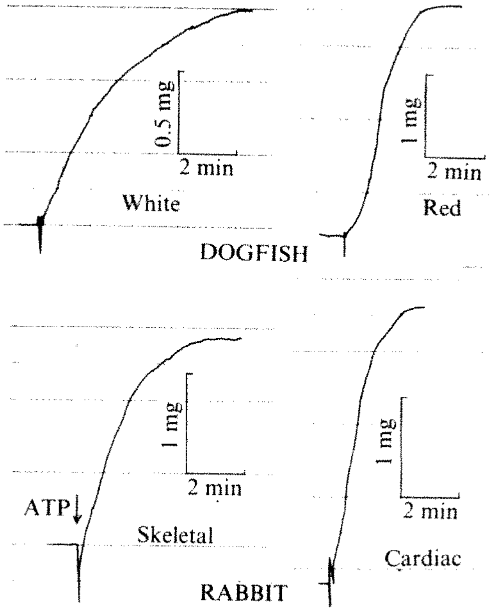

Fig. 1 Development of isometric tension with time in actomyosin threads activated with ATP. Incubation medium contained 50 mM imidazole, 40 mM KCl, 5 mM EGTA, 5 mM $CaCl_2$, 3 mM $MgCl_2$, 0.5 mM $Na_4P_2O_7$ and ATP added to a final concentration of 500 µM. An ATP regenerating system was also present (10 mM creatine phosphate, creatine phosphokinase at >20 units ml^{-1}). Protein purity was examined by SDS-polyacrylamide gel electrophoresis and electron microscopy. Natural actomyosins were used the same day as preparation, purified component proteins directly after purification. Protein concentrations varied from 50 to 65 mg ml^{-1} (determined by a microbiuret method[18]). Tension and force–velocity parameters were measured on a sensitive tensiometer similar in design to that described by Crooks and Cooke[1] (sensitivity in isotonic: 100 mV per 70 µm; in isometric: 135 mV mg^{-1}; drift 0.02 mg h^{-1}; compliance 0.1 µm mg^{-1}). Threads 5 mm long and 240 µm in diameter were attached to the tensiometer using a Plexiglass–acetone glue.

Ultrastructural studies by D'Haese and Komnick[12] have shown that contraction of actomysin threads results in a condensation of the parallel filament system, in cross-section, and increased overlap of filaments in longitudinal section, suggesting that contraction is due to a sliding filament mechanism. These studies also indicate that the conditions of myosin filament formation may determine the properties of the threads. For example, threads prepared by rapid precipitation contain actin filaments decorated with myosin molecules and oligomeric myosin bridges. During isometric contraction, myosin filaments form and, with actin filaments, align themselves along the long axis of the thread. Dialysis of the actomyosin solution before thread extrusion, to give slower myosin precipitation, produces threads with both actin and myosin filaments in the relaxed state. The initial unloaded contraction velocities of these threads is over four times greater than those of rapidly precipitated threads.

Other studies have shown that filament formation by purified myosin depends to a large extent on the conditions of formation

White	0.18±0.06	26.0±9.7	0.55
Red	0.39±0.12	57.0±4.1	0.18

$L s^{-1}$ = thread lengths s^{-1}; errors indicate ±1 s.d. ATPase activities were determined in an incubation medium of 50 mM imidazole, 40 mM KCl, 0.1 mM $CaCl_2$, 3 mM $MgCl_2$, 2.5 mM ATP and protein concentration 0.1–0.5 mg ml^{-1}; rabbit activities were measured at 37 °C, *p*H 7.0, dogfish activities at 15 °C, *p*H 7.4.

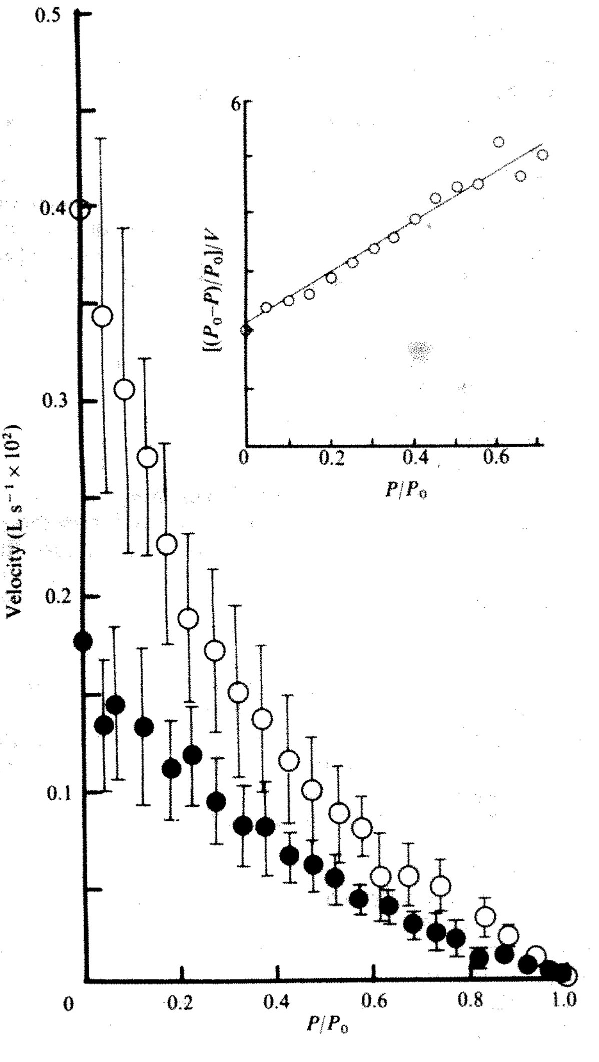

Fig. 2 Force–velocity relationships for dogfish threads at 15 °C, *p*H 7.4. ○, Red muscle; ●, white muscle. Velocities are in thread lengths s^{-1}; P/P_0 = force applied/maximal isometric tension. Error bars indicate ±1 s.d. The data are derived from 6 threads of red actomyosin from 3 animals, and 14 threads of white actomyosin from 6 animals. The inset shows a typical curve for red actomyosin plotted according to the linear form of Hill's equation[19]. Points below 0.7 P_0 lie on a straight line. A similar fit has been described for intact single fibres[9].

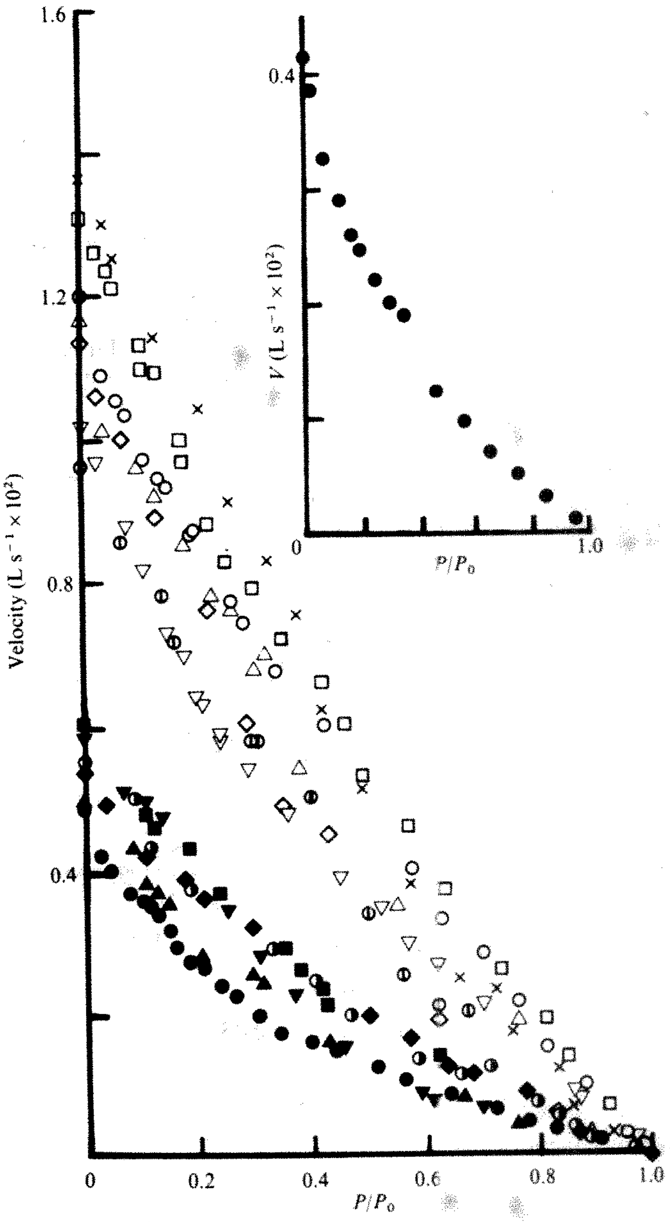

Fig. 3 Force–velocity relationships for rabbit threads at 37 °C, *p*H 7.0. Open symbols represent seven individual threads of cardiac muscle from three animals; solid symbols present six threads of fast skeletal muscle from three animals. The inset shows a typical force–velocity curve for a thread prepared from purified actin, myosin and regulatory proteins of skeletal muscle, demonstrating its similarity to threads of skeletal natural actomyosin.

and the age of the myosin. The length, diameter and shape of synthetic myosin filaments are affected by *p*H (refs 13, 14), ionic strength[14] and the concentrations of ATP, PO_4^{3-}, Mg^{2+} and Ca^{2+} (ref. 15). Specific concentrations of ATP and Mg^{2+} are needed for the formation of filaments with physiological diameters, tapered ends and a central zone of polarity reversal[15]. Storage of myosin in the cold results in the loss of the ability to form these 'physiological' filaments[16]. During storage there is a loss of the LC2 light chain; removal of the LC2 chain from fresh myosin by treatment with dithionitrobenzene (DTNB) mimics this ageing process.

Structural differences among the myosins of fast, slow and cardiac muscles have been well documented[17], and it is possible that these myosins will differ in their abilities to form filaments in the conditions required to prepare and activate threads.

Our results, in conjunction with the above studies, suggest that filament formation, geometry and packing, and not differences in cross-bridge cycling rates, largely determine the observed properties of actomyosin threads. Thus, any physical or chemical manipulation (such as protein concentration, storage time, ion concentrations, DTNB treatment) of the actomyosin that alters its ability to form filaments is likely to result in secondary, unphysiological changes in the contractile properties of threads.

This work was supported by grants from the SRC and the Wellcome Trust. P.H.Y. was in receipt of a NATO Postdoctoral Fellowship and J.D.A. is supported by an SRC Research Studentship. Part of this work was carried out at the Marine Biological Association Laboratories, Plymouth, UK. We thank the Director, Professor E. Denton, for provision of facilities, and Dr Q. Bone for the loan of equipment and for his hospitality.

Nuclear accumulation of epidermal growth factor in cultured rat pituitary cells

L. K. Johnson*, I. Vlodavsky†, J. D. Baxter* & D. Gospodarowicz†

Howard Hughes Medical Institute Laboratories, * Endocrine Research Division, † Cancer Research Institute and the Department of Medicine, University of California, San Francisco, California 94143

Epidermal growth factor (EGF) is a mitogen for epidermal cells *in vivo*[1,2] and for a wide variety of cells in culture[3–5]. Recently, we and others have reported that EGF can also regulate the cellular levels of various hormones[6] and fibronectin[7] at concentrations which only minimally influence cell division. In addition, EGF treatment of GH$_3$ cells affects chromatin structure such that isolated nuclei from treated cells have an increased capacity to bind bacterial RNA polymerase in initiation site complexes[6]. Thus, the data suggest that various nuclear functions are modulated by EGF in GH$_3$ cells despite its failure to affect DNA synthesis or cell proliferation. Recently, Yanker and Shooter[8] have reported on the nuclear accumulation of nerve growth factor (NGF) in PC12 cells in which NGF does not promote cell division but does influence RNA and protein synthesis while inducing overt differentiation (neurite outgrowth). The similarities between the two systems and the various theories regarding the mechanism by which mitogens exert their growth-promoting and other effects[9,10] led us to investigate whether an interaction between EGF and the cell nucleus can be demonstrated after surface binding and internalization of EGF in GH$_3$ cells. We report here that when its lysosomal degradation is inhibited by chloroquine, EGF accumulates in the nucleus.

Previous studies with GH$_3$ and other cell types have demonstrated that the cell-bound ^{125}I-EGF is rapidly degraded ($t_{1/2}$ = 20 min) to mono-^{125}I-iodotyrosine by lysosomal proteases following endocytotic internalization[6,11,12]. Due to this process, the intracellular amount of intact EGF reaches, within 1–2 h of exposure to EGF, a steady-state concentration which is much lower than the actual amount of internalized EGF and which later decreases even more due to a loss (down regulation) of the cell-surface receptors for the factor. Furthermore, if translocation of EGF into the nucleus does occur, this might require a time longer than the mean half life of the internalized EGF molecules, thereby even further reducing the possibility of detecting significant quantities of nuclear-bound ^{125}I-EGF. Therefore, our approach in probing for nuclear accumulation of EGF in GH$_3$ cells was to use the lysosomal inhibitor chloroquine, which has been shown to inhibit, in this and other cell types, the degradation of EGF and thus allows the intracellular accumulation of EGF[4,6].

In the following experiments, cells were incubated with ^{125}I-EGF in the absence and presence of chloroquine, lysed with buffer containing 0.5% NP40, and tested for the amount of radioactivity associated with the nuclear pellet and cell lysate. As shown in Fig. 1*a*, nuclei isolated from detergent-lysed cells which were exposed to 12.5 ng ml^{-1} ^{125}I-EGF for 18 h contained about 1% of the cell-associated label. In contrast, when cells were incubated with EGF in the presence of increasing concentrations of chloroquine, the amount of nuclear-associated radioactivity increased and reached a plateau of about 14% of the cell-bound counts at a concentration of 75 μM chloroquine. In these conditions, the total amount of cell-associated ^{125}I-EGF (bound plus internalized) was increased sixfold. As shown in Fig. 1*b*, the nuclear accumulation of EGF in chloroquine-treated (75 μM) cells lags significantly behind the rate of internalization of the growth factor. Thus, after a 4-h incubation with EGF, only about 2% of the internalized EGF (measured in the NP40 lysate) was associated with the isolated nuclei, whereas a 24-h incubation resulted in a nuclear accumulation of as much as 12% of the internalized EGF. Such a difference in the kinetics of cytoplasmic accumulation and nuclear binding also suggests that the observed nuclear accumulation of EGF is not due to contamination of the nuclei by membrane- or cytoplasm-bound EGF. This was further documented by electron microscopy of nuclei prepared from control and chloroquine-treated cells (Fig. 1*c*, *d*). In both cases the nuclei were free of the lysosomal vesicles known to accumulate in chloroquine-treated cells. Nuclei were also tested for lysosomal and plasma membrane contamination by assaying the biochemical marker enzymes acid phosphatase and (NA$^+$+K$^+$)ATPase respectively. Acid phosphatase activity in the nuclei measured by the method of Brandenberger *et al.*[13] was less than 0.5% of the total cellular activity in both control and chloroquine-treated cells. Nuclear (Na$^+$+K$^+$)ATPase measured according to Jackson[14] was less than 0.3% of the total cellular activity and similarly was not influenced by chloroquine treatment of the cells.

The possibility that the observed nuclear binding occurred not within the cell but upon lysis in detergent buffer was next examined. Cells were incubated for 18 h with 75 μM chloroquine in the presence or absence of 2 ng ml^{-1} ^{125}I-EGF. After washing the cultures were lysed with the NP40 buffer containing no EGF, 10 μg ml^{-1} unlabelled EGF (in the case of prelabelled cells) or 2 ng ml^{-1} ^{125}I-EGF (in the case of unlabelled cells). Nuclei were then isolated as in Fig. 1 and the bound EGF determined. Nuclei isolated from 10^6 cells prelabelled for 18 h with ^{125}I-EGF contained 5.1 fmol of ^{125}I-EGF while those prelabelled and lysed in buffer containing 10μg ml^{-1} unlabelled EGF contained 4.98 fmol ^{125}I-EGF. However, nuclei isolated with lysis buffer containing ^{125}I-EGF contained only background levels of radioactivity. This suggests that the observed nuclear binding occurs before lysis of the cell. Furthermore, incubation of cells with ^{125}I-EGF and chloroquine at 4 °C rather than 37 °C was not associated with cytoplasmic or nuclear

0028-0836/80/390340—04$01.00

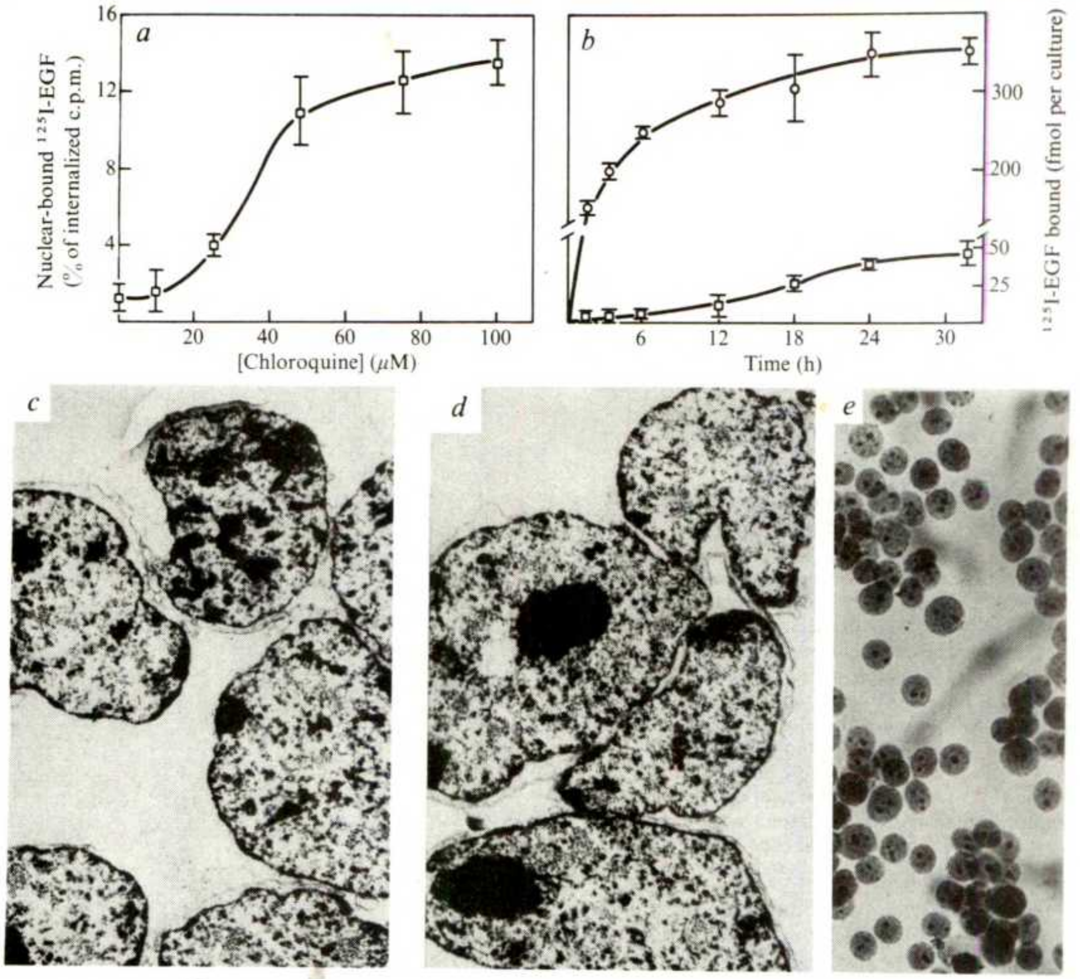

Fig. 1 Nuclear accumulation of ^{125}I-EGF in GH_3 cells. *a*, Effect of chloroquine concentration on the per cent of total cell-associated ^{125}I-EGF found in the nuclear fraction after 18 h. *b*, Kinetics of ^{125}I-EGF accumulation in GH_3 cell lysates and nuclei. 5×10^6 GH_3 cells, maintained as previously described[6], were seeded into 35-mm culture dishes. After 24 h the medium was replaced by 1.0 ml of medium containing 0.5% fetal calf serum and the indicated chloroquine concentrations. One hour later 12.5 ng ml^{-1} ^{125}I-EGF (purified and iodinated as described[4]; specific activity, 460,000 c.p.m. ng^{-1}), was added in the presence and absence of 2.5 μg ml^{-1} unlabelled EGF. After incubation at 37 °C cultures were washed 10 times with phosphate-buffered saline containing 1 mg ml^{-1} BSA and lysed in buffer containing 0.5% NP40 (ref. 6). The initial supernatant after removal of the nuclei (1,000*g*, 5 min) was designated the lysate fraction (open circles) and the nuclei were purified further as described[6] before counting of radioactivity (open squares). The mean and range of triplicate determinations are shown for each experiment. Electron microscopy of nuclear pellets from control (*c*) and chloroquine-treated (*d*) cells. Pellets were fixed on ice in 4% gluteraldehyde, 3.6% formaldehyde, 0.2 M cacodylate buffer (*p*H 7.2). Pellets were postfixed in 1% osmium tetroxide, 0.1 M Na cacodylate (*p*H 7.2), dehydrated in acetone and embedded in epon 812. Sections were stained with uranylacetate and lead citrate and photographed at an initial magnification of 4,500×. *e*, Phase contrast micrograph of nuclei from chloroquine-treated cells. Nuclei were stained with 1% trypan blue and photographed at an initial magnification of 200×.

accumulation of ^{125}I-EGF, demonstrating that the nuclear uptake is dependent on internalization of the growth factor.

Having found conditions for experimentally detecting nuclear-associated ^{125}I-EGF, we next asked if this process strictly paralleled the inhibition of EGF degradation by chloroquine. Alternatively, the nuclear accumulation of EGF could have been due to some other effect of the inhibitor, probably on the outer nuclear membrane. It was found that exposure to chloroquine (75 μM) had no effect on, or increased by at most twofold, the amount of surface-bound ^{125}I-EGF (measured by its release by trypsin). However, chloroquine-treated cultures contained as much as 19.3 times more immunoprecipitable and hence, presumably intact ^{125}I-EGF in their cell lysates than control cells (Table 1). This increase was directly paralleled by a 19-fold increase in the amount of nuclear-associated ^{125}I-EGF. As in the lysate of chloroquine-treated cells, 75% of the nuclear-bound ^{125}I-EGF could be precipitated with anti-EGF after solubilization from the nuclei. The results of these experiments suggest that in control cells, due to rapid degradation of the internalized EGF, only a small percentage (1%) of the internalized growth factor could be detected in the nucleus. In contrast, in chloroquine-treated cultures EGF degradation is greatly diminished, thus allowing a cytoplasmic accumulation of EGF and making a greater proportion of the internalized, intact EGF available for nuclear binding.

The nature of the nuclear sites which interact with ^{125}I-EGF was examined next. Scatchard analysis of the ^{125}I-EGF nuclear accumulation (Fig. 2) shows that the observed nuclear binding is saturable and of high affinity. Two distinct classes of binding affinity are apparent: a high affinity component with a K_d of 0.28 nM and a lower affinity class of sites possessing a K_d of 2.7 nM. The binding capacity of each class of sites estimated from the Scatchard plots is 10^3 and 1.2×10^4 sites per nucleus, respectively. Interestingly, this observation is similar to findings regarding the nuclear binding of NGF in PC12 cells. In that system, two classes of binding sites which differ in affinity by an order of magnitude were also observed[8], although the number of high-affinity sites was two- to fivefold greater than that seen for EGF in GH_3 cells. The NGF nuclear receptor sites in PC12 cells are resistant to extraction with Triton detergents, suggesting that they may be localized at the inner membrane[8]. In that system, both intact nuclei and isolated nuclear membranes retain the ability to bind ^{125}I-NGF. In the case of GH_3 cells, nuclei isolated from either untreated or chloroquine-treated GH_3 cells showed no detectable binding of ^{125}I-EGF when the growth factor was added *in vitro*. Similar negative results were

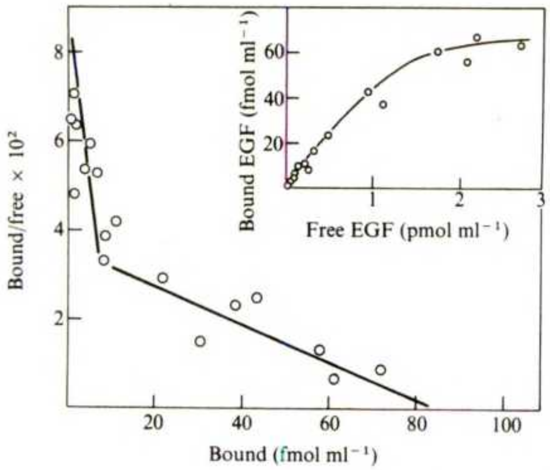

Fig. 2 Scatchard analysis of ^{125}I-EGF binding to GH$_3$ cell nuclei. Cells were seeded and media replaced as described in Fig. 1. Cultures were then incubated for 18 h at 37 °C in the presence of 75 μM chloroquine and increasing concentrations of ^{125}I-EGF (0.05–50 ng ml^{-1}) with or without 2.5 μg ml^{-1} unlabelled EGF. Nuclei were analysed for the amount of specifically bound EGF as described in Fig. 1 legend. The extracellular concentration of free, intact EGF was determined by double immunoprecipitation (rabbit anti-EGF antiserum followed by goat anti-rabbit IgG) of an aliquot (100 μl) of the culture medium before the cultures were washed, as described in Table 1. Plates without cells were used to control for spontaneous breakdown of ^{125}I-EGF during the incubation period at 37 °C. Up to 20% of the total radioactivity was no longer immunoprecipitable, after incubation without cells, as opposed to only 2% in freshly labelled EGF.

obtained with detergent-washed nuclei (nuclei lacking the outer membrane) or with nuclei prepared by mechanical disruption and centrifugation through 2.0 M sucrose[8] (nuclei with an intact outer membrane). We therefore examined the sub-nuclear localization of EGF by subjecting isolated nuclei with bound ^{125}I-EGF to enzymatic fractionation of the chromatin.

GH$_3$ cells were labelled for 24 h with ^{14}C-thymidine followed by a 12-h incubation with ^{125}I-EGF in the presence of chloroquine. The nuclei were then isolated and incubated with micrococcal nuclease at 22 °C. At various times, aliquots were taken and the amount of ^{125}I and ^{14}C released into the supernatant determined. As shown in Fig. 3, micrococcal nuclease solubilized approximately 90% of the labelled DNA within 10 min. The solubilized DNA fragments showed the characteristic nucleosome repeat pattern of chromatin and contained DNA fragment sizes from monomers (180 base pairs) to octamers (Fig. 3*b*). However, no ^{125}I-EGF was released by the nuclease above that which dissociated during the course of the experiment (approximately 9% in the zero time controls), nor was any spontaneous release observed when the EGF-loaded nuclei were lysed with 1.0 mM EDTA. This suggests that the bound EGF is not localized in the chromatin fraction of the nucleus but rather is associated with the inner nuclear membrane or nuclear matrix fraction. The latter contains the so-called 'nuclear scaffolding' (ref. 15), structures thought to participate in the higher-order condensation and packaging of chromatin into metaphase chromosomes before cytokinesis[16]. Direct EGF binding to receptors in the inner nuclear membrane seems unlikely, however, as nuclei isolated by detergent showed no binding when analysed *in vitro* despite their retention of the inner membrane. These findings are in contrast to the sub-nuclear location of two other regulators of growth hormone and prolactin mRNA synthesis, namely the thyroid and glucocorticoid hormone receptors[6]. Both of these receptors are liberated from GH cell chromatin upon DNase digestion[17] and in the case of T$_3$ there may be a preferential localization of the receptor in nuclear fractions more active in RNA synthesis[18,19].

Although a number of common steps appear to follow the initial cell surface binding of various polypeptide hormones and mitogens, the mechanism by which the respective cellular responses are exerted is still far from being understood. Some of these responses require a prolonged exposure to the effector, while others are temporary and occur within minutes. If internalization is a prerequisite, at least for the induction of long-term responses, then an interaction of either the intact polypeptide or its degradation product with the cell nucleus should be considered. Nuclear binding sites for insulin[20] and NGF[8] have been identified in rat liver cells and PC12 cells, respectively. In the case of GH$_3$ cells, although binding to isolated nuclei has not yet been observed, a translocation pathway leading to a nuclear accumulation of EGF can be described in accordance with the present observations.

The nuclear accumulation of EGF in GH$_3$ cells was a small percentage of the total internalized EFG (1%) but increased markedly when the lysosomal degradation of the growth factor

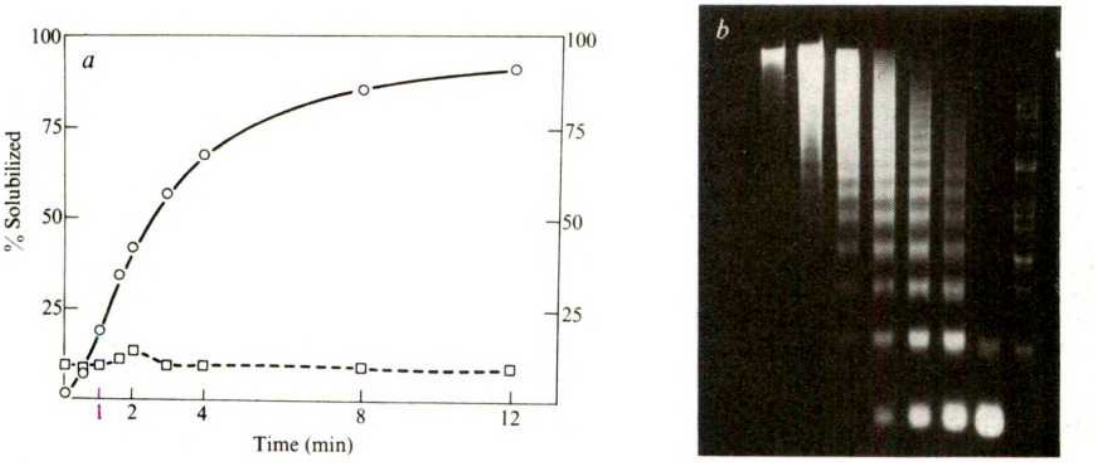

Fig. 3 Influence of micrococcal nuclease on release of ^{125}I-EGF and ^{14}C-thymidine - labelled DNA from isolated GH$_3$ nuclei. Cells (1.5×10^7) were labelled for 24 h with 25 μCi (5 μCi ml^{-1}) ^{14}C-thymidine, followed by an additional 18-h incubation with ^{125}I-EGF (12.5 ng ml^{-1}) in the presence of 75 μM chloroquine. After isolation of the nuclei, aliquots were incubated at 22 °C with 40 units ml^{-1} micrococcal nuclease (Worthington) for the indicated times. The reaction was stopped and nuclei lysed by the addition of a 10-fold volume of 1 mM EDTA and unreleased material was removed by centrifugation (15,000*g*, 5 min). ^{125}I-EGF in the two fractions (pellet and supernatant) was counted first. Each was subsequently brought to 1.0 M perchloric acid, heated to 70 °C for 30 min, and cooled on ice. Precipitated protein was removed by centrifugation and ^{14}C detected by scintillation counting in a Triton–toluene–omniflour cocktail. The per cent of each label released was determined by dividing the amount of label present in the supernatant by the total (supernatant plus pellet) for each time point. The distribution of DNA fragments in the supernatant was examined by subjecting equal ^{14}C c.p.m. to fractionation on a 1% agarose gel (*b*). Outside lanes are marker DNA restriction fragments from plasmid pBR322 while the inside lanes are from the 0.5, 1, 1.5, 2, 3, 4 and 12 min time point supernatants (right to left). ○, Thymidine; □, EGF.

Condition*	EGF concentration (fmol per 10^6 cells) Surface†	Lysate‡	Nuclei§
Control	5.07	1.88	0.303
Chloroquine (75 μM)	5.72	36.40	5.78
Increase (-fold)	1.12	19.3	19.0

* 10^6 cells were incubated (18 h, 37 °C) with 2 ng ml^{-1} ^{125}I-EGF, with or without chloroquine, in the presence and absence of 2.5 μg ml^{-1} unlabelled EGF.

† Trypsin-releasable radioactivity. Washed cultures were treated with STV (0.05% trypsin and 0.02% EDTA Gibco) for 5 min at 22 °C, further proteolysis inhibited by adding calf serum (10%), and the radioactivity measured in an aliquot of the supernatant after centrifugation (330*g*, 5 min).

‡ Amount of immunoprecipitable ^{125}I-EGF present in the NP40 lysate minus cell-surface-associated (trypsin-releasable) ^{125}I-EGF. Immunoprecipitation was carried out by incubating (2 h, 37 °C) 1 ml of cell lysate with rabbit anti-EGF antiserum (3 μl) followed by addition (1 h at 37°C and 16 h at 4 °C) of 10 μl goat anti-rabbit IgG antiserum (35% ammonium sulphate cut). Precipitable radioactivity (intact EGF) amounted, after correction for spontaneous breakdown of ^{125}I-EGF (Fig. 2 legend), to about 95% and 50% of the total radioactivity present in the lysates of chloroquine-treated and untreated cells, respectively. When tested in the tissue culture medium the amount of non-precipitable radioactivity did not exceed (in chloroquine-treated cultures) that found in the absence of cells, whereas in untreated cells release of ^{125}I-EGF degradation products, above the 'no cells' control, accounted for up to 90% of the amount of intact EGF accumulated in chloroquine-treated cells.

§ Nuclear pellets were dissolved in 9 M urea, insoluble material removed by centrifugation, and the supernatant (20 μl) subjected to immunoprecipitation as described above after dilution to 1.0 ml with phosphate-buffered saline. The percentage of immunoprecipitable radioactivity in nuclei prepared from chloroquine-treated and untreated cells was similar (65–75%).

was inhibited. This could occur through internalization of EGF by adsorptive endocytosis, followed by fusion of accumulated endocytotic vesicles with the outer nuclear membrane. Release of EGF, either bound or unbound to its surface receptor, into the perinuclear space, inner nuclear membrane or nuclear scaffolding structures could then follow. Such a process may be reflected by findings showing that cytoplasmic vesicles containing fluorescein-conjugated EGF form a perinuclear ring in A-431 cells[21]. In the immature rat uterus, fusion of lysosomal vesicles with the nuclear membrane has been considered as a possible means of introducing oestrogens into the nucleus[22].

No regulatory action of a protein hormone has yet been shown to require hormone degradation. On the contrary, results from our laboratory demonstrate a full induction of thymidine incorporation and cell proliferation by EGF, despite the inhibition of its degradation by either leupeptin or antipain[23]. Whether or not the nuclear accumulation of either intact or modified EGF is in fact responsible for the various nuclear effects exerted by EFG on GH$_3$ cells requires further investigation.

VIP occurs in intrathyroidal nerves and stimulates thyroid hormone secretion

B. Ahrén,* J. Alumets, M. Ericsson, J. Fahrenkrug, L. Fahrenkrug, R. Håkanson, P. Hedner, I. Lorén, A. Melander, C. Rerup & F. Sundler

Vasoactive intestinal polypeptide (VIP) is known to have powerful effects on the secretion from several endocrine and exocrine glands[1–3], and occurs in nerves with a ubiquitous distribution in the body[4,5]. This infers that neuronal VIP may be a regulator of such secretion, and there is evidence that it is involved in the regulation of exocrine pancreatic function[3]. Previous studies have shown that adrenergic and cholinergic nerves participate in the regulation of thyroid hormone secretion[6–9]. We describe here combined immunohistochemical and immunochemical studies which show that the thyroid of several species is supplied with VIP-containing nerve fibres that surround blood vessels and run between and along thyroid follicles and that in the mouse neuronal VIP participates in the regulation of thyroid hormone secretion through a mechanism that is mediated by cyclic AMP.

Thyroid tissue specimens from cat, pig and man were fixed by immersion in ice-cold 4% formalin buffered to *p*H 7.0. The human material was obtained at surgery for benign autonomous nodules. Mice, rats and guinea pigs were anaesthetized with sodium pentobarbitone or diethyl ether and perfused via the ascending aorta with large volumes of the fixative solution. The thyroid glands were dissected out and stored in the fixative for 24–48 h and rinsed for 24 h in an ice-cold Tyrode solution containing 5% sucrose. The tissue specimens were frozen in dry ice and sectioned in a cryostat at −15 °C. Sections, cut at 8 μm, were processed for the immunocytochemical demonstration of VIP, using an antiserum (5603) raised against highly purified porcine VIP[10]. The dilution of the antiserum was 1 : 80. The site of antigen–antibody reaction was revealed by the indirect immunofluorescence method of Coons *et al.*[11]. Fluoresceinated goat anti-rabbit IgG was from SBL, Stockholm, Sweden. Controls were sections exposed to VIP antiserum which had been inactivated by incubation with pure porcine VIP (0.3–30 nmol per ml diluted antiserum) for at least 24 h.

The concentration of VIP in the thyroid was determined by radioimmunoassay. Thyroid glands were dissected out from anaesthetized cats, mice, pigs and rats. Normal thyroid gland tissue was also obtained from patients undergoing surgery for thyroid adenoma. The number of specimens are given in Table 1. The tissue was immediately frozen on dry ice, weighed and stored at −20 °C until extraction. VIP was extracted by homogenization at 0 °C in a glass homogenizer containing 5 vol of

n, No. of glands analysed in each species.

acidified ethanol (70% ethanol containing 0.74% HCl, w/v). After centrifugation (1,500*g*) at 4 °C for 15 min, the supernatant was decanted and the residues resuspended and homogenized with additional 5 vol of acidified ethanol. After centrifugation, the combined supernatant fractions were evaporated to dryness *in vacuo*. The samples were reconstituted and diluted in assay buffer (sodium phosphate buffer, 0.4 mol l^{-1}, *p*H 7.4, containing 58 μmol human serum albumin (Behringwerke) and sodium chloride (0.1 mol l^{-1}) and assayed in at least three different dilutions. The concentration of VIP in the extracts was measured radioimmunochemically using antiserum no 5603–6 (refs 10, 12).

For studies on the effect of VIP, female mice of the NMRI strain (Anticimex) weighing 20–25 g at the time of experiments, were used. They were fed a standard pellet diet or a low-iodine diet (Astra-Ewos), and tap water *ad libitum*. Porcine VIP, bovine thyrotropic hormone (TSH; Ferring AB) or saline was injected intravenously (i.v.) and the animals were killed after 30 min. The thyroid glands were dissected out, fixed for 18 h at 4 °C in Bouin's solution, dehydrated with ethanol, embedded in paraffin, sectioned at 6 μm and stained by the periodic acid-Schiff (PAS) technique. This technique stains colloid in the follicle lumen as well as colloid droplets in the follicle cells[7]. Radioiodine release from the thyroid was assessed according to McKenzie[13], as modified by Rerup and Melander[14]. The animals were given a low-iodine diet 10 days before experimentation to ensure adequate thyroidal uptake of radioiodine. Each animal was injected intraperitoneally (i.p.) with 16 μCi Na^{125}I (Radiochemical Centre) three days before the experiments, and was given 20 μg L-thyroxine (British Drug Houses Ltd) subcutaneously (s.c.) 72 and 24 h before the experiments. Blood (100 μl) was sampled by orbital puncture before and at specified intervals after the i.v. injection of VIP, TSH and saline, respectively. The injection volumes were 0.1 ml (s.c. and i.p.) or 0.2 ml (i.v.). The radioactivity was measured in an autogamma spectrometer.

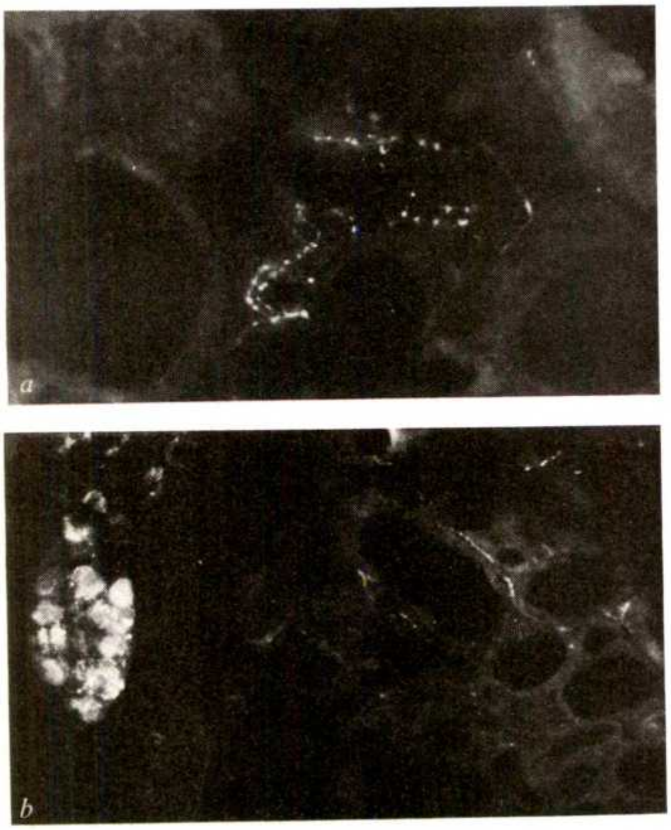

Fig. 1 Immunohistochemical demonstration of VIP nerves in rat (*a*) and mouse (*b*) thyroid. VIP nerves were distributed both around blood vessels (*a*) and between and along thyroid follicles (*b*). In the mouse, VIP immunoreactivity was seen in cell bodies in a local ganglion (left of *b*). Magnification *a*, ×125; *b*, ×190.

The influence of VIP and TSH on the production of cyclic AMP in the thyroid was investigated according to Ahrén *et al.*[15], with an ion exchange step included. Briefly, the animals were killed by neck dislocation. The thyroid lobes were dissected out and placed in tubes with 1 ml Krebs–Ringer bicarbonate buffer containing 10 mmol l^{-1} glucose. The preincubation lasted for 30 min and the incubation 25 min. During preincubation and incubation, the medium was bubbled with 95% O_2/5% CO_2 to ensure constant *p*H and oxygenation. To reduce degradation of newly formed cyclic AMP, theophylline (1.0 mmol l^{-1}) was added. Cyclic AMP content was determined in the tissue and in the incubation medium. The tissue was homogenized in ice-cold 10% trichloroacetic acid and centrifuged at 1,500*g* at 4 °C for 30 min. The supernatant was passed through a Dowex-50 column with 1.5 ml bed volume and eluted with distilled water. The eluate was freeze-dried, redissolved in 500 μl distilled water and analysed for its cyclic AMP content by the method of Gilman[16], as modified by Tovey *et al.*[17]. The cyclic AMP content was expressed as pmol per mg tissue protein, determined by the method of Lowry *et al.*[18]. The production of cyclic AMP was calculated as the sum of tissue and medium content. ^{3}H-cyclic AMP was from NEN and cyclic AMP-dependent protein kinase from Sigma. All commercial chemicals were reagent grade.

Immunoreactive nerve fibres were observed in the thyroid of all species examined. They were most frequent in mouse, less frequent in rat and cat and scarce in guinea pig, pig and man. The nerve fibres were thin and beaded, occurred both around blood vessels (Fig. 1*a*) and between and along thyroid follicles (Fig. 1*b*). In the cat and mouse the fibres were rather uniformly distributed within the gland, whereas in the rat they had a characteristically patchy occurrence with areas totally devoid of immunoreactive fibres. In man, single fibres were observed in the stromal tissue surrounding follicles.

In the mouse, a small ganglion containing VIP-immunoreactive nerve cell bodies and fibres was regularly encountered close to the thyroid capsule at the dorso-medial surface of each lobe (Fig. 1*b*). The ganglion was sometimes seen to issue a bundle of immunoreactive fibres projecting into the thyroid parenchyma. This suggests a local origin of at least some of the VIP fibres.

The concentrations of VIP in the thyroid gland of five mammalian species are given in Table 1. Concentrations measured by radioimmunoassay roughly agreed with the relative number of VIP-containing nerve fibres found by immunohistochemistry.

Injection of VIP, like TSH, was associated with formation of numerous intracellular colloid droplets in the mouse thyroid. The increase in the number of colloid droplets was significant compared to saline-injected controls (Fig. 2). VIP, like TSH, raised the blood ^{125}I levels in mice pretreated with ^{125}I and thyroxine. For both VIP and TSH, maximum radioiodine concentrations were reached at 2 h (Fig. 3). Therefore, in subsequent experiments, samples were collected at 0 and 2 h. Figure 3 shows the responses to different doses of VIP or TSH, and to their combination. The dose-response curve for VIP was less steep than that for TSH. The response to 5.0 nmol VIP was roughly equivalent to that to 65 μU TSH. VIP (5.0 nmol) and TSH (50 μU) potentiated the effect of each other. Most, if not all, thyroidal effects of TSH are thought to be mediated[19,20] by cyclic AMP. Like TSH, VIP increased the cyclic AMP production, although to a lesser degree (Fig. 4). VIP has previously been shown to stimulate cyclic AMP formation in several tissues[21–23].

The findings that VIP occurs in nerve fibres in the thyroid and has a stimulatory effect on thyroid hormone secretion suggest that neuronal VIP participates in the regulation of thyroid activity. Earlier studies have revealed that both adrenergic and cholinergic nerves are involved in the regulation of thyroid activity[6–9]. The interaction between the various nervous mechanisms in the control of thyroid function remains to be elucidated.

We thank Prof. V. Mutt for porcine VIP, and Kristine Fogelström, Åsa Gustafson, Anita Hansen, Lena Kvist, Marianne Maxe-Colschen and Lena Poulson for technical assistance. Intracellular studies showing modulation of facial motoneurone excitability by serotonin

C. P. VanderMaelen & G. K. Aghajanian

Yale University School of Medicine, Departments of Psychiatry and Pharmacology, 34 Park Street, New Haven, Connecticut 06508

The application of serotonin to certain myenteric plexus neurones in the guinea pig small intestine causes a slow depolarization of membrane potential, accompanied by increased neuronal excitability and input resistance[1]. On the other hand, microiontophoretic application of large amounts of serotonin onto mammalian spinal motoneurones is reported to cause membrane hyperpolarization and decreased excitability[2]. However, on the basis of recording spinal reflex activity, serotonin has been reported to enhance net motoneurone activity[3]. Moreover, studies using extracellular single-cell recording techniques indicate that serotonin in small amounts facilitates synaptically or glutamate-induced excitation of mammalian motoneurones in the facial nucleus[4] and spinal cord[5]. It was suggested that these facilitatory actions were modulatory in nature, as serotonin did not induce motoneurone spiking in the absence of extrinsic excitatory input. The study reported here investigated the membrane mechanisms underlying these modulatory effects by obtaining intracellular recordings from rat facial motoneurones during extracellular microiontophoretic application of serotonin, methysergide (a serotonin antagonist) and noradrenaline. Serotonin caused a slow depolarization of membrane potential of about 5 mV which remained subthreshold, accompanied by an increase in electrical excitability of the neurone, and an increase in input resistance. Noradrenaline caused the same changes. Methysergide antagonized the effects of serotonin, but not noradrenaline, indicating that these actions of serotonin are selective and receptor mediated.

Figure 1 illustrates the changes which occurred in a rat facial motoneurone with the iontophoretic administration of a relatively low dose (+25 nA ejection current) of serotonin. Within 32 s, the resting potential shifted from −68 mV to −63.5 mV (Fig. 1*b*), input resistance increased by 32% from an average value of 4.7 MΩ to one of 6.2 MΩ (Fig. 1*c*), and a constant current intracellular depolarizing pulse (1.1 nA, 182 ms duration) which had been adjusted to 73% of rheobase became effective in triggering action potentials (Fig. 1*a*, *d*), indicating an increase in excitability of the neurone.

Increased excitability and slow depolarization in response to iontophoretically applied serotonin were seen in 35 of 41 facial motoneurones analysed. The maximal depolarization seen was 8 mV with 50 nA of serotonin applied for 2 min. The typical amount of depolarization was 3–6 mV with iontophoretic currents of 10–60 nA applied for 0.5–2.0 min. Changes in input resistance were more difficult to detect, due in part to fluctuations in electrode resistance which caused imbalances in the bridge circuit adjustment. However, all changes in input resistance which were clearly seen were increases. No decreases in input resistance were detected in response to iontophoretically applied serotonin. Excitability changes in response to very low doses of serotonin were particularly evident when the amplitude of the long (130–200 ms) depolarizing pulse was adjusted to rheobase so that only one action potential was triggered from it. In such cases, iontophoretic currents of serotonin as low as 5 nA

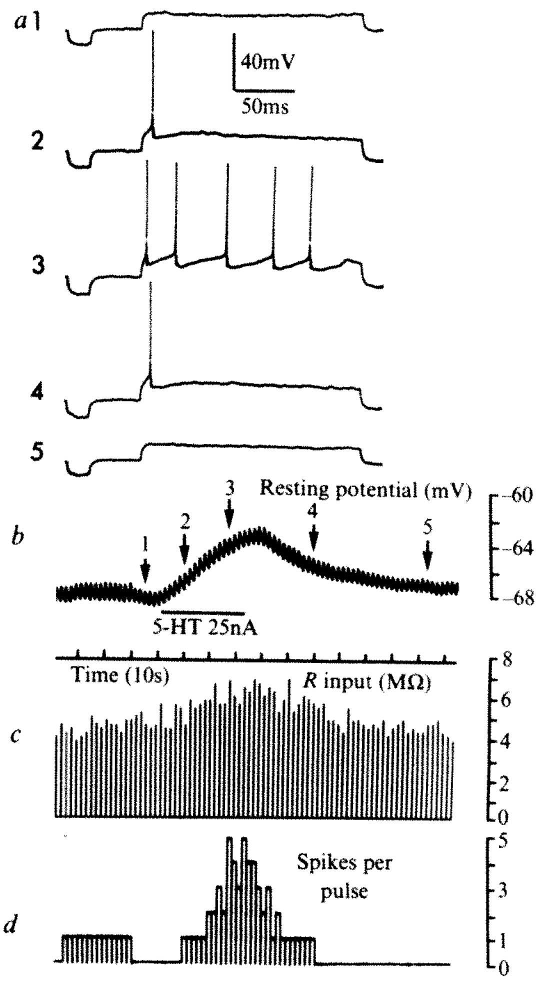

Fig. 1 Effects of iontophoretically applied serotonin (5-HT) on membrane resting potential, input resistance and excitability of a rat facial motoneurone. *a*1–5, Selected sweeps of the oscilloscope taken before, during and after serotonin iontophoresis. Each sweep consisted of a 1.0-nA hyperpolarizing pulse used for input resistance measurement, followed by a longer depolarizing pulse. The depolarizing pulse was set at 1.1 nA, which was 73% of rheobase. Sweeps occurred once every 1.9 s. *b–d*, Simultaneous records of resting membrane potential (*b*), input resistance (*c*) and number of spikes triggered by the depolarizing pulse (*d*). Time marker occurred once every 10 s and applies to *b–d*. The numbered arrows in *b* indicate the points in time at which the numbered sweeps in *a* were taken. The bar in *b* indicates the time during which serotonin (25 nA) was iontophoretically applied. The saw-toothed appearance of the trace in *b* was due to deflections of the pen that remained after filtering, caused by the depolarizing pulse. Input resistance was determined by transferring the stored data from FM tape to a storage oscilloscope where each hyperpolarizing pulse was displayed at high gain and fast time base. The voltage displacement was carefully measured, with compensation for any imbalance in the bridge circuit. Calculated values for input resistance are shown graphically in *c*. The 14 individual spikes in *d* preceding the onset of the serotonin were caused by the depolarizing pulse set at rheobase, before being adjusted to 73% of rheobase. Intracellular recording micropipettes were filled with 2 M KCl and had resistances of 15–25 MΩ. These were affixed with dental acrylic to five-barrel iontophoretic micropipettes, with tip separations between recording and iontophoretic electrodes of 25–60 μm. Iontophoretic barrels were filled with serotonin creatinine sulphate (Regis, 40 mM, *p*H 4.0), methysergide maleate (Sandoz, 5 mM, *p*H 4.0), (−)noradrenaline bitartrate (Regis, 100 mM, *p*H 4.0) and NaCl (2 or 4 M) which was used for the current balance channel such that net current flow from the iontophoretic electrodes was zero at all times. Retaining currents of −15 nA were applied to drug barrels between periods of ejection. The facial nucleus was located in anaesthetized (chloral hydrate, 400 mg per kg, intraperitoneal) male albino rats by the presence of a characteristic antidromic field potential[14] in response to electrical stimulation of the zygomatic branch of the facial nerve.

0028-0836/80/390346—02$01.00

applied for 30 s caused multiple spikes to be triggered from the depolarizing pulse (not shown).

Figure 2 illustrates the selective antagonism by methysergide of the serotonin induced increase in motoneurone excitability. A depolarizing pulse (5.4 nA intensity, 132 ms duration, Fig. 2*a*) was delivered intracellularly to a facial motoneurone once every 2.1 s. This pulse had been adjusted to 90% of rheobase. With the iontophoretic administration (40 nA for approximately 1 min) of either serotonin (Fig. 2*b*1) or noradrenaline (Fig. 2*c*1), excitability was increased, as indicated by the fact that the depolarizing pulses triggered multiple spikes. However, in the presence of iontophoretically applied methysergide (7 nA) and with the same current of serotonin, no spikes were triggered from the depolarizing pulse during 1 min (Fig. 2*b*2), indicating a greatly reduced effect of serotonin on excitability. Methysergide had only a small effect on responses to noradrenaline (Fig. 2*c*2), and this may have been due to a slight decrease in excitability caused by the methysergide itself.

The mechanism for this methysergide-induced decrease in motoneurone excitability was not explored, although we did find that iontophoretically applied methysergide, as well as intravenously administered methysergide or cyproheptadine (another serotonin antagonist), cause decreases in motoneurone excitability, determined by rheobase measurements. It is possible that the serotonin blockers antagonize a tonic facilitatory serotonin input, as facial motoneurones are known to receive a dense serotonin innervation[4,6,7]. A similar explanation has previously been proposed to explain the effects of the serotonin antagonist metergoline on spinal motoneurones recorded extracellularly[5].

Our experiments, using intracellular recording techniques, agree with previous studies using extracellular single unit recording. These showed that microiontophoretically applied serotonin facilitates the excitation of motoneurones caused by stimulation of excitatory afferents or by the microiontophoretic application of glutamate, but that serotonin alone does not elicit action potentials[4,5]. We have shown that this modulatory action of serotonin is associated with a slow, subthreshold depolarization which is accompanied by an increase in both electrical excitability and input resistance. The ionic mechanisms for these serotonin-induced membrane changes are not known, but similar changes in guinea pig small intestine neurones are postulated to be caused by a decrease in Ca^{2+}-dependent potassium conductance (g_{K^+})[8]. Similarly, serotonin causes a depolarization of certain molluscan neurones by decreasing g_{K^+} (ref. 9).

Because we measured excitability directly by means of intracellular injection of depolarizing current, we conclude that serotonin (and noradrenaline) causes a generalized increase in excitability to all types of excitatory input, rather than causing specific increases in receptor sensitivity to a particular neurotransmitter (for example, glutamate). Evidence for selective effects of noradrenaline on γ-aminobutyric acid but not glycine 'postsynaptic mechanisms' in cerebellar Purkinje cells has been reported[10]. Although our data do not rule out possible additional actions of serotonin on various pre- and postsynaptic receptors, the slow depolarization and increased excitability caused by serotonin in facial motoneurones cannot be due to increased tonic release of or increased sensitivity to a conventional excitatory neurotransmitter which would act by increasing ionic conductance to depolarize the membrane. If this were the case, input resistance would decrease rather than increase. Rather, serotonin seems to act via its own receptor to change certain membrane conductances (perhaps g_{K^+}), resulting in a generalized increase in motoneurone excitability. Such a general physiological action is consistent with results from electron microscopic autoradiographic studies which show that ^{3}H-serotonin-labelled terminals form direct axosomatic and axodendritic synaptic junctions on facial motoneurones[11]. A generalized facilitation of excitatory inputs to motoneurones would account for some of the diverse motor components of the excitatory behavioural '5-HT syndrome' seen in animals injected with pharmacological agents which increase stimulation of postsynaptic serotonin receptors[12,13].

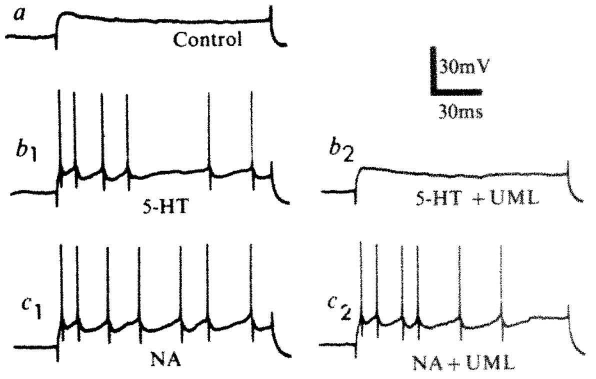

Fig. 2 Selective antagonism of the serotonin (5-HT)-induced increase in excitability by methysergide (UML). *a*, A depolarizing pulse (5.4 nA, 132 ms), which was adjusted to 90% of rheobase, did not elicit any action potentials. *b*1, In the presence of iontophoretically applied serotonin (40 nA for 56.5 s) the depolarizing pulse elicited multiple spikes, indicating increased excitability of the neurone. *c*1, Similarly in the presence of noradrenaline (NA, 40 nA for 55.3 s) multiple spikes were triggered by the depolarizing pulse. Three minutes were allowed for recovery, between the offset of serotonin and onset of noradrenaline. *b*2, After methysergide had been on continuously for 3.5 min (7 nA), iontophoretically applied serotonin (40 nA for 59.5 s) did not cause spikes to be triggered by the depolarizing pulse. *c*2, Iontophoretically applied noradrenaline (40 nA for 56.0 s) still caused multiple spikes to be triggered by the depolarizing pulse, even though the methysergide had been on continuously for 8.5 min. Four minutes were allowed for recovery from the effects of the serotonin before turning on the noradrenaline. To control for changes in methysergide-induced excitability, we ran a second series of tests (data not shown) on the same neurone, in which the depolarizing pulse was adjusted to compensate for changes in rheobase. After 10 min of iontophoretically applied methysergide (7.3 nA), rheobase had increased 13%, indicating decreased excitability. The amplitude of the depolarizing pulse was then adjusted to 90% of the new rheobase, and the effects of serotonin and noradrenaline determined as before. The results were essentially the same as those shown above, except that this time there was not even a small reduction in the effectiveness of the noradrenaline. In fact, the number of spikes triggered was actually slightly more than with noradrenaline alone, probably because of the larger amplitude of the depolarizing pulse. However, the serotonin-induced increase in excitability was strongly antagonized by methysergide, and no spikes were triggered by the depolarizing pulse in the presence of serotonin plus methysergide. Similar findings were obtained in two other neurones in which the depolarizing pulse amplitude was readjusted to compensate for methysergide-induced changes in rheobase.

Absence of potassium conductance in central myelinated axons

Jeffery D. Kocsis* & Stephen G. Waxman

Department of Neurology, Veterans Administration Medical Center
and Stanford University School of Medicine, Palo Alto,
California 94304

Two voltage-dependent changes in ionic permeability are responsible for the action potential in squid giant axon[1]. The depolarization phase of the action potential is due to an initial increase in sodium ion permeability, and repolarization is primarily the result of a later increase in potassium permeability. However, voltage-clamp experiments on mammalian peripheral nodes of Ranvier indicate that potassium conductances (g_k) may be minimal or lacking for intact mammalian peripheral myelinated axons[2–4]. Repolarization for these fibres has been explained in terms of a rapid sodium inactivation and large leakage current[3]. When the myelin around these fibres is acutely disrupted, an immediate and prominent g_k appears[4]. Following demyelination, g_k blocking agents have been shown to reduce late outward currents that are not present in normal myelinated fibres[5]. This suggests that K^+ channels are present in the axonal membrane under the myelin but are 'masked' in normal peripheral myelinated axons. Previous studies have not investigated the presence or role of K^+ channels in central myelinated axons. We here establish that g_k is not detectable in mammalian dorsal column axons.

The effects of superfusion of myelinated axons in the rat dorsal columns (DCs) with the voltage-dependent g_k blocking agents tetraethylammonium hydrochloride (TEA) and 4-aminopyridine (4-AP) were studied. We also recorded intra-axonally from the axons with glass microelectrodes filled with TEA. This allowed us to reach internodal as well as nodal axon membrane in the intact myelinated central axon. Although TEA injection into spinal motoneurones elicited a rapid and powerful prolongation of the motoneurone (soma-dendritic) action potential, the axonal action potential recorded from DC axons remained virtually unchanged even after prolonged TEA injection. In addition, superfusion of the spinal cord with 4-AP or TEA neither changed the action potential waveform nor altered the fibre refractory period.

Extra- and intra-axonal potentials were recorded from the DCs of the rat spinal cord following local DC or sciatic nerve stimulation. The animals were deeply anaesthetized with urethane (1.5 g kg^{-1}) and prepared for acute experimentation. An agar pool was built around the exposed lumbar spinal cord to allow for superfusion of the DC surface with oxygenated and warmed (38 °C) normal Ringer solution (NS) into which 4-AP or TEA could be added[6]. Recordings were confined to within 50 μm of the surface of the spinal cord for the superfusion experiments.

Glass microelectrodes were filled with 3.0 M NaCl for field potential recordings and 2.0 M TEA for intracellular or intra-axonal recordings. Figure 1*a* shows the DC fibre field potential elicited from local surface stimulation of the DC superfused with normal Ringer. The early positive-negative component of the field corresponds to the collective action potential activity of fast conducting myelinated DC axons. The field remains virtually unchanged after introduction of 4-AP (Fig. 1*b*) or TEA (Fig. 1*c*) into the superfusion pool. When the potassium concentration of the NS was increased from 3.0–30 mM, a reversible conduction block occurred promptly, thus indicating the efficacy of the superfusion (Fig. 1*d*). In addition to not affecting the field potential waveform, elicited from a single stimulus, external 4-AP or TEA application also did not alter the refractory period of the fibres as determined from paired stimulation experiments (data not shown). In contrast to the absence of response of the myelinated DC fibres to superfusion with TEA and 4-AP, the compound action potential of nonmyelinated cerebellar parallel fibres is markedly altered by both of these agents[7]. Although 4-AP[8–10], and in some instances TEA[11], have been shown to block voltage-dependent g_k by external application, the accessibility of either 4-AP or TEA to K^+ channel sites following external application is open to question. This is particularly important in view of the recent studies of Chiu and Ritchie[4] showing that K^+ channel distribution may be inhomogeneous, with K^+ channels present at internodal or paranodal membrane regions but not at nodal membrane.

Prolongation of the somatic action potential has been reported[12–14] following intracellular recordings from neuronal cell bodies with TEA electrodes. This effect appears rapidly after diffusion of TEA from the microelectrode or is facilitated by depolarizing currents. Figure 2*a* shows an action potential recorded from a motoneurone immediately after impalement with a TEA microelectrode. The responses shown in Fig. 2*b* and *c* were recorded 4.0 and 12.0 min later, respectively. The action potentials are much prolonged (compare Fig. 2*b* and *c* to *a*), indicating a block of g_k (ref. 12). The same microelectrode was used for recording the intra-axonal responses from DC axons shown in Fig. 2*d–f*. All electrode probes for DC axons were confined to the dorsal 200 μm of the spinal cord, within 300 μm of the spinal cord midline. Intra-axonal impalements were identified by: (1) the presence of negative resting potential; (2) the all-or-none character of the action potential with no underlying synaptic potential; and (3) when possible, collision of directly induced action potentials with those induced from

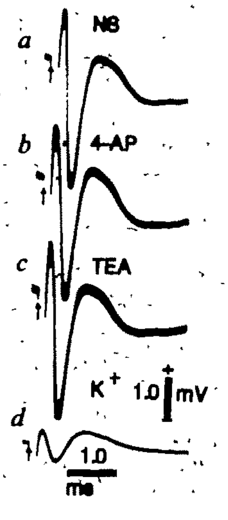

Fig. 1 Field potentials elicited from surface stimulation of the lumbar DC and recorded 3 mm anterior to the stimulation site within 20 μm of the surface. *a*, Responses recorded when the spinal cord was continuously superfused with normal Ringer solution NS. The early positive-negative components of the field correspond to action potential activity of the fast conducting myelinated fibres of the DC. The responses in *b* and *c* were obtained after 30 min of superfusion in 4-AP (3.0 mM) and TEA (10 mM) solutions, respectively. Virtually no change occurs in the waveform of the early positive-negative field component, thus indicating the ineffectiveness of these voltage-dependent g_k blocking agents on these fibres. *d*, A response recorded within 2 min after the K^+ concentration was increased from 3 to 30 mM. A significant reduction in the field occurs at high K^+ concentrations. This effect is reversible within minutes after superfusion with NS. The K^+ blocking action indicates the efficacy of the superfusion system, and shows that the superfusate gains access to the nodal extracellular space. The calibration in *e* pertains to all records.

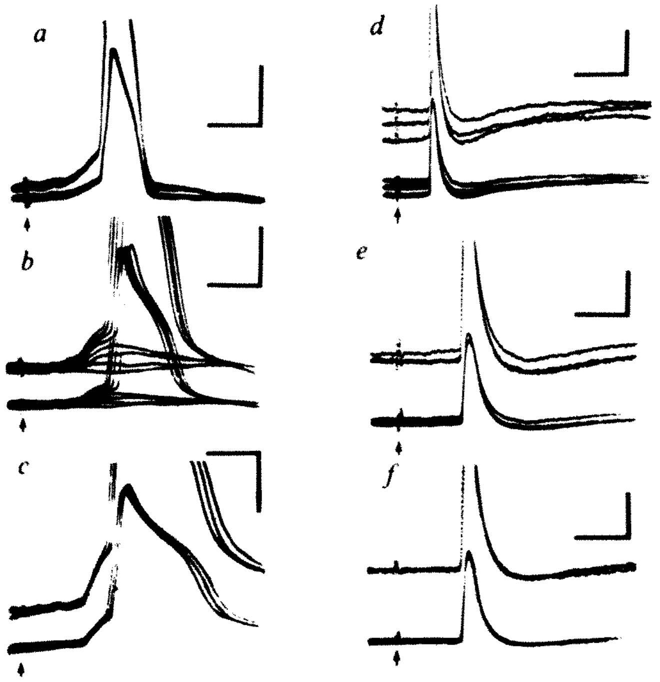

Fig. 2 *a–c*, Intracellular recordings obtained from spinal motoneurones with TEA microelectrodes following stimulation of the ipsilateral sciatic nerve. Orthodromic action potentials can be seen arising from an excitatory postsynaptic potential (EPSP). The upper traces correspond to high gain recordings and the lower traces to low gain recordings. *a*, Records obtained immediately after impalement of the motoneurone. *b*, Records obtained at about 4 min after impalement. Stimulation intensity was varied to demonstrate the graded nature of the EPSP and all-or-none properties of the action potential. Note the broadening of the action potential as the TEA diffuses into the cell. *c*, Records from same cell at about 12 min post-impalement. A marked prolongation of the action potential is evident. *d–f*, Intra-axonal action potentials recorded with same TEA microelectrode as used for *a–c*, from a DC axon near the midline surface of the lumbar cord. *d* and *e* show the axonal action potential at different oscilloscope sweeps, near the time of axonal impalement. *f*, Responses recorded about 25 min after impalement. Depolarizing currents were passed at the time between the records of *e* and *f*. No appreciable prolongation of the axon action potential can be seen after TEA injection. Vertical calibrations indicate 20 mV for lower traces and 10 mV for upper traces for *a–f*. Horizontal calibrations indicate 4 ms in *a–d* and 2 ms in *e* and *f*. Positive voltage deflection is upward.

sciatic nerve stimulation. Conduction velocities for these fibres were greater than 15 m s^{-1}, indicating their myelinated nature. After 25 min of impalement with a TEA microelectrode, virtually no change in the axonal action potential duration can be seen (Fig. 2*f*). We also passed depolarization pulses through the microelectrode to facilitate TEA entry, but still no change in action potential waveform occurred. For five axons, intra-axonal penetrations were held for over 45 min each. No significant change in spike waveform or refractory period was seen in these axons or in 26 other axons held for periods greater than 5 min but less than 45 min. During the passage of depolarization currents, the action potential amplitude was decreased, and hyperpolarization increased the action potential amplitude, thus indicating that the site of impalement was electrotonically close to the site of impulse origin.

The observation here, that external application of either TEA or 4-AP does not prolong the action potential of DC myelinated axons, extends observations made in peripheral nerves to DC axons in the mammalian central nervous system. Also, the lack of action potential prolongation or changes in refractory period after direct intra-axonal injections of TEA into these central myelinated axons suggests that K$^+$ channels contribute little to action potential waveform and recovery for these axons. One might question whether TEA effectively passed from our microelectrode into the axons, and once inside if it diffused sufficiently to present itself to nearby internodal as well as nodal axon surfaces. However, other observations[12–14] and this study show that TEA readily diffuses from electrode to cytoplasm of neurone somata. Although geometrical differences are present between soma-dendritic and axonal regions that could vary diffusion properties, the rapidity of the TEA action on large volume motoneurones, the facilitation of TEA ejection by depolarization pulses, and the relatively long duration impalements of the axons (several over 45 min), suggest that TEA may have passed over a significant axonal length.

Voltage-clamp experiments in mammalian peripheral nerve[4] reveal an immediate appearance of g_k after acute myelin disruption, suggesting that K$^+$ channels are present under the myelin in normal myelinated axons. The absence of demonstrable g_k at intact mammalian peripheral nodes of Ranvier[3] and the lack of effect on the action potential of direct intra-axonal injections of TEA into DC fibres suggest that g_k does not contribute significantly to spike electrogenesis in at least several types of intact mammalian myelinated fibres. Chiu and Ritchie (personal communication) have suggested that potassium channels in the internodal axon membrane may have a normal role in preventing repetitive firing at the node. Although we did not observe repetitive firing after TEA or 4-AP application, our experiments cannot rule this out.

Spontaneous quantal events induced in toad rods by pigment bleaching

T. D. Lamb

Physiological Laboratory, Downing Street, Cambridge CB2 3EG, UK

Barlow proposed that absolute visual threshold is limited by photon-like noise events in the rod photoreceptors[1], and he later extended the idea to explain the elevation of threshold following bright bleaching lights in terms of increased noise in the photoreceptors[2]. Rushton, on the other hand, has proposed that the threshold elevation during dark adaptation involves changes not within the photoreceptors themselves but rather in the gain of a subsequent 'pool'[3]. I report here measurements of outer segment current in individual rod photoreceptors which demonstrate that spontaneous fluctuations occur at a greatly increased rate following bleaches of around 1%, and that these fluctuations have the form expected for random occurrences of the single photon events. This is consistent with Barlow's ideas but does not indicate whether a gain change subsequent to the receptors also occurs.

The experiments were performed on toad rods using a suction pipette[4–8]. Briefly, a fully dark-adapted animal was pithed and one eye was enucleated under dim red light; then, using IR illumination, the retina was removed and cut into small pieces. With the aid of an IR-sensitive television camera system attached to an inverted microscope the pieces were manipulated under high magnification, and single rod outer segments were drawn into a fine glass pipette by gentle suction, so that membrane current could be measured and the outer segment stimulated with visible light. When recording spontaneous dark events the IR-light was turned off, and stringent precautions were taken to exclude stray light. As in the experiments of Lamb *et al.*[8], two different Ringer solutions were used, one buffered with HEPES[4,5,9–11] and the other with bicarbonate/CO_2 (ref. 12), both at *p*H 7.8. The observed noise increase on bleaching was similar in the two cases, but in HEPES–Ringer the cells gave slower and more sensitive responses which facilitated detection of quantal responses, while the bicarbonate/CO_2–Ringer was probably more physiological but gave faster, less sensitive responses[8].

Figure 1 shows the effect in a cell recorded in HEPES–Ringer, with two traces before the bleach and one trace during recovery. In this Ringer the single photon event is quite large and, as reported by Baylor *et al.*[7], spontaneous occurrences of the quantal events are apparent in the dark-adapted state. Within the 400 s of the first two records, ten such events (marked by arrows) can be seen, in good agreement with the reported mean of 1 per 50 s (ref. 7). The events have an amplitude of almost 1 pA and a time course similar to that of the average flash response to dim light. In the bottom trace, 3 min after a bleach of about 0.4%, the cell showed very marked current fluctuations, even though the flash sensitivity measured at this time had declined slightly from its pre-bleach level. The power spectrum of these fluctuations is shown in Fig. 2, and is compared with the power spectrum predicted for randomly occurring photon-like events. The inset shows the average flash response measured after the bleach, and has been fitted by the independent activation equation[5,6,13] with $n = 4$ stages, and $t_{\text{peak}} = 1.75$ s. The power spectrum associated with this kinetic form consists of the product of $n = 4$ lorentzians:

$$S(f) = S(0) \Big/ \prod_{k=1}^{n} \left[1 + \left(\frac{2\pi f \tau}{k}\right)^2\right], \qquad (1)$$

with $\tau = t_{\text{peak}}/(n-1)$ and is shown by the continuous curve. The vertical position has been chosen to give the best fit by eye, and the broken line is the expected thermal noise. Figure 2 shows that the post-bleach fluctuations have the form expected for randomly occurring single photon events.

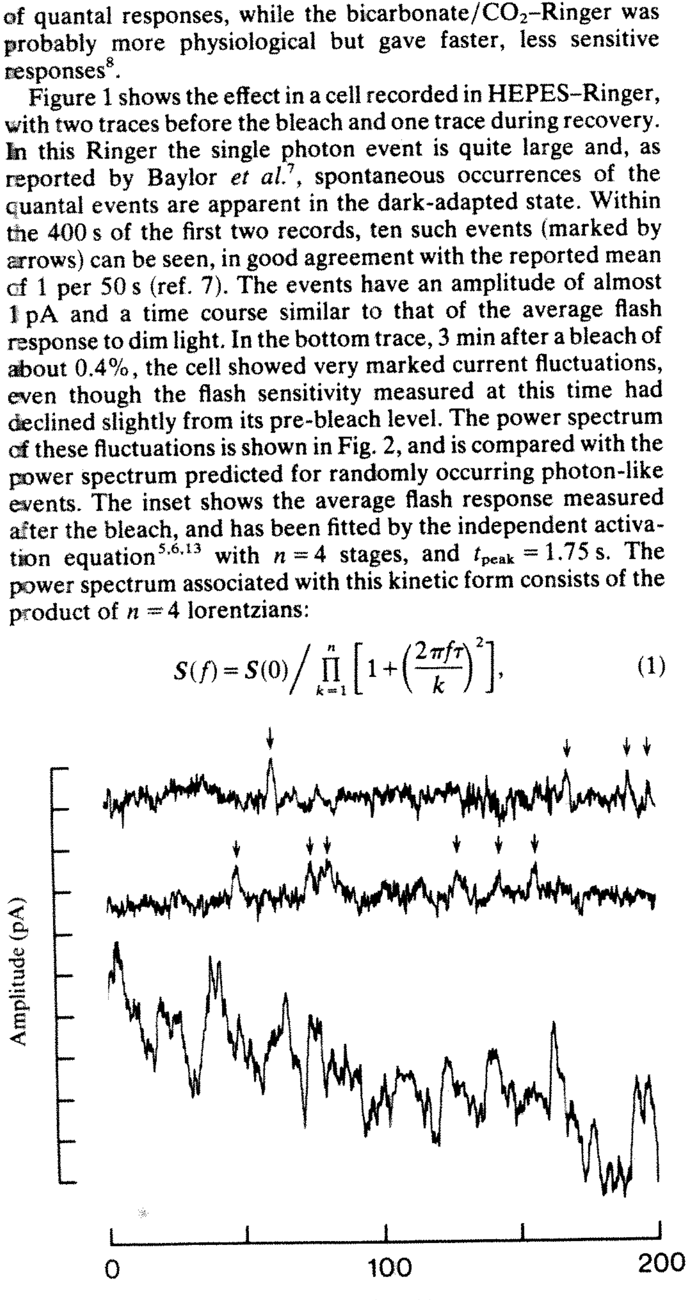

Fig. 1 Increased fluctuations following a bleach. Traces are 200 s records before (upper two traces) and 3 min after a bleach (lowest trace); arrows mark presumed quantal events. Bleach of about 0.4% (3.6×10^5 photons μm^{-2}, calculated to isomerize 9×10^6 rhodopsins); saturating response 18 pA; 23.0 °C; HEPES-Ringer. Each ordinate division represents 1 pA.

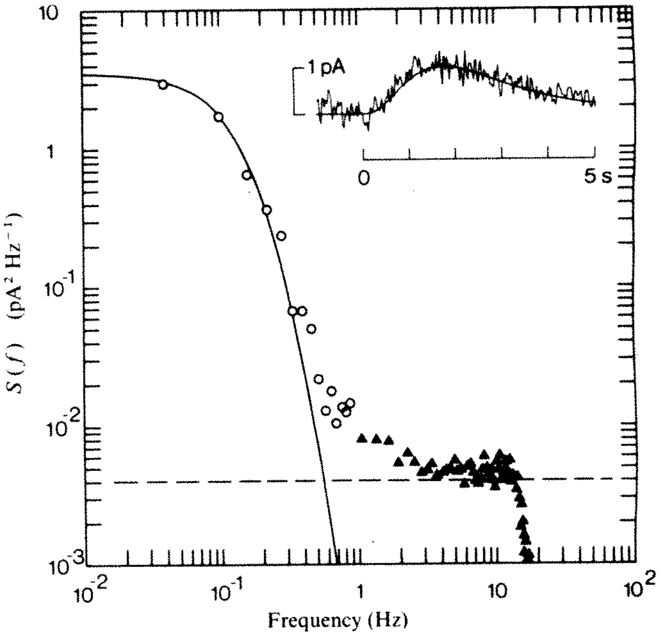

Fig. 2 Power spectrum of post-bleach fluctuations from cell of Fig. 1. Open symbols, averages of 3 raw frequency points; filled symbols, averages of 15. From five records, each 2,048 points at 25-ms intervals (51.2 s); filtered by 15 Hz 6-pole low pass filter and 10 s RC high pass filter. Continuous curve is equation (1) with $S(0) = 3.5$ pA^2 Hz^{-1}; broken line is thermal noise of 4×10^{-3} pA^2 Hz^{-1} for leakage resistance 4 MΩ. Inset shows average flash response determined from six flashes immediately before and six flashes immediately after the lowest record in Fig. 1.

However, the lack of stationarity of the spectral data causes a slight computational difficulty here, as the cell was inevitably recovering during the post-bleach period, and the sensitivity and time course of the flash response changed. Before the lowest record in Fig. 1 the time to peak was 1.5 s, and after the record it was 2.2 s. The averaged response from flashes before and after the fluctuating record is shown in the inset of Fig. 2, and had a time to peak of 1.75 s; it is this averaged response which has been used in computing the expected form of the spectrum. It seems unlikely that this gradual and unavoidable change would significantly affect the form of the predicted spectrum, and the measured fluctuations certainly appear to be explained in terms of spontaneous quantal events.

The rate of equivalent isomerizations may be calculated from the required vertical scaling of the theoretical spectrum. For a random series of identical 'shot' events, the zero frequency asymptote is found from the Fourier transform with $f = 0$, and is simply twice the event rate multiplied by the square of the time integral of the shot event (see, for example, ref. 6). For the case of independent activation kinetics this may be shown to reduce to:

$$S(0) = 5.85 \nu\, t_{\text{peak}}^2 r_{\text{peak}}^2 \qquad (2)$$

where $S(0)$ is the zero frequency asymptote, ν s^{-1} is the rate, and t_{peak} and r_{peak} are the time to peak and peak amplitude of the single photon response respectively. For the cell in Figs 1 and 2, the amplitude of the quantal event in the dark-adapted state averaged about 0.8 pA, but after bleaching the sensitivity was reduced by about 0.12 log units, giving a quantal event amplitude of $r_{\text{peak}} = 0.61$ pA. With $t_{\text{peak}} = 1.75$ s and $S(0) = 3.5$ pA^2 Hz^{-1}, the rate of events is predicted to be $\nu = 3.1$

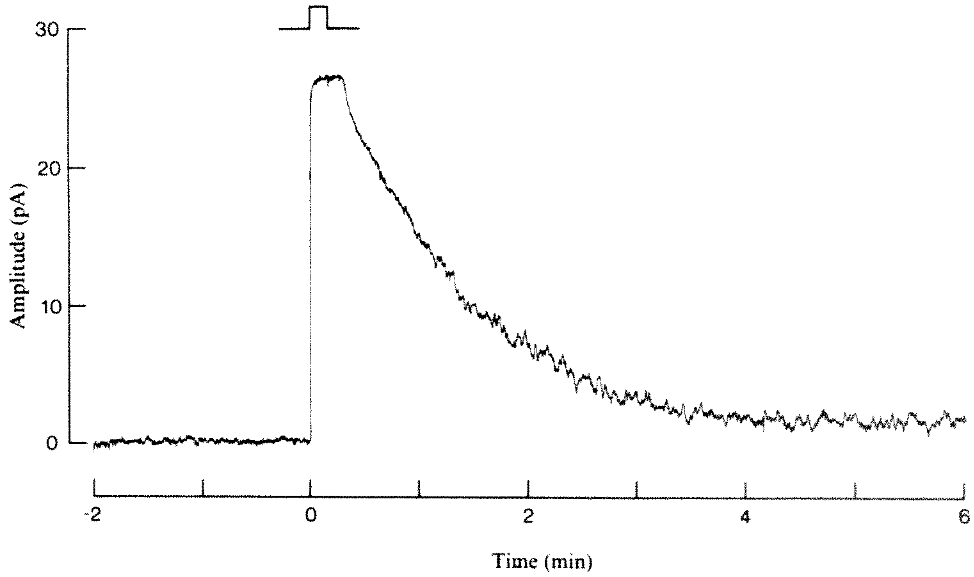

Fig. 3 Response of another cell to a bleach of about 0.7% (7.2×10^5 photons μm^{-2}, calculated to isomerize 1.8×10^7 rhodopsins). Quantal events before the bleach are not visible as the cell was relatively insensitive. Bicarbonate/CO$_2$–Ringer; 23.6 °C; low pass filtered at 5 Hz.

equivalent isomerizations per s. This is about 2.2 log units greater than the spontaneous rate in the fully dark adapted state (0.02 isomerizations per s, ref. 7).

A similar effect from a cell recorded in bicarbonate/CO$_2$–Ringer is shown in Fig. 3. Before the bleach the baseline was relatively quiet, but during recovery the trace became quite noisy, despite a slight reduction in its flash sensitivity. The power spectrum of these fluctuations was again well fitted by the form predicted from the average post-bleach flash response (not shown). This cell was less sensitive than the previous one and the post-bleach quantal event amplitude was estimated to be $r_{\text{peak}} =$ 0.12 pA per isomerization. The zero frequency asymptote $S(0)$ of the spectrum was 0.7 pA^2 Hz^{-1} and substitution in equation (2) gave an estimated mean rate of $\nu = 11$ isomerizations per s for this bleach of 0.7%, about 2.7 log units higher than in absolute dark adaptation.

The conclusion from these results is that, as proposed by Barlow[2], spontaneous photon-like events occur in the rod outer segments at a much higher rate after a bleach than in absolute dark adaptation. This phenomenon seems to explain qualitatively the existence of the psychophysical equivalent background[14] or dark light[1,2] which limits visual detection, and the extent to which it may quantitatively account for dark adaptation behaviour is under investigation (D. A. Baylor and T.D.L.). It is interesting that the situation appears similar in invertebrates, where exposure of a dark-adapted locust retinula cell to intense light causes an increased rate of occurrence of quantal events[15].

I thank Professors H. B. Barlow, D. A. Baylor and A. L. Hodgkin for suggesting the experiment and for helpful discussions. This work was supported by a fellowship from the Wellcome Trust.

Light isomerizes the chromophore of bacteriorhodopsin

Motoyuki Tsuda*, Moira Glaccum†, Burr Nelson & Thomas G. Ebrey

Department of Physiology and Biophysics, 524 Burrill Hall,
University of Illinois, Urbana, Illinois 61801

The primary photochemical event in the two light-transducing pigments whose chromophore is retinal, rhodopsin or bacteriorhodopsin, is a source of controversy. It was originally proposed that the primary photoevent in the bleaching of rhodopsin is the photoisomerization of the chromophore from 11-*cis* to all-*trans* retinal[1,2]. Photochemical considerations suggested that a photoisomerization is the primary event in both rhodopsin and bacteriorhodopsin[3–7]. However, this description of bacteriorhodopsin's photochemistry has been questioned[8–10]. To elucidate this problem, we determined the isomeric conformation of retinal for two of the photolytic intermediates of bacteriorhodopsin, using a method that enables us to extract chromophores from the photocycle intermediates L and M at low temperatures (−74 °C), and have determined the isomeric conformation of the extracted retinals by HPLC[11,12]. Here we provide direct evidence that isomerization of the chromophore has taken place in two of the early photocycle intermediates (L and M) of bacteriorhodopsin.

The absorption of a photon by light-adapted bacteriorhodopsin (bR$^{\text{LA}}$), the purple membrane protein of the *Halobacterium halobium*, initiates a series of transformations[13], reminiscent of the bleaching sequence of rhodopsin. The primary photochemical product, K, is a bathochromically shifted species; it decays to the photocycle intermediate L and then to M, which eventually returns to bR$^{\text{LA}}$ through the intermediates N and O. bR$^{\text{LA}}$ slowly converts to the dark-adapted bacteriorhodopsin (bR$^{\text{DA}}$). It has been determined that the isomeric form of chromophore of bR$^{\text{LA}}$ is almost completely all-*trans* retinal, whereas bR$^{\text{DA}}$ has a mixture of 13-*cis* and all-*trans* retinals with a ratio of 1:1. The isomeric compositions were

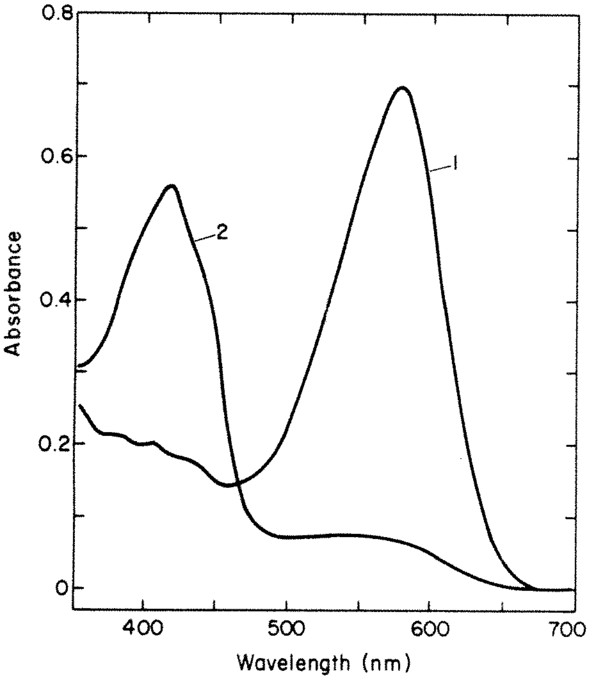

Fig. 1 Photochemical conversion of bR^{LA} to M at −74 °C. Curve 1, bR^{LA} in a 25% NaCl solution adjusted to *p*H 9.5 (0.1 M carbonate buffer) and mixed with glycerol (1 : 2) at −74 °C. Curve 2, the photosteady-state mixture produced by irradiating with $\lambda > 580$ nm light (Corning filter 2–73) for 15 min at −74 °C. The sample was irradiated with the light from a 200-W tungsten lamp using a glass filter. The light was routed to the sample cell through an optical glass fibre (5-mm diameter).

originally determined by chromophore extraction methods[11,14,15]. The validity of determining the isomeric composition by the extraction technique was later verified by several non-destructive spectroscopic techniques[16–19].

To extract chromophores from the L and M intermediates at low temperatures, the extraction solvent should not freeze at low temperatures (−74 °C), it should denature the pigments at the low temperature, and the retinal should not be isomerized by the solvent itself. We found an extraction solvent composed of buffer/glycerol/dichloromethane/hexane (1.6 : 3.3 : 1 : 4) which satisfied the above conditions. The solvent was first emulsified by sonication (30 s). Then a syringe cylinder with the tip blocked by a Teflon plug, containing the bR sample in 67% glycerol was inserted into a test tube containing the solvent. This in turn was immersed in a dry ice–ethanol bath (−74 °C) and the bR irradiated in the syringe with an optical light guide. The plunger was then inserted into the syringe cylinder and the irradiated bR injected into the extraction solvent. Next, the bR sample was mixed thoroughly with the extraction solvent, using a precooled (−74 °C) spatula. The temperature of the sample was monitored with a thermocouple. This procedure denatured the irradiated bR sample at −74 °C as shown by the total fading of the colour to pale yellow. The mixture was then warmed to 0 °C and chromophores extracted by sonication. Extraction by the sonication method gave a substantially greater yield (60 ± 20%) than the syringe method (<10%) and exhibited no preferential extraction of either isomer.

To insure that the isomeric composition of the extracted retinals represented that of the intact pigment and that no isomerization had taken place during our extraction procedure, we extracted the chromophores of bR^{LA} and bR^{DA}. Table 1 shows that isomerization of bR^{LA} and bR^{DA} extracted in our conditions are basically the same as the compositions previously reported. The *p*H, glycerol and temperature we used affected the isomeric composition of the chromophore slightly.

bR^{LA} suspended in a 25% NaCl solution adjusted to *p*H9.5 was mixed with glycerol (1 : 2) to prevent crystallization at low temperatures. The extraction of retinals from bR^{LA} at 0 °C yielded 94 ± 3% all-*trans* retinal and 6 ± 3% 13-*cis* retinal. When bR^{LA} was cooled to −74 °C (Fig. 1, curve 1) and irradiated with light of wavelengths greater than 580 nm ($\lambda > 580$ nm light), the M intermediate was formed (Fig. 1, curve 2). In the dark, the absorption spectrum was stable. Extraction of the chromophores from this preparation yielded 14 ± 3% all-*trans* retinal and 86 ± 3% 13-*cis* retinal. The amount of M, based on the decrease in absorption at 570 nm, was estimated to be 91% (Fig. 1, curve 2). Therefore, our results suggested that the isomeric form of retinal in M was at least 95% 13-*cis* retinal. After making the M intermediate at −74 °C, the sample was warmed to 0 °C, and after waiting for 10 min to ensure that M had returned to bR^{LA}, the chromophores were extracted. This preparation yielded 93 ± 4% all-*trans* retinal and 7 ± 4% 13-*cis* retinal, which corresponds to the composition in bR^{LA} before making M. These results suggested that light isomerized the chromophore in the conversion of bR^{LA} to M and the chromophore was thermally re-isomerized in returning from M to bR^{LA} in the dark.

The intermediate L, which is the precursor of M, is produced as a member of a photosteady-state mixture containing L, M and bR^{LA} when bR^{LA} (in a 25% NaCl solution adjusted to *p*H 7.2) is irradiated with $\lambda > 630$ nm light as shown in Fig. 2, curve 2. Table 1 shows that before making L, bR^{LA} in glycerol contains 92 ± 2% all-*trans* retinal and 8 ± 2% 13-*cis* retinal; after making L and warming the sample to 0 °C for 10 min it contains 92 ± 2% all-*trans* retinal and 8 ± 2% 13-*cis* retinal. Denaturation of the photosteady state formed at −74 °C and extraction of its chromophores yields 53 ± 4% all-*trans* retinal and 47 ± 4% 13-*cis* retinal. The content of L, M, and bR^{LA} in this preparation is difficult to determine precisely because two different extinction coefficients for L have been proposed[20,21]. The amounts of L, M and bR^{LA} in the mixture shown in spectrum 2 of Fig. 1 are calculated to the 57%, 13% and 30%, respectively, assuming $\varepsilon_L = 61{,}000$ (ref. 20) (without consideration of bypass of $L \rightarrow bR^{LA}$) and as 29%, 13% and 58%, respectively, assuming

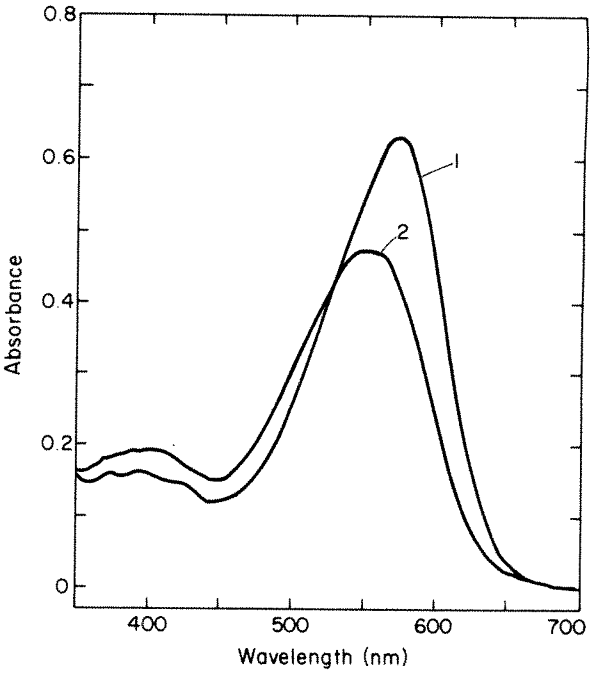

Fig. 2 Photochemical conversion of bR^{LA} to L at −74 °C. Curve 1, bR^{LA} in a 25% NaCl solution adjusted to *p*H 7.2 (0.1 M imidazole-HCl) and mixed with glycerol (1 : 2) at −74 °C. Curve 2, the photosteady-state mixture produced by irradiating with $\lambda >$ 630 nm light (Corning filter 2–59) for 15 min at −74 °C. Irradiation of sample was carried out as shown in Fig. 1.

Table 1 Retinal isomers extracted from bR^{LA}, bR^{DA}, M and L

Species	Conditions	% Composition 13-*cis*	% Composition All-*trans*	Yield (%)
a *p*H 9.5, 25% NaCl				
bR^{D}		55 ± 2	45 ± 2	43 ± 13
bR^{DA} (glycerol)		54 ± 2	46 ± 2	45 ± 9
bR^{DA} (glycerol)	denatured at −74 °C and extracted at 0 °C	54 ± 3	45 ± 3	56 ± 4
bR^{LA}		6 ± 3	94 ± 3	57 ± 8
bR^{LA} (glycerol)		7 ± 4	93 ± 4	45 ± 12
bR^{LA} (glycerol)	denatured at −74 °C and extracted at 0 °C	11 ± 3	89 ± 3	55 ± 9
M (glycerol)	bR^{LA} irradiated with $\lambda >$ 580 nm light for 15 min, denatured at −74 °C and extracted at 0 °C	86 ± 3	14 ± 3	55 ± 15
bR^{LA} (glycerol)	M was warmed up to 0 °C and kept 10 min at 0 °C	7 ± 4	93 ± 4	46 ± 8
b *p*H 7.2, 25% NaCl				
bR^{DA}		52 ± 2	48 ± 2	59 ± 8
bR^{DA} (glycerol)		54 ± 2	46 ± 2	65 ± 20
bR^{DA} (glycerol)	denatured at −74 °C and extracted at 0 °C	56 ± 2	44 ± 2	70 ± 15
bR^{LA}		3 ± 2	97 ± 2	56 ± 10
bR^{LA} (glycerol)		8 ± 2	92 ± 2	53 ± 10
bR^{LA} (glycerol)	denatured at −74 °C and extracted at 0 °C	11 ± 2	89 ± 2	60 ± 8
L	bR^{LA} irradiated with $\lambda >$ 630 nm light for 15 min, denatured at −74 °C and extracted at 0 °C	47 ± 4	53 ± 4	52 ± 10
bR^{LA} (glycerol)	L was warmed up to 0 °C and kept for 10 min at 0 °C	8 ± 2	92 ± 2	60 ± 12

Each experiment was repeated at least five times. Dark adaptation (bR^{DA}) was assured by allowing the bR sample to stand overnight at room temperature for each set of conditions (*p*H, glycerol). Light adaptation (bR^{L}) was accomplished by irradiating the sample with a slide projector for 20 min at 0 °C, followed by immediate extraction. Denaturation and extraction were performed at 0 °C unless otherwise described. An attempt to quantify the efficiency of retinal extraction was made by measuring the A_{365} in hexane solution after extraction. The retinal concentrations in the solution were determined by the retinal composition and using the following extinction coefficients: (4.58×10^4 for all-*trans*, 3.84×10^4 for 13-*cis* at 365 nm)[24]. Separation and analysis of retinals in the extract were carried out by HPLC with micro-Porasil column (Waters Associates). The sample was eluted at a constant flow rate (2 ml min^{-1}) with 4% ether–hexane (v/v). Two well resolved peaks were detected spectrophotometrically (λ = 365 nm). They were identified as the 13-*cis* and all-*trans* isomers of retinal by a comparison of their retention times with those of authentic samples.

$\varepsilon_L = 49{,}000$ (ref. 21) (with consideration of bypass of $L \rightarrow bR^{LA}$). Taking bR^{LA} as all-*trans* and M as 13-*cis* (see above) there is a reasonable correlation between the per cent L and M present spectroscopically from (42–70%) and the per cent of the 13-*cis*isomer present (47 ± 4%) if we assume that chromophore of L is 100% 13-*cis* retinal.

Thus, the present results suggest that light has initiated an event which results in the chromophore of bR^{LA} being isomerized from the all-*trans* to 13-*cis* conformation by the time of the appearance of the L intermediate, and that the 13-*cis* chromophore is thermally re-isomerized to the all-*trans* form in going from M to bR^{LA} in the dark. By far the simplest explanation of our results is the general hypothesis, based on photochemical studies by Rosenfeld *et al.*[3] and Hurley *et al.*[4], that the primary event in bacteriorhodopsin is a photoisomerization requiring that the isomeric conformation of retinal in bR^{LA} be different from its conformation in L and M. Some indications of an isomerization step have also been noticed on the basis of resonance Raman measurements[22,23] although there is still controversy about the interpretation of these spectra.

Our results may be compared with the work of Pettei *et al.*[11], who first suggested the isomerization event was from the all-*trans* to the 13-*cis* isomer. These authors extracted chromophores from 'M-like intermediates' in ether/high salt preparations and guanidinum HCl/high *p*H preparations at 0 °C and concluded that M yields the 13-*cis* isomer, although the correlation between M and the 13-*cis* isomer of the former preparation was rather poor. We find a quite good correlation between the amount of 13-*cis* retinal present and the amount of the M intermediate present. It is possible that the nature of M in ether/high salt and guanidinum HCl/high *p*H at 0 °C is different from M at normal conditions. More likely, as Pettei *et al.* did not actually measure the absorption spectra of their solutions, they had not achieved full photoconversion of bR to M.

Leukaemia virus infection promotes fibroblast transformation by normal BALB/c mouse DNA

V. Krump-Konvalinkova & K. J. van den Berg

Radiobiological Institute TNO, 151 Lange Kleiweg,
2288 GJ Rijswijk, The Netherlands

All normal cells are thought to carry genetic information for oncogenic transformation, which, on activation to continuous expression, might make the cell cancerous[1]. The presently known transforming retroviruses contain transforming genes which were probably derived by recombination of a slow oncogenic retrovirus with cellular sequences closely related to these genes[2]. It was recently reported[3] that cellular DNA fragments from normal tissue culture cells could transform mouse fibroblasts *in vitro* with a low efficiency. High efficiency of transformation was observed in secondary transfections only when high molecular weight DNA from transformed recipient cells was used as the transforming agent[3]. We observed that DNA isolated from different BALB/c mouse organs can transform both NIH/3T3 and BALB/3T3 cells, although at a low frequency[4]. In attempts to increase the initial efficiency of transformation, we have found that preinfection of recipient 3T3 cells with murine leukaemia viruses markedly enhances focus formation by normal BALB/c DNA fragments.

Table 1 Effect of leukaemia virus preinfection on early transformation of NIH/3T3 fibroblasts with normal BALB/c DNA

Recipient cells	Treatment	Fraction of transformed cultures*	Average no. of foci per dish*	Average frequency of transformation ($\times 10^{-6}$ per μg DNA per cell)
NIH/3T3	BALB/c DNA	0/33	0	0
	Escherichia coli DNA	0/33	0	0
	Transfection buffer	0/33	0	0
NIH/3T3/RMuLV† (Rauscher LV)	BALB/c DNA	3/3	4	2
	E. coli DNA	0/3	0	0
	Transfection buffer	0/3	0	0
NIH/3T3/MoMuLV‡ (Moloney LV)	BALB/c DNA	33/33	18	7
	E. coli DNA	0/33	0	0
	Transfection buffer	0/33	0	0

DNA was isolated from liver, spleen and thymus of 5-week-old germ-free BALB/c mice as previously described[10]. DNA solutions were exhaustively dialysed against 0.1 × SSC (0.015 M NaCl, 0.0015 M trisodium citrate, *p*H 7.0) before use. The transfection experiments were performed by a modification of the Graham and van der Eb method[11]. DNA was dissolved in transfection buffer (*p*H 6.95) to a concentration of 25 μg ml^{-1}, sheared by passing the solutions 20 times through a 0.8-mm needle to a molecular weight of about 10×10^6, as determined by agarose gel electrophoresis, and precipitated with 2.5 M $CaCl_2$ to a final concentration of 125 mM; 0.5 ml of DNA precipitate was added to 2.5 ml of fresh medium on dishes of 3T3 cells seeded 20 h earlier at a concentration of 3×10^5 cells per 60 mm dish. Eighteen hours after the addition of DNA, the cells were trypsinized. Focus formation was evaluated 12–15 days after the DNA treatment.

* Average values from one (NIH/3T3/RMuLV) to four (NIH/3T3/MoMuLV) experiments.

† NIH/3T3 cells were infected with Rauscher leukaemia virus four days before the transfection experiment.

‡ NIH/3T3/MoMuLV is a clonal isolate of NIH/3T3 cells productively infected with Moloney leukaemia virus (gift of Dr H. P. J. Bloemers).

To increase the efficiency of transformation of recipient cells by normal BALB/c DNA fragments, we manipulated the DNA-treated cells using procedures reported to heighten the expression of newly acquired DNA in recipient cells. This involved adjuvant treatment with dimethyl sulphoxide (DMSO) or glycerol[5,6] or the cultivation of DNA-treated cells in the presence of polybrene, insulin and hydrocortisone[7]. However, with none of these procedures did we observe the focus formation directly on DNA-treated cells or soon after the DNA treatment. Instead, DMSO treatment and cultivation of the DNA-treated cells in the presence of polybrene, hydrocortisone and insulin had a toxic effect on the 3T3 cells.

We then investigated whether infection of recipient cells with non-transforming leukaemia viruses had any positive effect, as it has been reported that a similar procedure had a promoting effect on chemical carcinogenesis *in vitro*[8]. The recipient NIH/3T3 cells were productively infected with either Moloney (MoMuLV) or Rauscher (RMuLV) leukaemia virus. The morphology of the 3T3 cells infected with these leukaemia viruses was indistinguishable from that of uninfected controls. The transformation efficiency was greatly enhanced by this procedure. On both MoMuLV- and RMuLV-infected NIH/3T3 fibroblasts, focus formation could be scored as early as 12–15 days after exposure to BALB/c DNA fragments in the cells of the first passage after the DNA treatment (Table 1). In preliminary experiments, supernatants from these transformed cultures showed no transforming activity.

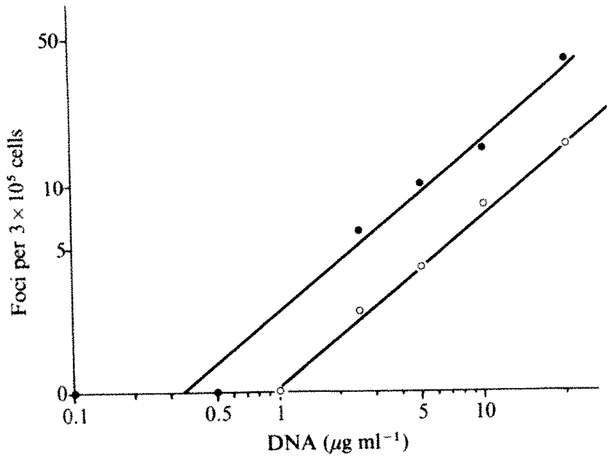

Fig. 1 Kinetics of transformation of NIH/3T3 cells productively infected with Moloney leukaemia virus by fragments of normal BALB/c DNA. The total amount of DNA in each DNA inoculum was adjusted to 25 μg ml^{-1} by the addition of calf thymus DNA before calcium precipitation. ● and ○ represent results of two independent experiments. Three recipient cultures were treated with each dose of DNA. Foci were scored 12–15 days after the treatment with DNA fragments.

The leukaemia virus-infected fibroblasts are transformed by single-hit kinetics (Fig. 1). This indicates that, with the promoting effect of a viral gene, focus formation of fibroblasts is induced by a single BALB/c gene which could be any of the various transforming genes supposed to be present in the mouse genome. The frequency of transformation reached a value of 0.5–1 focus forming units per μg of DNA, which is comparable to that observed for transformation induced with proviral DNA fragments (molecular weight 10×10^6) isolated from Abelson virus-transformed lymphoma cells (V. K.-K. and K. J. B., in preparation).

The nature of the observed enhancement of fibroblast transformation by normal BALB/c DNA fragments after leukaemia virus infection is not clear. The leukaemia virus might provide complementary functions required for expression of endogenous mouse transforming genes[9] such as promoter sites.

Inhibition of 40S-Met-tRNA$_f^{Met}$ ribosomal initiation complex formation by vaccinia virus

Anne Person, Fakher Ben-Hamida & Georges Beaud

Institut de Recherche en Biologie Moléculaire du Centre National de la Recherche Scientifique et de l'Université Paris VII, Tour 43, 2 place Jussieu, F-75221 Paris Cedex 05, France

Infection with vaccinia virus (a poxvirus) quickly[1,2] and efficiently shuts off host protein synthesis in the presence of actinomycin D (refs 3–5) or cycloheximide[6–8]. The cellular messenger RNA apparently remains stable in the infected cells exposed to inhibitors of viral gene transcription[5,9,10]. In some cases vaccinia viral RNA or poly(A) synthesis have been implicated in the establishment of this effect[5,7,11]. However, in the presence of cordycepin (3-deoxyadenosine) which blocks viral gene transcription[12] and cytoplasmic poly(A) synthesis[9], cellular protein synthesis is still efficiently inhibited in vaccinia virus-infected cells[9,12]. This shutoff is also observed *in vitro*, in the corresponding cell-free extracts[13], and in a reticulocyte lysate[14–16]. Therefore the shutoff of host protein synthesis is probably mediated by a factor associated with vaccinia virions. We now report that the formation of the 40S-Met-tRNA$_f^{Met}$ initiation complex is inhibited in cytoplasmic extracts derived from vaccinia virus-infected cells exposed to cordycepin to block viral gene expression. A similar inhibition is found in reticulocyte lysates incubated with purified vaccinia cores, confirming the hypothesis that the factor associated with the viral cores is responsible for the inhibition observed in vaccinia virus-infected cells exposed to inhibitors of transcription.

The binding of initiator Met-tRNA$_f^{Met}$ to 40S ribosomal subunits was measured as previously described[17] after adding either ^{35}S-methionine or purified ^{35}S-Met-tRNA$_f^{Met}$ to cytoplasmic extracts derived from vaccinia virus-infected or uninfected cells. The extracts were pre-incubated with sparsomycin to block the elongation step. Figure 1 shows that 40S-Met-tRNA$_f^{Met}$ initiation complex formation was inhibited to 60% in the infected cell extracts. A similar inhibition was observed when using unwashed ribosomes and post-ribosomal supernatant fractions (S100) instead of the corresponding infected cell extracts; moreover the inhibition was associated with the unwashed ribosomes from the infected cells (data not shown). This reduced amount of ^{35}S-methionine associated with 40S ribosomes indeed represented a reduced formation (or increased dissociation) of the 40S-Met-tRNA$_f^{Met}$ initiation complex as proved by the following results: (1) increasing the incubation time after the addition of ^{35}S-methionine led to a plateau value of 40S-Met-tRNA$_f^{Met}$ complex formation after 30–45 min for control and infected cell extracts; this plateau was 50% lower in the infected cell extracts (data not shown). It is worth noting that the time needed to reach equilibration was much longer in the Ehrlich ascites tumour (EAT) cell-free system than previously observed in the reticulocyte lysate[17]. (2) The addition of purified ^{35}S-Met-tRNA$_f^{Met}$ instead of ^{35}S-methionine to the cytoplasmic extracts from vaccinia virus-infected cells exposed to cordycepin, resulted in a similar inhibition (50–60%) of 40S-Met-tRNA$_f^{Met}$ initiation complex formation. Figure 2*a* shows that the amount of free charged tRNA decreased identically in control and infected cell extracts, probably as a result of degradation or deacylation. Figure 2*b* reveals a plateau value of the ^{35}S-Met-tRNA$_f^{Met}$ bound to the 40S subunit (expressed in ‰ of residual labelled initiator tRNA), reached within 5–10 min for both extracts. This value was 50% lower in the infected cell extract.

The following arguments indicate that this decrease in 40S-Met-tRNA$_f^{Met}$ complex formation is likely to account for the block in initiation of polypeptide chains previously observed in the vaccinia virus-infected cell extracts[13]: (1) the rate of protein synthesis *in vitro* in vaccinia virus-infected cell extracts is inhibited[13] to a similar extent (50–70%) to that of binding of ^{35}S-Met-tRNA$_f^{Met}$ to 40S ribosomes (Fig. 2, Table 1); (2) the inhibition of the 40S-Met-tRNA$_f^{Met}$ complex formation in the infected cell extract was also observed when the corresponding ribosomes and S100 fraction were incubated as described in Fig. 1 but in the absence of sparsomycin; these conditions allow protein synthesis to occur and the ^{35}S-radioactivity associated with the more rapidly sedimenting ribosomal particles was also strongly reduced in the infected cell extract (data not shown); (3) the addition of ribosomal salt wash (RSW) from uninfected cells stimulated three- to five-fold the amount of labelled initiator tRNA bound to 40S particles in the control and infected cell extracts but did not overcome the inhibition of the infected cell

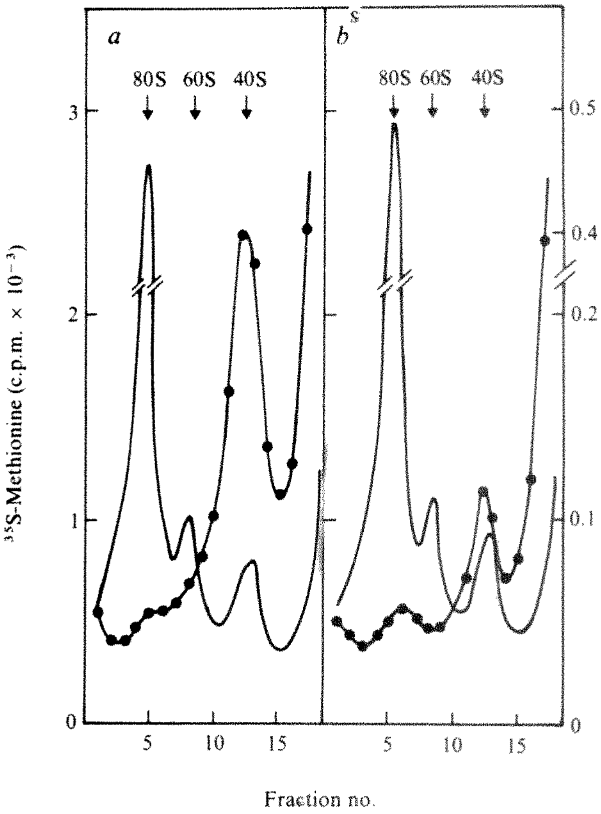

Fig. 1 Binding of ^{35}S-Met-tRNA$_f^{Met}$ to 40S ribosomal subunits in the cytoplasmic extracts from uninfected (*a*) and vaccinia virus-infected (*b*) cells exposed to cordycepin. The lysates prepared from EAT[13] were diluted to 50 A_{260} units ml^{-1} in 3.5 mM Mg acetate, 0.1 M K acetate and all the other components of standard protein synthesis *in vitro*[13]. Incubation (50 µl samples) was at 30 °C for 5 min in the presence of 0.3 mM sparsomycin. Then ^{35}S-methionine was added (800 µCi ml^{-1}) and after a further 10 min incubation, the reaction mixture was diluted with 5 vols cold buffer H: 20 mM HEPES–KOH, *p*H 7.5, 20 mM KCl, 2 mM Mg acetate, 0.1 mM EDTA and centrifuged through 15–30% (w/v) sucrose gradients prepared in buffer H, for 100 min at 49,000 r.p.m. in a Beckman SW 50.1 rotor at 4 °C. The gradients were scanned at 254 nm with an Isco monitor (5 mm path) and collected into 23 fractions. ^{35}S-Met-tRNA (•—•) was measured after cetyltrimethylammonium bromide (CTAB) precipitation[17] and filtration on Whatmann GF/C. The amount of CTAB-precipitable radioactivity was similar for control and infected cell extracts in the top fractions (not shown). About 0.35 molecules of charged initiator tRNA was bound per 40S ribosome particle in the control extract, as estimated from the values of the endogenous methionine pool[13] and from the determination of the free 40S ribosomes based on the optical scans. (Trace of A_{254} shown as continuous lines.)

0028-0836/80/390355—03$01.00

extracts (Table 1). This corroborates a similar effect of these additions on protein synthesis in the corresponding extracts[13].

As protein synthesis is also inhibited at the level of initiation in the reticulocyte lysates incubated with vaccinia cores[14], it was important to measure the 40S–Met–tRNA$_f^{Met}$ initiation complex formation in this *in vitro* system to demonstrate a similar mechanism for the viral core-mediated inhibition. Figure 3 shows that the binding of endogenously labelled ^{35}S–Met–tRNA$_f^{Met}$ to 40S ribosomes is strongly inhibited when the reticulocyte lysate is incubated with purified viral cores. A similar inhibition was observed when adding purified ^{35}S–Met–tRNA$_f^{Met}$ to the reticulocyte lysate preincubated with the vaccinia cores (data not shown). When the concentration of viral cores was varied, the inhibition of 40S initiation complex formation was equal to the inhibition of protein synthesis: adding 3 A_{260} units per ml of cores caused 42% inhibition of 40S–Met–tRNA$_f^{Met}$ complex and 49% inhibition of *in vitro* protein synthesis, whereas adding 9 A_{260} units per ml of cores induced 65 and 66% inhibition respectively. This result confirms the hypothesis whereby the reduced binding of initiator Met–tRNA to 40S ribosomes is indeed responsible for the inhibition of initiation of protein synthesis previously observed[14].

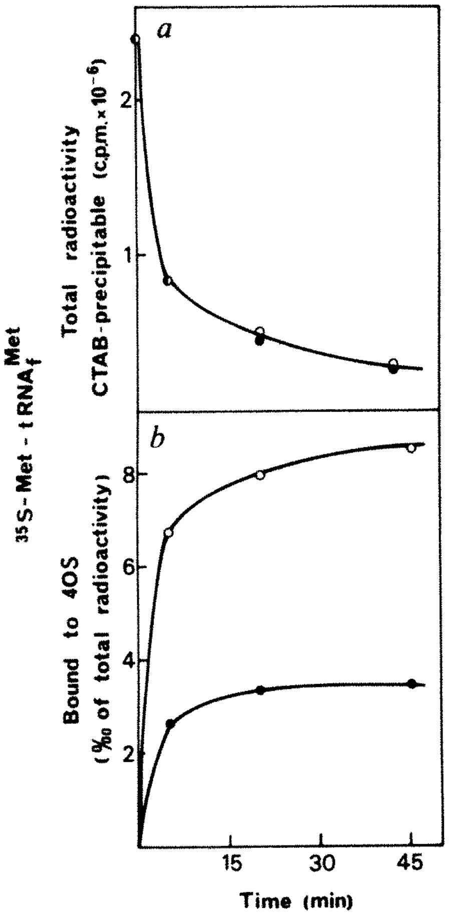

Fig. 2 Kinetics of ^{35}S–Met–tRNA$_f^{Met}$ binding to 40S ribosomal subunits from ribosomes of uninfected and vaccinia virus-infected cells exposed to cordycepin. Ribosomes and supernatant (S100) fractions were prepared by centrifuging cytoplasmic extracts[13] at 198,000*g* for 1 h. The ribosomal pellet was suspended in 10 mM HEPES–KOH, *p*H 7.5, 10 mM KCl, 1.5 mM Mg acetate, 2.5 mM dithiothreitol. The S100 fraction and ribosomes were stored in liquid nitrogen. Ribosomes (40 A_{260} units ml^{-1}) and S100 fraction (7.5 A_{260} units ml^{-1}) were incubated and analysed on sucrose gradients as described in Fig. 1 except that purified ^{35}S–Met–tRNA$_f^{Met}$ (2.4 × 10^6 c.p.m., 30 μg ml^{-1}) was added instead of ^{35}S-methionine. The time of incubation is indicated on the abcissa. Total amount of radioactivity was calculated from the summation of fractions from each gradient. Ribosomes and S100 were from control (○) or infected (●) cells.

Table 1 Effect of RSW addition on the formation of the 40S–Met–tRNA$_f^{Met}$ complex

			^{35}S–Met–tRNA$_f^{Met}$ bound to 40S			
			−RSW		+RSW	
Experiment	Extract from cells	Ribosome concentration (mg ml^{-1})	Radioactivity (c.p.m.)	Inhibition (%)	Radioactivity (c.p.m.)	Inhibition (%)
I	Control	2.7	13,000		42,000	
	Infected	2.9	5,500	58	22,000	47
II	Control	1.4	3,700		16,800	
	Infected	1.5	1,700	54	9,100	46

The binding of ^{35}S–Met–tRNA$_f^{Met}$ to 40S subunits was measured as described in Fig. 2. RSW free of 40S subunits was prepared from uninfected cells[13] and used at 1 mg protein ml^{-1}. Mg acetate was added at 2 mM together with 50 μM spermine when RSW was present[13]. The addition of RSW induces an increase of 38% (expt I) or 57% (expt II) in the amount of native 40S subunits, as measured from the optical scans.

The results presented here reveal that the shutoff of host protein synthesis mediated by vaccinia virus (in the absence of viral gene expression) occurs at the level of Met–tRNA$_f^{Met}$ binding to 40S ribosomes both in reticulocyte lysate incubated in the presence of vaccinia cores and in lysates from vaccinia virus-infected cells exposed to cordycepin. The fact that the same site of lesion is found in both cases strongly suggests a similar mechanism of inhibition. This inhibition in initiation of protein synthesis is generally believed to occur before the binding of mRNA and therefore would result in an inhibition of both cellular and viral mRNA translations. This agrees with previous studies which demonstrated a nonspecific inhibition of cellular and early viral mRNA translation in some experimental conditions[6,10,18]. Presumably a virus-coded protein, synthesized very early in the infection, is involved in releasing the translational block associated with the input virions[6,10,18].

The formation of the 40S–Met–tRNA$_f^{Met}$ complex appears to be an important target for the translational regulation in different physiological systems[19–22] and in most cases, the corresponding inhibition is released by the addition of ribosomal salt wash or purified eIF-2 (refs 23, 24). Although the addition of ribosomal salt wash from uninfected cells stimulated the binding of Met–tRNA$_f^{Met}$ to 40S subunits from infected cells, and also protein synthesis in these extracts[13], it did not abolish the difference between control and infected cells, suggesting the existence of a lesion which may lie in the ribosomes themselves rather than in the initiation factors. This conclusion is reinforced by the finding that addition of purified eIF-2 to reticulocyte lysates inhibited by vaccinia cores produced at best only a partial stimulation of protein synthesis (ref. 14 and R. Kaempfer and E. Katz, personal communication), confirmed the inhibition of protein synthesis by vaccinia cores and did not detect reversal by the addition of 2-aminopurine or purified eIF-2. We must conclude that although the inhibition caused by vaccinia infection superficially resembles the inhibition seen in reticulocyte lysates incubated with double-stranded RNA or in the absence of haemin, where the impairment of 40S–Met–tRNA$_f^{Met}$ complex formation is believed to result from alterations to eIF-2, it must have a different cause. Apparently another mechanism to regulate the level of 40S–Met–tRNA$_f^{Met}$ complexes must exist. The identification of the inhibitor associated with vaccinia cores, now being carried out in the laboratory, may help to elucidate the mechanism of inhibition. A possible role for a vaccinia structural protein in the establishment of the shutoff of host protein synthesis has previously been suggested[25].

We thank Professor F. Chapeville for continuous interest and advice, A. Dru for purifying vaccinia virus, Dr A. L. Haenni for reading the manuscript and Dr H. Trachsel for discussions. Sparsomycin was a gift from Dr J. Douros. Purified tRNA$_f^{Met}$ from beef liver was isolated and provided by O. Kellerman and Professor J. P. Waller. This work was supported by a grant from

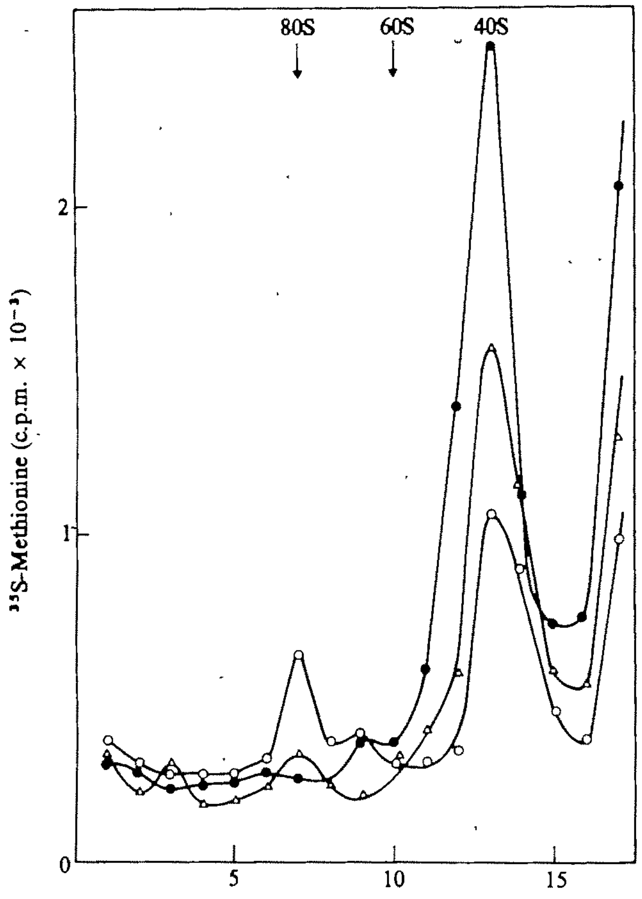

Fig. 3 Inhibition of 40S–Met–tRNA$_f^{Met}$ complex formation by purified vaccinia virus cores. First the reticulocyte lysate (20 μl) was preincubated at 25 °C for 10 min with vaccinia cores (Δ, 3A_{260} units ml^{-1}; 0, g A_{260} units ml^{-1}) or without cores (●) in the presence of 0.33 mM sparsomycin in a total volume of 50 μl of protein synthesis reaction mixture[14]. Then 5 μl of ^{35}S-methionine were added (839 Ci mol^{-1}, 43 μCi) and after a further incubation of 5 min at 30 °C the reaction mixtures were analysed as described in Fig. 1, except for the centrifugation step which was carried out in a Beckman SW 41 rotor for 220 min at 40,000 r.p.m. The amount of CTAB-precipitable radioactivity in the top fractions was similar in the control and in the presence of the cores (not shown).

S-adenosylmethionine—a novel regulator of aspartate kinase

Sven Erik Rognes*, Peter J. Lea & Benjamin J. Miflin

Biochemistry Department, Rothamsted Experimental Station,
Harpenden AL5 2JQ, UK

Man derives 70% of his dietary requirement of protein directly from the grains of cereals and legumes. These sources are respectively deficient in lysine (and secondarily threonine) and methionine and much effort is being devoted to their improvement[1]. All three amino acids are derived from aspartate via a common metabolic pathway (Fig. 1) in which the first reaction catalysed by aspartate kinase is a key regulatory step limiting their production. In microorganisms, regulation of aspartate kinase occurs by a variety of mechanisms, commonly involving feedback inhibition of one or more isoenzymes by Lys plus Thr, Lys alone or Thr alone[2]. On the other hand, Met control of this step does not seem to conform to a general pattern. Met represses, but does not inhibit aspartate kinase II of *Escherichia coli*; in other species Met can enhance or modify the effects of Lys or Thr[3]. Similarly, varied controls involving Lys and Thr have been reported for the enzymes from higher plants[4] with only one report of an effect of Met[5]. In contrast to these previous results, we suggest here that the methionine derivative (*S*)-*S*-adenosyl-L-methione (AdoMet) is an important regulator of the Lys-sensitive aspartate kinase of higher plants, and that this regulatory mechanism is highly conserved. There is thus a major synergistic interaction of the two nutritionally deficient amino acids Lys and Met to inhibit their own syntheses at the primary regulatory step in the pathway.

Initial studies suggested that plant aspartate kinases may be inhibited by Lys alone[6,7], Thr alone[8] or in a concerted manner by Lys plus Thr[9]. More recent work has shown that certain plants contain two isoenzymes, one sensitive to Thr and one to Lys, the relative proportions of which may vary at different stages of plant development[10–12]. Thr also regulates the activity of homoserine dehydrogenase[4] (Fig. 1(3)). So far the only effect of Met that has been reported in detail is a concerted effect with Lys in which barley aspartate kinase was inhibited 35% by 0.5 mM Lys and 70% by 0.5 mM Lys plus 0.5 mM Met; Met had no effect on its own[5]. Evidence that Met, or a product derived from it, inhibits Met synthesis *in vivo* has been obtained from feeding studies with [^{35}S]O$_4^{2-}$ in *Lemna paucicostata*[13] and barley (S. W. J. Bright, personal communication). Recently it has been found[14,15] that AdoMet regulates the latter part of the pathway by strongly activating Thr synthase (Fig. 1(4)), implying that Thr synthesis may occur only when the cell has made sufficient Met to satisfy its needs for AdoMet. AdoMet has a very important role in plant metabolism, being the predominant biological methyl donor in methyl transfer reactions and a precursor of polyamines and the plant hormone ethylene[13]. AdoMet is rapidly synthesized if Met is fed to intact plants[13,16]. It may thus be that AdoMet rather than Met itself acts as a regulator of Met synthesis. We have therefore investigated its effect on aspartate kinase from a range of higher plants.

Lys-sensitive aspartate kinase was partially purified from barley and muskmelon seedlings, pea and maize leaves and developing seeds of pea and field bean. The effect of various concentrations of Lys and AdoMet on its activity was tested. AdoMet on its own had little effect at concentrations up to 0.4 mM but Lys inhibited the activity from all species studied.

Aspartate
(1) (2)
Aspartyl-P
Aspartic semialdehyde → → → Lysine
(3)
Homoserine → O-Acyl-homoserine
Homoserine-P — — — — → Cystathionine → → Methionine (5) → S-Adenosylmethionine
(4)
Threonine → → → Isoleucine

Fig. 1 Diagram of the biosynthetic pathway for the aspartate family of amino acids. Enzymes: (1) and (2) lysine-sensitive and threonine-sensitive aspartate kinases (EC 2.7.2.4); (3) homoserine dehydrogenase (EC 1.1.1.3); (4) threonine synthase (EC 4.2.99.2); (5) methionine adenosyltransferase (EC 2.5.1.6). The pathway in higher plants (→) differs from that in microorganisms (— — — —→) which synthesize cystathionine via *O*-acetyl- or *O*-succinyl-homoserine rather than *O*-phosphohomoserine.

However, when equal amounts of AdoMet and Lys were added together, a marked synergistic inhibition was observed, with the strongest effect on the barley enzyme (Fig. 2). The AdoMet used was about 90% pure and contained small amounts of *S*-adenosylhomocysteine, 5′-methylthioadenosine and homoserine as detected by TLC. However, inhibition was due to AdoMet since: (1) hydrolysis of the product at *p*H 3 (100 °C, 30 min), which completely breaks down AdoMet to 5′-methylthioadenosine and homoserine[17], reduced the inhibition (by 0.25 mM AdoMet or hydrolysis products) in the presence of 25 μM Lys from 60% to 19%; and (2) *S*-adenosylhomocysteine at 0.25 mM together with 25 μM Lys gave only 9% inhibition. Thr (5 mM) also inhibited part of the isolated aspartate kinase activity from pea leaves (25%) and field bean and pea seed (10%); Thr-sensitive activity was always additive to the (Lys + AdoMet)-sensitive activity. When AdoMet was added to a separate preparation from cotyledons of 4-day-old pea seedlings, which was 90% inhibited by Thr and insensitive to Lys[8], there was no effect on activity either in the presence or absence of Thr. We therefore conclude that AdoMet acts only on the Lys-sensitive aspartate kinase. It is possible that the previously reported effect of Met plus Lys on the barley enzyme[5] was due to the presence of methionine adenosyltransferase (Fig. 1(5)) in the preparation and all the required substrates for AdoMet formation in the assay tube.

Although aspartate kinase can be completely inhibited by Lys alone, the presence of AdoMet greatly enhances its sensitivity toward Lys, decreasing the concentration of Lys required to cause half-maximal inhibition severalfold (Table 1). Conversely, when small amounts of Lys are present, the activity of the enzyme becomes strongly dependent on the AdoMet concentration (Fig. 3). Threonine synthase (Fig. 1(4)) is half-maximally activated by AdoMet within a similar concentration range (60–210 μM)[14,15]; this range corresponds to measured pool sizes

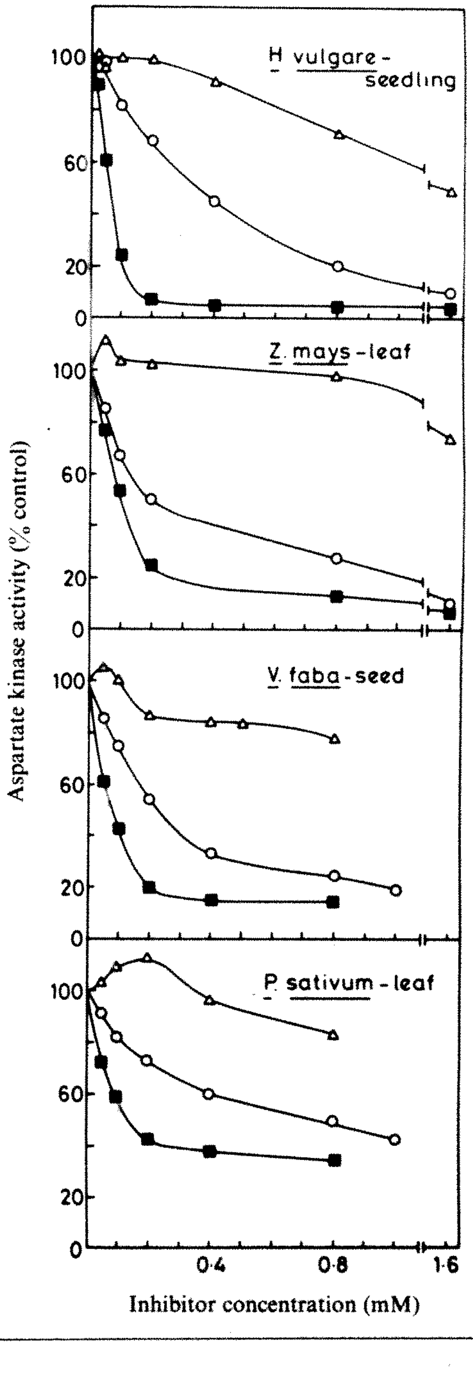

Fig. 2 Synergistic inhibition of higher plant aspartate kinases by Lys and AdoMet. Developing seeds of *Pisum sativum* and *Vicia faba* were collected from pods 18 and 36 days after flowering, respectively. Leaves were collected from light-grown 14-day-old *Zea mays* and 11-day-old *Pisum sativum* seedlings. *Cucumis melo* seedlings were grown in vermiculite for 10 days in light. Excised *Hordeum vulgare* embryos were grown aseptically for 7 days on a sucrose–mineral salts medium. The plant tissues were homogenized and extracted with 50 mM potassium phosphate, *p*H 7.5, containing 100 mM KCl, 2 mM $MgCl_2$, 2 mM EDTA, 15% (v/v) glycerol and 0.2% (v/v) 2-mercaptoethanol (buffer A). Supernatant protein extracts after centrifugation (20,000*g*, 30 min) were fractionated using $(NH_4)_2SO_4$ (0–60% saturation), gel filtration (Sephadex G-75) and ion exchange (DEAE-cellulose). Aspartate kinase (95–100% Lys-sensitive and Thr-insensitive) from *Hordeum*, *Cucumis* and *Zea* was eluted from DEAE-cellulose using buffer A plus 0.4 M KCl. *Pisum* and *Vicia* extracts were treated as described previously[12]. The radioactive aspartate kinase assay[8] was used. Reaction mixtures contained in 100 μl: 12 mM [U-^{14}C]aspartate (purified over a Dowex 1-X8 column, 0.7 Ci mol^{-1}), 25 mM $MgCl_2$, 20 mM ATP, 400 mM NH_2OH-HCl adjusted to *p*H 7.5 with KOH, 1 mM dithiothreitol, 60–200 μg enzyme protein and various concentrations of Lys and AdoMet (Boehringer Mannheim). Labelled aspartylhydroxamate formed after 60–240 min incubation at 30 °C was determined[8]. Control activities (100%) were (in pkat per mg protein): *Hordeum* 58, *Zea* 28, *Vicia* 40, *Pisum* seed 62, *Pisum* leaf 36, *Cucumis* 48. △, AdoMet alone; ○, Lys alone; ■, Lys plus AdoMet (equimolar concentrations).

Table 1 Effect of AdoMet concentration on the sensitivity of plant aspartate kinases to Lys inhibition

	Enzyme source					
	P. sativum leaf	*P. sativum* seed	*V. faba* seed	*Z. mays* leaf	*H. vulgare* seedling	*C. melo* seedling
[AdoMet] (μM)	[Lys] required for half-maximal inhibition (μM)					
0	270	240	180	190	340	250
50	130	120	80	ND	80	125
100	70	90	55	95	48	90
250	30	70	20	ND	22	68

Various concentrations of AdoMet and Lys were added to standard assay mixtures. The concentrations of AdoMet used had no significant effect (activity not less than 95% of control) on the enzyme activities when added alone. ND, not determined. For details of assays see Fig. 2 legend.

in vivo[13]. Our results suggest that the Lys-sensitive aspartate kinase of higher plants also contains a regulatory binding site(s) for AdoMet. Thus the flux through the pathway may be strongly influenced by AdoMet at Lys concentrations of 20 to 200 μM. A potential consequence of this control is that plants could be starved of Thr unless they contained an isoenzyme of aspartate kinase insensitive to AdoMet and Lys. Although a Lys-insensitive, Thr-sensitive enzyme is found in carrot[10,11] and legumes[8,12,18] there is no previous report of such an isoenzyme in cereals. However, our recent but preliminary findings indicate that such an enzyme is present. The likelihood is that, contrary to previous ideas[4,9], the control mechanisms for aspartate kinase in higher plants are remarkably conserved between different species, with two isoenzymes being present: one synergistically inhibited by Lys and AdoMet and the other one inhibited by Thr. Understanding the complex regulatory action of the end products is a prerequisite to devising new selection strategies for obtaining mutants of higher plants that produce enhanced levels of amino acids. Further, it is very important in the analysis of mutants already isolated. For instance a mutant of barley has been selected that has a modified Lys, but not AdoMet, site in its aspartate kinase and contains significantly greater amounts of Thr in the seed[19,20]. The proposed regulation of the aspartate pathway by AdoMet in higher plants differs from that so far reported for microorganisms where Met and/or AdoMet inhibit enzymes specific to the Met branch of the pathway[21]. However, AdoMet may well have regulatory effects, so far unexplored, on other steps of the pathway.

S.E.R. acknowledges the receipt of a Council of Europe Scholarship through the British Council. We also thank J. S. Kueh for growing the barley embryos and S. W. J. Bright for helpful discussion.

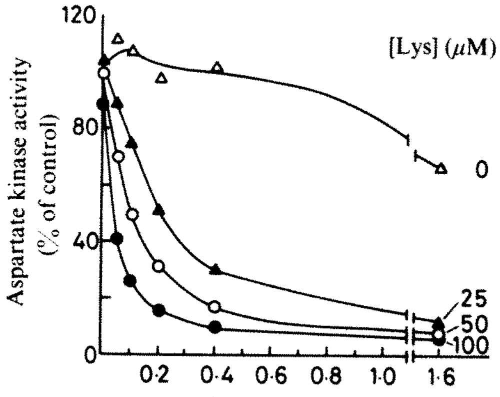

Fig. 3 Effect of Lys concentration on the sensitivity of barley embryo aspartate kinase to AdoMet inhibition. Data obtained as described in Fig. 2 legend.

The Gram-negative soil bacterium *Agrobacterium tumefaciens* induces crown gall tumours on most dicotyledonous plants[1,2], its Ti plasmids causing the neoplastic transformation of plant cells[3–5]. Molecular hybridization has shown that transformed cells contain a segment of the Ti plasmid (T-DNA) of molecular weight 8–15 × 10^6 (refs 6–9), of which at least part is transcribed[10,11]. Some copies of the T-DNA are integrated into the plant DNA (unpublished work). In view of the prokaryotic origin of the T-DNA, the possibility of its localization within either mitochondria or chloroplasts must be considered. We present here evidence for the absence of T-DNA from mitochondria and chloroplasts. Our results clearly show its presence within the nucleus.

Two lines of evidence support this conclusion. First, the different organelles were separated and isolated, their DNA was extracted, digested with various restriction endonucleases and hybridized according to the Southern procedure[12] to radioactive probes containing cloned segments of the T-DNA. In the second

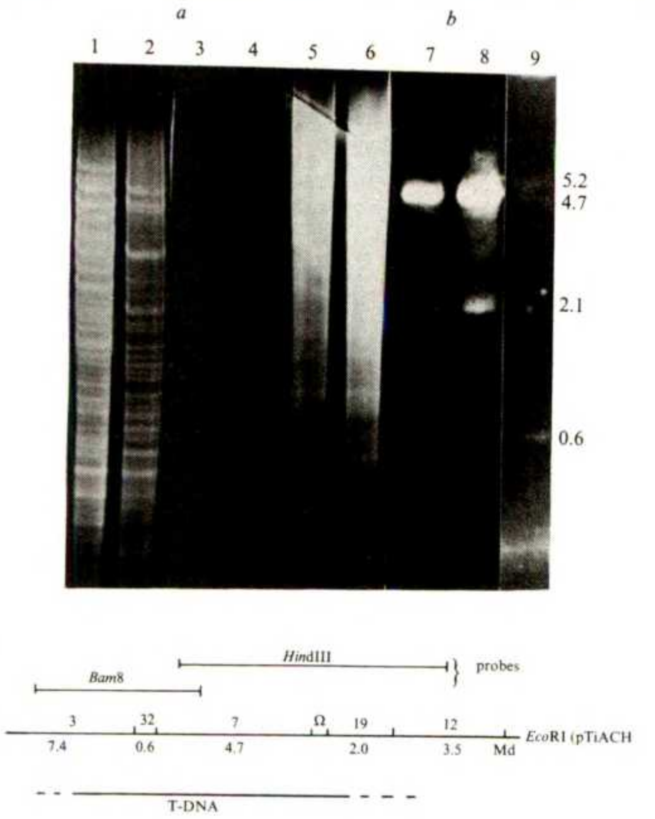

Fig. 1 Hybridization of mitochondrial, chloroplast and nuclear DNA from suspension cultures of *Nicotiana tabacum* variety White Burley transformed by *A. tumefaciens* A6 and B6S3 (both lines originated from the collection of R. A. Schilperoort, University of Leiden) against ^{32}P-labelled fragments of pTiACH5. For isolation of mitochondria and chloroplasts, suspension cultured cells were disrupted by a new cell mill (L. Willmitzer *et al.*, in preparation) in buffer A (ref. 13). The homogenates were filtered through an 80-μm and a 20-μm nylon cloth, centrifuged for 10 min at 1,200*g*, and mitochondria were pelleted by centrifuging the supernatant for 15 min at 12,000*g*. The pellet was redispersed in buffer A and again centrifuged at 12,000*g*. The final pellet was treated with DNaseI (100 μg ml^{-1}) for 30 min at 4 °C. DNase was removed by two washings at 12,000*g* in buffer A, and the dispersed pellet was loaded on a 30–60% sucrose gradient in buffer A, centrifuged for 1h at 22,000 r.p.m. in a SW27 rotor and the mitochondrial band was recovered. Chloroplasts were isolated in the same way but pelleted by two subsequent rounds of centrifugation at 2,000*g* for 5 min. Nuclei were prepared according to Willmitzer[20], substituting 0.5 mM spermidin and 0.15 mM spermin for $MgCl_2$ and incubating the cells overnight with cellulase and pectinase. The purity of the nuclei was checked routinely by phase contrast microscopy, which showed the absence of other subcellular particles. The same result was obtained by electron microscopy. DNA was isolated from the organelles according to Gross-Bellard *et al.*[21] with subsequent iurification on a CsCl gradient. DNA was digested with *Eco*RI in 50 mM, Tris, *p*H 7.5, 100 mM NaCl and 7 mM $MgCl_2$, and the fragments obtained were separated by electrophoresis in 0.8% agarose formed in 40 mM Tris–acetic acid *p*H 8.0, 20 mM NaAc, 1 mM EDTA and ethidium bromide (0.3 μg ml^{-1}), on a horizontal slab gel apparatus at 40 V for 12 h[22]. DNA was then blotted on to nitrocellulose (Schleicher and Schuell) and hybridized against a nick-translated probe of cloned segments of the T-DNA (specific activity 20–40 10^6 c.p.m. μg^{-1}). Hybridization was performed routinely for 36–40 h at 68 °C in 3× SSC, 0.5% SDS, 1 mM EDTA, 0.02% polyvinylpyrrolidone, 0.02% bovine serum albumin and 0.02% Ficoll. After washing filters were exposed for 1–4 weeks. Lanes 1–4, *Eco*RI restriction pattern of mitochondrial (lane 1) and chloroplast (lane 2) DNA and the corresponding autoradiograms obtained after hybridization with nick-translated *Hin*dIII fragment 1 of pTiACH5 (lane 3, mitochondrial DNA; lane 4, chloroplast DNA) 15 μg of DNA was applied each. Lanes 5–8, *Eco*RI restriction pattern of two concentrations of nuclear DNA (lane 5, 15 μg; lane 6, 22 μg) and the corresponding autoradiograms obtained after hybridization with nick-translated *Hin*dIII fragment 1 of pTiACH5 (lane 7, 8). Lane 9, autoradiogram obtained after hybridization of *Eco*RI digested nuclear DNA with nick-translated *Bam* fragment 8 of pTiACH5. The lower intensity of the bands in lane 9 compared with lanes 7 and 8 is due to a lower specific activity of the nick-translated probe. The lower diagram shows a schematic representation of the parts of the Ti plasmid ACH5 (octopine) integrated into nuclear DNA of tobacco cells transformed by *A. tumefaciens* A6 and B6S3. The detailed experiments for the construction of the map will be described elsewhere.

approach, isolated nuclei from transformed cells were incubated in conditions facilitating transcription and the RNA synthesized was analysed for sequences derived from T-DNA.

An efficient method was developed for the isolation of nuclei in plant cell suspension culture, details of which will be described elsewhere (L. Willmitzer, in preparation). Nuclei thus isolated were physiologically active and free from other subcellular particles as revealed by electron microscopy. Standard procedures[13–15] were followed for the isolation of mitochondria and chloroplasts by DNase treatment and sucrose density centrifugation.

Figure 1*a* shows the pattern of mitochondrial and chloroplast DNA from a tobacco octopine tumour line transformed by *A. tumefaciens* A6, after digestion with *Eco*RI and separation of the fragments by electrophoresis on 0.8% agarose gels. Figure 1*a* also shows the corresponding autoradiogram obtained after hybridization with the *Hin*dIII fragment I of the octopine plasmid pTiACH5, which has been shown to be part of the transferred plasmid DNA (T-DNA)[9] (De Beuckeleer *et al.*, in preparation). The chloroplast DNA restriction pattern agrees well with reports of the chloroplast pattern of *Nicotiana* species[16–18]. The mitochondrial DNA shows a higher complexity in comparison with chloroplast DNA as judged by the larger number of distinct bands, in agreement with published data[15,19]. Mitochondrial DNA preparations were characterized by analytical CsCl density gradient centrifugation, exhibiting a distinct peak at the expected density of 1.706 g cm^{-3}. Lack of hybridization was observed consistently in four independently derived chloroplast and mitochondrial DNA preparations of two different tobacco octopine tumours transformed by *A. tumefaciens* A6 and B6S3.

Figure 1*b* shows the pattern of nuclear DNA obtained after digestion with *Eco*RI and separation of the resulting fragments by electrophoresis on 0.8% agarose gels, together with the corresponding autoradiogram obtained after hybridization with *Hin*dIII fragment I and *Bam*HI fragment 8 of pTiACH5. Two bands with molecular weights of 4.7×10^6 and 2.1×10^6 hybridize with the *Hin*dIII fragment I. These fragments correspond, respectively, to the *Eco*RI fragment 7, molecular weight 4.7×10^6, of pTiACH5 plasmid DNA which is therefore an internal fragment of the transferred T-DNA, and to a junction fragment presumably linking the right border of the T-DNA to plant DNA (De Beuckeleer *et al.*, in preparation). When *Bam* fragment 8 was used as hybridization probe, three bands with molecular weights of 0.6×10^6, 4.7×10^6 and 5.2×10^6 emerged, corresponding, respectively, to the internal pTiACH5 *Eco*RI fragments 32 and 7 and the left-hand border fragment (De Beuckeleer *et al.*, in preparation). These data therefore reveal the presence of T-DNA integrated in nuclear DNA.

Hybridization was achieved repeatedly using 11 independently derived preparations of nuclear DNA from two octopine tumour tissues. Because hybridization was achieved with the nuclear DNA, which is enriched by only a factor of 1.1 compared with total cellular DNA, the absence of any hybridization with chloroplast and mitochondrial DNA, which are enriched by a factor of 20 and 100, respectively[23,24], suggests that the T-DNA is not located in plasmids. But there is a possible pitfall: because there is extensive homology between 16S and 23S rDNA of *Escherichia coli* and the rDNA of chloroplasts[25,26] and mitochondria[27], erroneous hybridizations were observed when we used cloned T-DNA probes that were not entirely free of chromosomal *E. coli* DNA.

To substantiate further the presence of the T-DNA within the nucleus, isolated and highly purified nuclei from octopine tumour tissue were incubated in conditions that facilitated active transcription. After a 20-min pulse with α-^{32}P-UTP, labelled RNA was isolated and hybridized to Southern blots of cloned T-DNA fragments. Figure 2*a* shows the stained gel together with the corresponding autoradiogram. The T-DNA appears to be transcribed very actively within the isolated nuclei, providing further strong evidence for the presence of the T-DNA within the nucleus. The autoradiogram indicates that the left as well as the right-hand part of T-DNA are transcribed, for hybridization to the *Hin*dIII fragments 1, 18 and 22 of pTiACH5 is visible. (The nuclear transcription of the T-DNA is under thorough investigation.)

We excluded the possibility that T-DNA is located in the cytoplasm but adsorbs to and penetrates into the nuclei during isolation. To do this, 20 μg of Ti-plasmid (ACH5) representing a 1,000-fold excess over the concentration present in crown gall cells, assuming five copies of T-DNA per transformed cell[28], was added to untransformed plant cells at the onset of nuclear purification. After isolation, nuclei were incubated in conditions facilitating transcription, and ^{32}P-labelled RNA was isolated and hybridized against blots of T-DNA as described above. No hybridization was detectable (Fig. 2*b*).

In summary, this report provides strong structural as well as functional evidence for the presence of the T-DNA within the nucleus of the transformed plant cell.

We thank Professor K. G. Wagner for stimulating discussions; Professor R. Herrmann, for an introduction to the isolation of plasmid DNA, and W. Schmalenbach and G. Simons for technical assistance. This work was supported by the Max-Planck-Gesellschaft, München, and by grants from the Kankerfonds van de ASLK and from the Fonds voor Kollektief Fundamenteel Onderzoek (10.316) to J.S. and M.V.M., M.D.B. and M.L. are indebted for a fellowship to the IWONL.

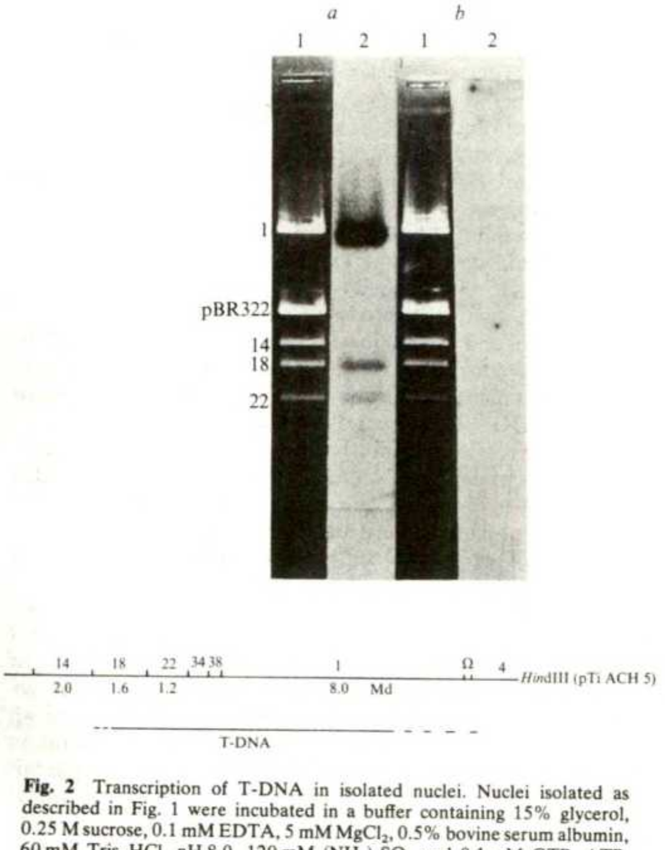

Fig. 2 Transcription of T-DNA in isolated nuclei. Nuclei isolated as described in Fig. 1 were incubated in a buffer containing 15% glycerol, 0.25 M sucrose, 0.1 mM EDTA, 5 mM $MgCl_2$, 0.5% bovine serum albumin, 60 mM Tris–HCl, *p*H 8.0, 120 mM $(NH_4)_2SO_4$ and 0.1 mM GTP, ATP, CTP and 200 μCi α-^{32}P-UTP (specific activity 350 Ci mmol^{-1}) for 20 min at 25 °C. RNA was isolated by two rounds of DNase digestion, proteinase K treatment, phenolization and subsequent chromatography on Sephadex G50. RNA was hybridized against blots of T-DNA clones containing *Hin*dIII fragments 1, 14, 18 and 22 at 68 °C in 3 × SSC, 0.2% SDS, 1 mM EDTA for 40 h. *a*, Hybridization (lane 2) of RNA (10 × 10^6 c.p.m.) transcribed in nuclei isolated from a tobacco crown gall transformed by *A. tumefaciens* A6 to blots of T-DNA clones containing *Hin*dIII fragments 1, 14, 18 and 22. *b*, Autoradiogram (lane 2) obtained after hybridizing RNA (12 × 10^6 c.p.m.) transcribed within the nucleus of untransformed cells where 20 μg of Ti-plasmid (pTiACH5) DNA had been added to the cells at the onset of isolation of the nuclei, representing a 1,000–fold excess over the amount of T-DNA present in transformed cells. The lower diagram shows a schematic representation of the parts of the Ti-plasmid ACH5 integrated into nuclear DNA of tobacco cells transformed by *A. tumefaciens* A6.

Although both prokaryotic and eukaryotic messenger RNAs can be easily translated in heterologous protein-synthesizing systems, attempts to achieve correct synthesis of mitochondrial proteins by translation of mitochondrial mRNAs in such systems have failed[1–3]. In general, the products of synthesis are of low molecular weight and presumably represent fragments of mitochondrial proteins[1,2]. These fragments display a strong tendency to aggregate[4]. Explanations have included the use by mitochondria of codons requiring a specialized tRNA population[5] and the fortuitous occurrence within genes of purine-rich sequences resembling bacterial ribosome binding sites[6]. In addition, the long 5′-leader sequences present in many mitochondrial (mt) RNAs may also contribute to difficulties in mRNA recognition by heterologous ribosomes[7]. Recent sequence analysis of human mtDNA[8] suggests that the genetic code used by mammalian mitochondria deviates in a number o respects from the 'universal' code, the most striking of thes being the use of the UGA termination codon to specify tryp tophan. That this may also apply in yeast mitochondria has bee shown by Fox[9] and Macino *et al.*[10], thus providing an obvio and easily testable explanation for the inability of heterologo systems to synthesize full-length mitochondrial proteins. confirm this explanation and describe here the *in vitro* synthe of a full-length subunit II of yeast cytochrome *c* oxidase i wheat-germ extract supplemented with a partially purif mitochondrial mRNA for this protein and a UGA-suppres tRNA from *Schizosaccharomyces pombe*[11].

Our choice of mRNA was based on two considerations. Fi previous cell-free translation experiments had shown that u 27% of the products synthesized under the direction of

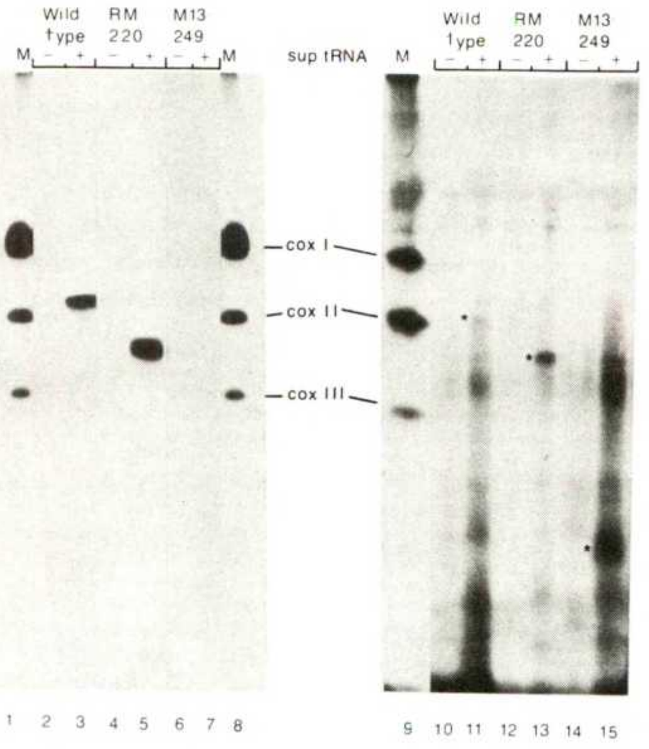

Fig. 1 Autoradiogram of the products synthesized *in vitro* under the direction of mitochondrial mRNA in the presence or absence of $\text{tRNA}^{\text{ser}}_{\text{UGA}}$. Mitochondrial RNA was isolated from the wild-type strain *Saccharomyces carlsbergensis* NCYC74 and from two mutants in the structural gene for subunit II of cytochrome *c* oxidase, *Saccharomyces cerevisiae* M13-249 and RM220 (refs 9, 12). An 11–13S fraction of these RNAs, which is enriched in the mRNA for subunit II, was obtained by sucrose gradient centrifugation[2] and used to programme a wheat-germ cell-free system in the presence or absence of $\text{tRNA}^{\text{ser}}_{\text{UGA}}$ from *S. pombe*[11]. Reaction mixtures (25 μl) contained 12.5 μl wheat-germ extract, prepared as described by Marcu *et al.*[16], 20 mM HEPES (*p*H 7.5), 2.5 mM magnesium acetate, 85 mM potassium acetate, 2 mM dithiothreitol, 0.5 mM spermidine, 0.04 mM of each amino acid, excluding methionine, 3.5 μM [^{35}S]-methionine (260 Ci mmol^{-1}: The Radiochemical Centre, Amersham, UK), 1 mM ATP, 0.03 mM GTP, 4 mM phosphoenol pyruvate, 4 μg pyruvate kinase per ml (Boehringer Mannheim), 5 μM S-adenosylmethionine and 2–3 μg mitochondrial mRNA. Suppressor $\text{tRNA}^{\text{ser}}_{\text{UGA}}$, when present, was added to a final concentration of 40 μg ml^{-1}. Protein synthesis was allowed to proceed for 1 h at 25 °C. 1-μl samples were withdrawn for measurement of incorporation by trichloroacetic acid precipitation and for electrophoretic analysis of total product. The remainder of the reaction mixture was subjected to immunoprecipitation, following the procedure of Maccecchini *et al.*[17]. Immunoprecipitation was carried out in consecutive steps with a pre-immune serum and anti-holo-cytochrome *c* oxidase, using a goat anti-rabbit serum to recover immune complexes in each case. Electrophoresis was performed according to Laemmli[18] on 15% polyacrylamide gels, using subunits I–III of cytochrome *c* oxidase as molecular weight markers. These were prepared by labelling of protoplasts of *S. carlsbergensis* with [^{35}S]-methionine[19] in the presence of cycloheximide (0.6 mg ml^{-1}) after pretreatment with chloramphenicol[20]. Cell lysates were then immunoprecipitated with anti-cytochrome *c* oxidase as described above. After electrophoresis, gels were fixed, impregnated with sodium salicylate[21], dried and autoradiographed for 4–8 days at −70 °C on Kodak XR-1 film with an Ilford tungstate intensifier screen. Lanes 2–7, Samples after immunoprecipitation with anti-cytochrome *c* oxidase; lanes 10–15, the total products of *in vitro* synthesis. Lanes 1, 8 and 9 show subunits I–III of cytochrome c oxidase, labelled *in vivo* before lane 9) and after (lanes 1 and 8) immunoprecipitation as described above. The remaining lanes show the products synthesized *in vitro* under the direction of the various mRNA preparations: wild type, in the absence (lanes 2, 10) and presence (lanes 3, 11) of suppressor tRNA; RM220, in the bsence (lanes 4, 12) and presence (lanes 5, 13) of suppressor tRNA; M13-249, in the absence (lanes 6, 14) and presence (lanes 7, 15) of uppressor tRNA. Due to the low immune reactivity of the subunit II-related olypeptide in M13-249 (ref. 12), the autoradiogram of lanes 6 and 7 was xposed for a slightly longer time to permit better photographic reproduc- on. In the electropherograms of total product, the positions of the various forms of subunit II are marked by *. cox, Cytochrome *c* oxidase.

11–13S fraction of mtRNA is reactive with an antiserum against cytochrome *c* oxidase[1,2]. Transcript mapping shows that the 11–13S fraction contains an 11S RNA which is the major transcript of the gene for subunit II on yeast mtDNA (the *OXI*-1 locus)[2]. Second, since DNA sequence analysis shows that the *OXI*-1 coding sequence is either 753 or 714 nucleotides long[9], depending on the start used, we reasoned that the 11S RNA with a length of only 800–900 nucleotides would be unlikely to contain extensive untranslated regions. Such an RNA may be more readily accepted by eukaryotic ribosomes than one containing a long 5′-leader characteristic of other mitochondrial mRNAs.

Accordingly, an 11–13S mtRNA fraction was prepared by sucrose gradient centrifugation and translated in a wheat-germ extract as described in Fig. 1 legend. To permit unambiguous identification of the *in vitro* product and to rule out possible artifacts resulting from aggregation, translations were performed not only with RNA from wild-type mitochondria, but also with RNA from two well-defined mutants in *OXI*-1. These mutants synthesize characteristically shortened forms of subunit II as a result of frameshifts induced by single base pair insertions or deletions at known sites in the gene[9,12]. Figure 1 shows the results obtained from parallel translations in the presence or absence of $\text{tRNA}^{\text{ser}}_{\text{UGA}}$ (~70% pure) from *S. pombe*. Although there is no significant difference in the total amount of trichloroacetic acid-precipitable counts, the presence of the suppressor tRNA results in the appearance of strong, discrete high-molecular-weight bands. These are evident not only in samples precipitated with anti-cytochrome *c* oxidase (lanes 2–7), but also in samples analysed before immunoprecipitation (lanes 10–15). The latter observation indicates that both translation and suppression must be proceeding extremely efficiently and this is quite remarkable in view of the heterologous nature of the mRNA and the fact that, according to the DNA sequence[9], five UGA stops have to be read through to achieve complete synthesis.

Wild-type subunit II has an M_r of 29,000, while RM220 and M13-249 should yield subunit II-related polypeptides with M_r's of 28,000 and 15,000, respectively, as derived from the DNA sequence[9]. In fact, the products synthesized have M_r's of 31,000, 27,000 and 17,000 in wild type, RM220 and M13-249, respectively. We therefore conclude that full-length cytochrome *c* oxidase subunit II has been synthesized and thus are able to confirm that UGA is translated in yeast mitochondria.

The difference in mobility between the product of *in vitro* synthesis with wild-type RNA and the mature *in vivo* subunit II (2,000) deserves comment. The possibility exists that the *in vitro* product is a precursor form of subunit II. Evidence for the existence of a precursor to this subunit has recently been presented[13]. Furthermore, alignment of the yeast amino acid sequence predicted from DNA sequence analysis[9] with that determined for the beef-heart protein[14], shows that the yeast protein could be larger by up to 27 residues which might represent the non-conserved part of a precursor. However, we cannot formally exclude that this difference merely reflects an altered electrophoretic behaviour arising from the substitution of five tryptophan residues by five serine residues, although this seems unlikely in view of the fact that neither intact subunit II nor the product synthesized in various chain termination mutants shows abnormal behaviour in Ferguson plots of electrophoretic mobility[12,15]. An alternative explanation is that the extra 2,000 results from initiation in the wheat-germ system at a site upstream of the normal initiation codon. Indeed, DNA sequence analysis has revealed two AUG codons separated by 39 base pairs[9] and at present it is not known which of these functions as the normal start. Initiation at the 5′-proximal AUG would generate a protein of M_r approximately 1,300 greater than one initiated at the second site. These three possibilities can be tested. If the existence of a precursor is confirmed, the present *in vitro* system should be valuable in providing sufficient quantities of this protein to permit further characterization and analysis of its mode of processing.

Finally, the present system has great potential for the identification and characterization of other mRNAs in mitochondria, including those with long 5′-leaders. It will be interesting to see whether their correct translation is achieved. Such experiments are now in progress.

We thank Drs R. O. Poyton and D. Deters for gifts of antisera and mutant yeast strains, respectively, Dr T. D. Fox for communicating sequence data before publication and Dr P. Borst for discussions. This work was supported in part by grants to P. Borst and L.A.G. from The Netherlands Foundation for Chemical Research (SON) with financial aid from The Netherlands Organization for the Advancement of Pure Research (ZWO) and to J.K. from the Swiss National Science Foundation.

Cooperative structural transition of PM2 DNA at high ionic strength and its dependence on DNA damages

Research Centre, 601 West 10th Avenue, Vancouver,
BC, Canada V5Z 1L3

Pohl and Jovin[1] have shown that poly(dG–dC) · poly(dG–dC) in solution undergoes a cooperative transition at 2.5 M NaCl at neutral *p*H. The two forms of the polymer are structurally different as indicated by a change in ethidium bromide intercalation and in circular dichroism (CD)[1,2]. Wang *et al.*[3] and Davies and Zimmerman[4] have suggested that the low salt form of the polymer might correspond to the B form of DNA (right-handed helix) and the high salt form to the Z form of DNA (left-handed helix). We describe here a salt-induced transition of supercoiled PM2 DNA from a form which passes through nitrocellulose filters to a form which is retained by these filters. The transition occurs between 2.5 and 3.5 M NaCl. The dependence of the apparent equilibrium constant on the salt concentration indicates a cooperative transition. Irradiation of DNA with UV light or alkylation with *N*-acetoxyacetylaminofluorene (AAAF) shifts the transition to lower salt concentrations. The transition can also be observed with linear DNA but requires a much higher salt concentration.

Figure 1 shows the retention of supercoiled PM2 DNA by nitrocellulose filters in dependence of the NaCl concentration. Relatively little DNA is retained below 2.5 M NaCl. However, at higher salt concentrations, DNA binding rapidly increases and at 3.5 M NaCl 80% binding is obtained. When PM2 DNA is irradiated with UV light or reacted with AAAF, the DNA binding profile shifts to lower salt concentrations (Fig. 1).

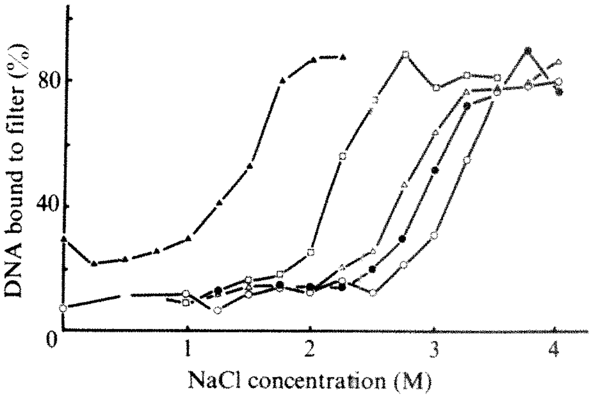

Fig. 1. Retention of supercoiled PM2 DNA by nitrocellulose filters in dependence of the NaCl concentration. ^{3}H-labelled PM2 DNA was isolated as described previously[15]. Aliquots (5 ml) of PM2 DNA at concentrations of 0.25 μM nucleotide in 10 mM Tris-HCl (*p*H 8.0) and various amounts of NaCl were filtered through nitrocellulose filters (Schleicher and Schuell, 0.20 μm pore size). The filters were dried and the radioactivity determined. ○, Untreated DNA; ●, DNA exposed to 60 J m^{-2} of UV light; △, DNA exposed to 120 J m^{-2}; □, DNA exposed to 600 J m^{-2}; ▲, DNA treated with AAAF. UV treatment was carried out at a concentration of 2.5 μM DNA nucleotide in a 10 mM Tris-HCl (*p*H 7.5) on ice. AAAF treatment was at a DNA concentration of 500 μM with 4.5 μg ml^{-1} of AAAF in 2.3% dimethyl sulphoxide and 10 mM Tris-HCl (*p*H 7.5). After incubation at 37 °C for 30 min, the DNA was extracted with ether and dialysed against 10 mM Tris-HCl (*p*H 7.5).

DNA binding could be caused by a salt-induced change of the binding properties of the nitrocellulose filters. However, the influence of DNA damages on DNA binding and the observation that linear DNA binds at a much higher salt concentration than circular DNA (Fig. 4) indicate that binding is caused by a salt-induced structural change of the DNA. This structural transition is reversible. When PM2 DNA is exposed to high salt and diluted to low salt concentrations immediately before filtration, no DNA binding is observed. Glass fiber filters (Whatman GF/C) do not retain DNA exposed to high salt, indicating that the DNA is not precipitated. We propose that high salt induces a transition of G–C rich regions of the DNA helix from a B-type structure to a Z-type structure and that the Z-type structure

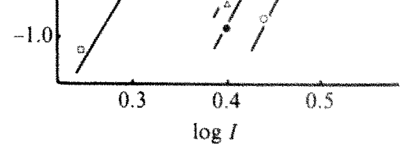

Fig. 2 Double logarithmic plot of the apparent equilibrium constant between the high- and low-salt form of supercoiled PM2 DNA in dependence of the molarity of NaCl (*I*). The values were calculated from Fig. 1 by dividing the amount of DNA bound to the filter by the amount of DNA passing through the filter. The values were corrected for a fraction of DNA (7.5%) which bound to the filters at all salt concentrations. ○, Untreated DNA; ●, DNA exposed to 60 J m^{-2} of UV light; △, DNA exposed to 120 J m^{-2} of UV light; □, DNA exposed to 600 J m^{-2} of UV light. The slopes varied between 13 and 10 with an average of 11.4.

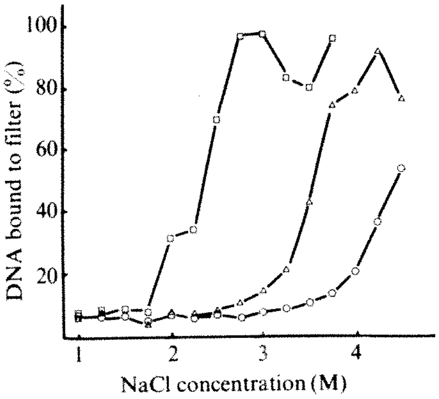

Fig. 3 Dependence of DNA binding on temperature. Aliquots (5 ml) of PM2 DNA at concentrations of 0.25 μM nucleotide in 10 mM Tris-HCl (*p*H 8.0) and various amounts of salt were incubated at 50 °C (□), 23 °C (△) and 0 °(○). They were then filtered through nitrocellulose filters which had been prewashed with 5 ml salt solutions at the same temperatures. The filter speed was 9 s per 5 ml.

itself, or single-strand regions formed in junctions between B and Z segments, bind the DNA to the nitrocellulose filter.

A double logarithmic plot of the apparent equilibrium constant (DNA bound to the filter divided by DNA passing through the filter), according to the equation $\log K = r \times \log(I) + \text{constant}$, where I = molar NaCl, gives approximately straight lines with slopes between 13 and 10 (Fig. 2). The high value of r indicates that the transition is cooperative. The average value of 11 is the same as that reported by Pohl and Jovin[1] for the salt-induced cooperative transition of poly(dG–dC)·poly(dG–dC) with an average length of 34 base pairs.

CD studies indicate that Z DNA segments can also be induced by high salt in naturally occurring DNA[5,6]. Changes of the CD spectrum similar to those induced by high salt have also been observed in DNA or in poly(dG–dC)·poly(dG–dC) alkylated with mitomycin C[7]. This observation and our observation with AAAF- and UV-treated DNA suggest that DNA damages facilitate the transition of the DNA helix from a B form to a Z form.

The Z form in damaged DNA might be favoured for steric reasons. Thus, in oligonucleotides *N*-(deoxyguanosin-8-yl)-acetylaminofluorene, the major adduct in AAAF-treated DNA, assumes the *syn* configuration found in the Z DNA rather than the *trans* configuration found in B DNA[8]. Alternatively, a DNA structure containing B and Z segments might require that the hydrogen bonding between some base pairs is disrupted. DNA damages might therefore favour the Z structure because of interference with hydrogen bonding. Indeed, AAAF treatment and UV treatment lower the melting point of DNA[9,10]. Furthermore, an increase in temperature leads to a transition at a lower salt concentration (Fig. 3). The influence of temperature on the transition is not at the level of the formation of Z form itself (at least in regions with an alternating G–C sequence), as the transition in poly(dG–dC)·poly(dG–dC) is not temperature-dependent[1].

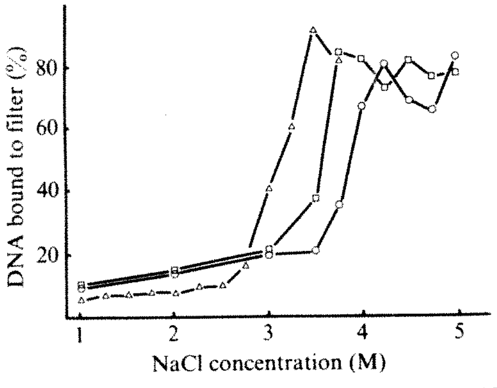

Fig. 4 Retention of native and linear PM2 DNA at 37 °C in dependence of the NaCl concentration. △, Native PM2 DNA; ○, linear PM2 DNA; □, linear PM2 DNA exposed to 600 J m^{-2} of UV light. Linear DNA was prepared by incubating 0.2 mM PM2 DNA nucleotide for 3.5 h with 25 units ml^{-1} of restriction endonuclease *Msp*I (New England Biolabs) in 10 mM Tris-HCl (*p*H 7.5), 10 mM $MgCl_2$, 6 mM KCl and 100 μg ml^{-1} acetylated bovine serum albumin. After incubation, the DNA was extracted with an equal volume of chloroform-octanol (9:1) and dialysed against 10 mM Tris-HCl (*p*H 7.5). Filtrations were carried out as described in Fig. 3 legend.

The transition of segments of the DNA from a B form to a Z form requires unwinding of the DNA helix. In a negatively supercoiled DNA molecule, unwinding of the DNA will remove the supercoils and, depending on the degree of transition, introduce positive supercoils. Since removal of negative supercoils is associated with a considerable decrease in free energy[11,12], one would expect that the B–Z transition is favoured in DNA containing negative supercoils. As shown in Fig. 4, when the negatively supercoiled PM2 DNA is converted to a linear form by treatment with the restriction endonuclease *Msp*I (*Msp*I is an isoschizomer of *Hpa*II which cleaves PM2 DNA at a unique site[13,14]), the transition is induced at a much higher salt concentration.

It will be of interest to demonstrate that Z DNA-like structures also occur at physiological salt concentrations. Indeed, this is the case for DNA damaged extensively with AAAF or with mitomycin C, and, with the appropriate DNA binding proteins present, the transition might also occur with DNA containing fewer lesions. Such Z DNA-like structures might be the trigger for the initiation of DNA repair processes. One would predict from such a mechanism that the presence of negative supercoils is important for DNA repair—it has been demonstrated in *Escherichia coli* that gyrase antagonists which prevent negative supercoiling inhibit the restoration of infectivity of UV-irradiated phage λ DNA[15]. Transitions of DNA segments from a B form to a Z form and vice versa might also be involved in other aspects of regulation of DNA metabolism, a mechanism which would be compatible with the key role of DNA gyrase in *E. coli*[16].

Corrigendum

In the letter '*β*-Endorphin alters luteinizing hormone secretion via the amygdala but not the hypothalamus' by N. Parvizi and F. Ellendorf, *Nature* **286,** 812–813 in paragraph 2, lines 2/3, the reference to 'Basolateral hypothalamus' is incorrect and it should read 'mediobasal hypothalamus'.

MATTERS ARISING

Giant solar flares in Antarctic ice

ROOD *et al.*[1] have discovered four prominent 'spikes' in a long time record (circa 1150 to the present) of the NO$_3^-$ concentration inside an Antarctic ice core. These four spikes rise 2–3 times higher than the upper envelope of a fluctuating background level of 0–20 μg l^{-1} that has been plausibly attributed to the action of high-energy solar radiation (photons and particles) impinging on the Earth's upper atmosphere and ionizing N$_2$, thereby leading to various chains of chemical reactions that culminate in the formation of NO$_3^-$, some of which is transported, within a few weeks or months, to Antarctica[1]. According to three alternative chronologies provided by Rood *et al.*, the estimated dates of the four NO$_3^-$ spikes lie within the intervals given in Table 1. Three of these dates have been tentatively associated by the same authors with the galactic supernovae of 1604, 1572 and 1181. At the outset, they have rejected energetic particles from the supernova explosion as a possible source of ionization of the terrestial N$_2$ because galactic magnetic fields would have greatly delayed and diffused the particles on their way to Earth. Instead , they have shown that photons of energy $\gtrsim 10$ keV are required. Unfortunately, as they admitted, the total energy requirements are difficult to meet, and the matching of dates with historical supernovae is not perfect.

As an alternative explanation, I suggest that the necessary ionizing radiation could have come from unusually powerful solar flares. These flares would be expected to have occurred preferentially during periods when the Sun was generally most active, that is around the times of the largest maxima in the solar cycle. Two good indices of solar activity are available: for the years elapsed since 1700, there are both sunspot numbers[2] and auroral numbers[3]; for earlier years auroral statistics[3–6] are preferred because the sunspot record (mostly from the Far East) is very sporadic[7]. Despite some incompleteness of the record before 1700, the main trends in the statistics are quite unmistakable (see refs 3 and 5).

The intervals of time in which the largest auroral and sunspot maxima occurred are listed in Table 1, where earlier dates are given only to the nearest half-decade. These intervals of time correlate very well with the known epochs of the NO$_3^-$ spikes. Only in one case is it necessary to recognize that episodes of solar flaring need not occur (as they have not always occurred in modern times) precisely at times of maximum auroral or maximum sunspot numbers. This therefore gives some flexibility in the possible dates of the giant solar flares that is not available in the case of the supernova hypothesis. However, there are no NO$_3^-$ spikes in the years around 1778 and 1957, at which times solar activity was also at a peak. Nevertheless, given the rarity of the proposed flaring events, this absence could simply be a product of statistical fluctuations. Also the Sun may now be somewhat different physically from its state before the long Maunder minimum in 1645–1715 (ref. 2).

According to Table 1, very large solar maxima seem to recur in cycles of ~200 yr, as Schove[4] originally noted. In the background NO$_3^-$ data, there is also some evidence of the Maunder minimum and of the normal 11-yr solar cycle[1]. Bauer[8] estimated that the background concentration could vary by a factor of two during the 11-yr cycle. To extend this further, I consider the largest solar flares in modern times. These have importance class 3+ or 4 and emit $E_{32}\times10^{32}$ erg of high-energy radiation (photons and particles), where $E_{32}\sim1$–2 (ref. 9). The Earth intercepts $4\times10^4\,E_{32}$ erg cm^{-2} of this. According to Rood *et al.*[1], the energy flux needed to produce a NO$_3^-$ concentration of 20 C_{20} μg l^{-1} near the South Pole is ~ $1\times10^5\,C_{20}$ erg cm^{-2} yr^{-1}. Since $C_{20}\lesssim1$, only one or two major flares per year is sufficient to produce all of the background NO$_3^-$. It is therefore not unreasonable to suppose that, every couple of hundred years or so, a giant flare, perhaps 2–3 times more intense than ordinary major flares, erupts on the Sun. An alternative possibility is that a very rapid succession of major flares of the ordinary type takes place. An event of this type may still develop during the current maximum of solar activity.

The Antarctic ice-core measurements are apparently now being pushed to deeper levels than before[1]. Much older NO$_3^-$ spikes may therefore be discovered. One immediate prediction of the solar flare hypothesis is the possibility (though no more than that) of a spike occurring around the year 1000, a time of heightened auroral activity[3–5]. On the other hand, a very bright supernova also appeared in 1006, as Rood *et al.* pointed out. But, fortunately, an *experimentum crucis* to discriminate between the two hypotheses can be made for the middle of the eleventh century, a time of profound auroral quiet but, equally importantly, of a brilliant supernova, the Crab explosion of 1054.

Table 1 Dates of the largest maxima in the Antarctic concentration of NO$_3^-$ and in solar activity indices

Largest NO$_3^-$ maxima	Largest solar maxima
1130–1160	1120–1140
1300–1340	1360–1375
.1590–1600	1565–1585
1610–1620	1605–1630
–	1778–1788
–	1947–1959

Magnetic fields and the solar constant

THOMAS[1] has suggested that changes in the magnetic flux content of the convection zone produces changes in radius. However, his calculations did not include the effect of structural changes in the superadiabatic region on the bulk of the convection zone. Theoretical studies[2–4] have shown that solar luminosity fluctuations can result from small structure adjustments in the convection zone, and can occur on time scales shorter than 1 yr. Such fluctuations are of interest in studies of the terrestrial climate.

The previous calculations have forced these structural changes by assuming a time-dependent mixing length. When the mixing length (physically the convective efficiency) changes, adjustments in the structure occur rapidly in the superadiabatic region, and in turn the bulk of the convection zone adjusts to maintain hydrostatic equilibrium. The result is a temporary luminosity change[3]. Any mechanism which affects the structure of the superadiabatic region will cause such a luminosity fluctuation. The effect of magnetic pressure changes on the superadiabatic region is described here.

We began by including a global magnetic pressure term in a stellar structure code. If the flux is assumed to be concentrated in vertical flux tubes, the pressure at a given radius (r) is given by

0028–0836/80/390365—02$01 00

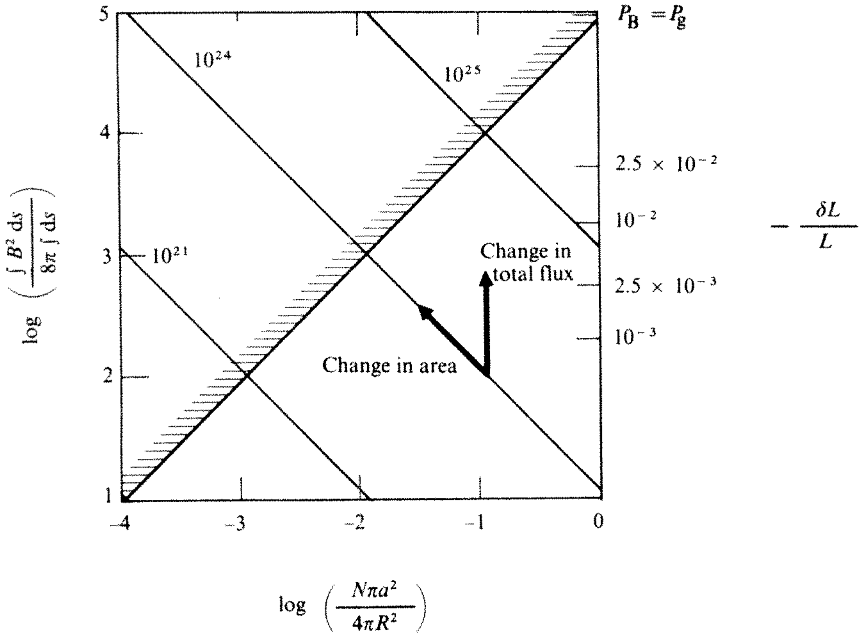

Fig. 1 Global magnetic pressure plotted against the fraction of the solar surface contained in the magnetic flux tubes. The luminosity scale on the right side gives the change resulting from the magnetic pressure change. The oblique lines are contours of constant flux.

$$P_m = \frac{1/8\pi \int B^2 ds}{\int ds} \approx \frac{NB^2 a^2}{32\pi r^2}$$

where N is the number of tubes with flux B and radius a. If the flux in a tube is constant and material is locked to the field lines, then the ratio of magnetic pressure to gas pressure decreases rapidly with depth in agreement with detailed sunspot models by Weiss[6].

The effect of changing the value of the magnetic pressure was explored by changing the surface value through the range $\log P_m = 1$ to 3.8 dyn cm^{-2}. Only in the superadiabatic region (upper few thousand kilometres) was the magnetic pressure term significant. Its gradient results in expansion and decreased density. In response to the lowered density in the superadiabatic region, the bulk of the convection zone begins to expand. The energy for expansion is obtained from the luminosity, and thus increasing the magnetic pressure decreases the solar luminosity.

The magnetic pressure depends on the total magnetic flux present and the area containing that flux. However, there is a minimum area over which a given amount of flux may be distributed that is determined by the requirement that the magnetic pressure in the flux tubes should not be greater than the gas pressure outside the tube.

The surface value of the global magnetic pressure is plotted against the fraction of the solar surface contained in the magnetic flux tubes in Fig. 1. Lines of constant total flux are shown as diagonals and the effect on the pressure of changing the area contained in flux tubes can be seen by moving along one of these lines. The effect on the pressure of changing the total amount of flux contained in the flux tubes is shown by vertical motion in this diagram. The luminosity scale along the right side of Fig. 1 gives the amplitude of the luminosity fluctuation produced by the magnetic pressure change.

The solar budget of magnetic flux is uncertain, but to produce a luminosity change of the order of 0.1% the flux penetrating the superadiabatic region must be $\geq 2 \times 10^{23}$ Mx. The radius change associated with this flux change was found to be $\Delta R/R \leq 10^{-4}$ which is slightly less than the value found by Thomas[1] for two reasons. First, the vertical flux tubes considered here contain less volume through the superadiabatic region than the horizontal flux tubes considered by Thomas. Second, the radius of the upper parts of the superadiabatic region is affected by the luminosity change because energy transport through the outer 1,000 km is partially by radiation[3,4]. Thus reducing the radiative flux causes this region to contract.

While the total amount of magnetic flux in the convection zone is uncertain, the amount of flux required for its pressure to produce a significant luminosity change is apparently high. A 1% luminosity change required a flux change of 2×10^{24} Mx in our model, and resulted in a radius change of $\Delta R/R = 2 \times 10^{-4}$. The action of such large amounts of magnetic flux on convective energy transport may actually dominate the effects discussed here. Unfortunately, although it is well known that strong fields can suppress convection locally (sunspots), the realistic inclusion of the effects of such flux tubes on global convective energy transport is a problem. As the effects of the field on convection have been neglected, the present results should represent the minimum effect of magnetic fields on the solar luminosity and radius.

A tectonic mélange of foreign eclogites and ultramafites in West Norway

MEDARIS[1] suggests that eclogites enclosed within the amphibolite-facies country-rock gneisses in the Basal Gneiss Region, West Norway "developed by *in situ* metamorphism of crustal materials"[1]; furthermore he attributes this to an "eclogite-facies metamorphic event"[1]. There are, however, some weaknesses in these hypotheses; also the simple *in situ* hypothesis may detract other geologists, especially geodynamicists, from pondering the genesis of these rocks, some of which are amongst the most exceptional on Earth[2], being the highest-pressure metamorphic rocks in the Caledonide Orogen[3].

Many different kinds of eclogite can be distinguished in the region according to mineralogical, textural, chemical, and pressure (P)-temperature (T) criteria, such that the frequent assumption[1,4–8] of a single origin (the simple *in situ* origin) for all eclogites within country-rock gneiss is difficult to justify. The 'dual' origin of eclogites and ultramafites, with only the ultramafites being foreign, suggested at Lien[1] and elsewhere[7,9], is less credible than my alternative multiple foreign origin[10] of the different eclogite types and also of those meta-igneous rocks (ultramafites, anorthosites, dolerites) for which adequate evidence of igneous intrusion into country-rock gneiss is unavailable (most published examples). A gigantic tectonic mélange is thus envisaged having been created by tectonic introduction of rock fragments from diverse foreign sources of diverse ages of equilibration [for example eclogite-facies eclogites + ultramafites (upper mantle); granulite-facies eclogites + anorthosites + gneisses + autometamorphosed dolerites

0028-0836/80/390366—03$01.00

(lower continental crust); blueschist-facies eclogites (subducting ocean crust); Ulstein-Dimnöy eclogite (subducted ocean crust); Ulstein-Dimnöy "garnet-biotite-gneiss" (subducted argillaceous sediments); marbles (subducted carbonate sediments)] into preserved Precambrian amphibolite-facies country-rock gneisses (also occasionally into each other) by lithospheric interdigitation during two-continent collision[11,12]. The final emplacement event was presumably of Caledonide age[12,13]. Age relationships between the diverse rock types in the Basal Gneiss Region are noted for their complexity[8,12]; the tectonic events deduced here would have produced just such a complexity.

Concerning the Lien locality, of the three rock types described by Medaris[1] (an ultramafite boudin, eclogite boudins, and country-rock gneisses which envelop the boudins), P–T estimates are provided[1] only for the boudins. No evidence is presented for P–T estimates for the country-rock gneisses, although demonstration of the identicalness of P–T and time conditions for equilibration of the eclogites and country-rock gneisses is essential[11,12] to sustain the deduced[1] *in situ* model. The use[1] of assumed co-existing core mineral compositions for geothermobarometry must be suspect when the cores are, by definition, not co-existing, especially when the raw data on zoning patterns is not provided for critical assessment of possible coexistence; confident interpretation of mineral zoning is notoriously difficult, for example in garnet[14].

Low-P estimates[1,6,15] for eclogite equilibration derive mainly from the intersection of iso-$K_{D\,\mathrm{gt/cp}}^{\mathrm{Fe/Mg}}$ P–T dependent lines with iso-$X_{\mathrm{cp}}^{\mathrm{Jd}}$ minimum P-variable T lines yielding minimum P only. Medaris[1] follows Krogh[6,7] in regarding only these minimum P estimates (7–12 kbar[1]) as reflecting the true P. Their trends are thus only consistent[1] in their method of derivation, which would yield a linear positive $\mathrm{d}P/\mathrm{d}T$ trend for any set of eclogites with variable $K_{D\,\mathrm{gt/cp}}^{\mathrm{Fe/Mg}}$ and approximately constant $X_{\mathrm{cp}}^{\mathrm{Jd}}$. Their published data[1,6] are perfectly compatible with any P estimates along the iso-K_{D} lines, easily 10–20 kbar higher than the minima (compare with 15–40 kbar, estimated for other eclogite boudins from the same district[12]). A near-infinite variety of P–T trends is thus possible, including depressurization trends; the supposed "prograde" trend, said[1] to have been "established by Krogh[6]", clearly needs independent corroboration. Medaris[1] claims convergence of his eclogite and ultramafite P–T trends, but they barely converge in his Fig. 2. His inferred eclogite trend[1] lies alongside the basic granulite/eclogite transition[4] based on the low-T linear extrapolation of high-T experimental work[16], an extrapolation inconsistent with other data[17–19] which suggests higher P at low T. Even if the documented[1] prograde eclogite P–T trend at Lien[1], or regionally[6–8], is genuine, it contributes little to support the *in situ* hypothesis if an identical trend is not discernible in the country-rock gneisses, evidence for which is apparently completely lacking. Whilst recognizing the feasibility of generating eclogite iarageneses and granulite- or amphibolite-facies gneisses *in situ* from adjacent basaltic and granitic rocks in certain P–T-composition conditions, I would anticipate the common occurrence of co-existing omphacite + plagioclase in intermediate compositions, but I am not aware of their existence in the country-rock gneisses of this region.

High-P equilibration (> 15 kbar) of at least some eclogite boudins has been implied or specifically estimated by advocates of the foreign tectonic emplacement origin[2,3,11,12,17,20–22,24,25], whilst low P equilibration (<15 kbar) for all eclogite boudins has been implied or specifically estimated for some by advocates of the *in situ* origin[1,4,5,9,15,26–28]. Krogh[6] broke through the <15 kbar threshold by proposing P estimates up to 23 kbar. The significant fact that this estimate[6] lies beyond[11] the known stability field of any plagioclase composition has been bypassed[7] and apparently disregarded[1]. Hence accepting[1,7,8] Krogh's[6] postulated prograde regional P–T trend necessitates the annihilation, kinetics permitting, of each grain of abundant plagioclase in ≈ 4,000 km^2 of country-rock gneisses, yielding ubiquitous eclogite-facies parageneses. The expected evidence for this substantial event is notable for its paucity and dubious validity, apparently being confined[7,8] to depressurization symplectites after omphacite in gneisses around the Ulstein-Dimnöy eclogite[5,15]. Considering published data only, and noting especially: (1) the outcrop of the symplectite-bearing 'garnet–biotite–gneiss'[5,15,29] which occurs only in contact with this eclogite[15,29], and which is "remarkably garnet-rich"[5]; (2) the lack of symplectites reported specifically from the 'dioritic'[5,15,29] typical country-rock gneisses, which are more deformed[29] and migmatitic[15], and (3) the 'uncommon'[5] amphibolitized margins of the eclogite boudin, and its 'welded'[5] contacts, allows, and indeed supports, my alternative interpretation that the so-called 'garnet–biotite–gneiss' is not real country-rock gneiss, but is merely a contiguous layer of amphibolitized K-, Al-and Si-rich quartz-phengite-eclogite tectonically independent of the 'dioritic' real country-rock gneiss. If this is true, then the assertion[15] that this eclogite is a type example of *in situ* metamorphism would be unsubstantiated. Furthermore, taking the absence of plagioclase as one of the essential features of an eclogite-facies group of parageneses[2], the suggested "eclogite-facies metamorphic event"[1] within the country-rock gneisses would be as unfounded as the postulated depression of the country-rock gneisses to depths of ≈ 70 km[1,6,8].

MEDARIS REPLIES—There is increasing evidence in the Basal Gneiss terrane of western Norway for high-pressure metamorphism due to tectonic thickening of continental crust, probably related to a continent–continent collision of Caledonian age[1–3]. Thus, Smith's suggestion that the Basal Gneiss terrane has originated as a gigantic tectonic mélange due to lithospheric interdigitation during a continent–continent collision deserves evaluation by further field and petrological investigations. Such a model provides a plausible mechanism for emplacement of large ultramafic bodies, such as that at Lien, and would be consistent with the P–T patterns preserved in Norwegian garnet peridotites[4–6].

As Smith has suggested, there may be diverse origins and histories for country-rock eclogites in the Basal Gneiss. Nevertheless, there is now compelling chemical, petrological, textural, and structural evidence[1–3] for *in situ* prograde metamorphism of at least some of the eclogites, and the country-rock eclogites at Lien properly belong in this group.

Unfortunately, I feel that Smith has misrepresented three points in my paper. (1) The garnet-bearing ultramafic rocks and country-rock eclogites are relicts of an earlier eclogite metamorphism that are now surrounded by chlorite peridotite and middle grade gneisses, respectively, and the eclogite-facies rocks themselves have been retrograded to assemblages that are compatible with those in the enclosing rocks. (2) Admittedly, there is no certainty that equilibrium has been preserved between mineral cores. However, mineral cores have relatively uniform compositions within each sample, and different mineral grains within each sample yield consistent core temperatures[6]. (3) I clearly stated that pressure estimates for the country-rock eclogites at Lien, based on the jadeite content of omphacite, are minimum values only. Although many of Kroghs' pressure estimates for eclogites in the Basal Gneiss terrane are minimum values, as he stipulated, others are true estimates, based on the coexistence of orthopyroxene or phengite with garnet and omphacite.

GABA mediated circling from substantia nigra

THE dialogue between Waddington[1] and Martin and Haubrich[2] emphasizes the complexity of the interaction between striatal dopamine systems and nigral γ-aminobutyric acid (GABA) mechanisms as recently pointed out by Arnt and Scheel-Kruger[3]. This is particularly true when interpreting behavioural changes in terms of biochemical parameters. The effects of manipulating nigral GABA mechanisms on striatal dopamine release are complex. While nigral application of GABAergic drugs, such as muscimol, increases the firing rate of dopaminergic neurones[4], and the release of dopamine in the ipsilateral caudate nucleus[5-7], GABA itself exerts a biphasic action first stimulating and then inhibiting striatal dopamine release[8]. Furthermore, the nigral application of picrotoxin stimulates dopamine release in the striatum, an effect which is prevented or reversed by diazepam[9], which itself decreases dopamine release in striatum[10] (presumably by facilitation of nigral GABA transmission). Some GABAergic terminals (possibly those projecting to zona compacta) therefore seem to inhibit the activity of nigral dopamine cells, while others (possibly those projecting to zona reticulata) may indirectly activate the same nigral dopamine cells, perhaps via a GABA interneurone. Whether turning behaviour induced by the intranigral administration of muscimol is due indirectly to alteration of dopamine release in the striatum is disputed. In fact, the effect of intranigral injection of GABAergic compounds is critically dependent on the exact site of injection, an issue which has been neglected in the correspondence on this topic.

The initial observation of Tarsy and his colleagues[11] that picrotoxin injected into substantia nigra zona compacta caused contraversive rotation was followed by the discovery of Scheel–Kruger *et al.*[12] that ipsiversive circling resulted from the injection of picrotoxin into a caudal nigral site. Subsequently, James and Starr[13] (and, independently, ourselves[14]) demonstrated that the direction of rotation produced by injection of picrotoxin into rostral nigra is reversed on injection of this compound into caudal nigra, suggesting the existence of separate GABA mechanisms. We obtained similar findings injecting picrotoxin, and also muscimol in caudal and rostral nigra.

The circling produced by the action of muscimol or picrotoxin at each nigral site can be distinguished on the basis of its dependence on intact striatal dopamine mechanisms. Thus, while circling induced by injection of GABA-active compounds into rostral nigra is reduced by 6-hydroxydopamine lesions of the nigrostriatal pathway, or by systemically administered haloperidol, the same treatments are ineffective in inhibiting circling induced by manipulation of GABA mechanisms in caudal nigra[1,13,14]. These findings support Waddington's assertions of non-dopamine-mediated contraversive circling being induced by muscimol injected into substantia nigra zona reticulata[1]. The exact site used by Martin and Haubrich[5] is not clear, but must have involved caudal nigra as muscimol induced contraversive rotation. However, the muscimol perfused into substantia nigra also may have reached GABA receptors in rostral nigra to activate the ascending nigro-striatal pathway so causing increased striatal dopamine release. This would account for the simultaneous occurrence of these phenomena.

The argument as to whether or not the striataldopamine release caused by intranigral muscimol is responsible for contraversive circling is redundant. The circling behaviour initiated by an asymmetry of striatal dopamine function is clearly mediated by strio-nigral fibres and the substantia nigra. Thus, lesioning of the descending strio-nigral pathway prevents contraversive circling behaviour induced by the administration of apomorphine to animals with a unilateral 6-hydroxydopamine lesion of the nigro-striatal pathway[15]. In addition, kainic acid-induced destruction of neurones in substantia nigra zona reticulata, or the injection of picrotoxin or bicuculline into nigra ipsilateral to a 6-hydroxydopamine lesion of the nigro-striatal dopamine pathway, results in reduction, abolition or reversal of the contraversive rotation produced by apomorphine[16]. All these data point to a primary role of a neuronal pathway from caudal nigra independent of dopamine, which is responsible for the mediation of the circling phenomena. The importance of this nigral mechanism is emphasized by the work of Papadopoulos and Huston[17] who showed that spontaneous circling behaviour induced by a unilateral electrolytic lesion of substantia nigra was not influenced by the removal of the telencephalon (including striatum and neocortex). Indeed, we have demonstrated that a hemi-transection rostral to nigra severing all rostral nigral afferents and efferents does not attenuate contraversive circling induced by intranigral administration of muscimol (unpublished observations).

In conclusion, we support Waddington in his assertion that the contraversive circling due to intranigral muscimol administration is not due to striatal events. There can be little doubt as to the importance of a non-dopaminergic nigral output pathway in the mediation of circling behaviour. The nature of this pathway remains unknown as does its target site. It does not seem to involve the known projections of the nigra to the superior colliculus[18] or thalamus[19] and we are now investigating the involvement of nigroreticular pathways.

BOOK REVIEWS

A question of language

Jean Berko Gleason

Nim: A Chimpanzee Who Learned Sign Language. By Herbert S. Terrace. Pp. 384. (Knopf: New York/Eyre Methuen: London, 1980.) $15, £6.50.

WHY would anyone want to try to teach a chimpanzee the sign language used by deaf human beings? For at least two compelling reasons. The first has to do with linguistic questions: is language a strictly human phenomenon, or is it possible that intelligent animals such as chimps, which are physiologically unable to speak, are nonetheless capable of combining symbols in a structured, grammatical way? The second reason is related to what Donald R. Griffin calls "the question of animal awareness": is it possible that we can teach non-human creatures to communicate to us their ideas, thoughts, their world view?

These tantalizing questions about language and cognition are what motivated Herbert S. Terrace, a Professor of Psychology at Columbia University, to adopt an infant male chimpanzee, whom he named Nim Chimpsky (Nim for short) after the linguist Noam Chomsky, a proponent of the view that only humans possess the special innate abilities that make true language possible. According to this view, language is a species-specific capacity, and all human languages share certain grammatical similarities because of the constraints imposed by the human intellect. Thus, all languages are composed of a small number of elements that can be combined in a great variety of utterances, have classes of words that roughly correspond to nouns and verbs, and so on. The fact that only humans possess language and that human infants master the complexities of their native tongue in just three or four years in a fairly effortless way and without extensive tutelage is evidence for the innatist view. By contrast, behaviourists hold that language is not basically different from other behaviours, and that its presence depends primarily on establishing a suitable system of rewards for linguistic behaviour.

Terrace himself has an extensive background in the behaviourist tradition, and in preparation for this project familiarized himself with the literature on language acquisition by children. His plan was to raise Nim in a rewarding human environment, teaching him American Sign Language (ASL), and then to analyse in a rigorous and linguistic way the young chimp's emerging ability to produce one sign at a time and later to combine signs into longer 'utterances'. There are, of course, other apes who have learned sign language, the first and most famous being Beatrice and Allen Gardner's Washoe; and there are apes who have learned to produce certain kinds of messages by manipulating plastic symbols or by striking the appropriate keys on a computer console. Project Nim was to go beyond these by providing a detailed record of Nim's acquisition of ASL, paying special attention to any evidence that he could produce grammatical signed sentences.

While the book gives a good picture of what it is like to live with an ape in New York City, and details the problems the project had in recruiting and keeping the 60 dedicated ASL teachers who worked with Nim, the essence of the book lies in its linguistic argument. The chimp's signed utterances were analysed for evidence of structure in much the same way as is young children's spoken language. By comparison, the chimp was found wanting. Even though he amazed everyone by producing his first ASL sign (*drink*) before the age of four months, his later utterances never went much beyond the two-sign stage. Reviewing the recorded utterances, the author concludes that "his three-sign combinations do not . . . provide new information. Consider, for example, Nim's most frequent two- and three-sign combinations: *play me* and *play me Nim*. Adding *Nim* to *play me* is simply redundant". Since tables of the most frequent combinations are provided, it is possible for the reader to do some armchair analysis, and in this case the conclusion appears to be based on a rather selective view of the data; there are a number of instances listed where a three-sign combination seems to build on earlier two-sign combinations in a way that very much resembles children's language. At the two-sign stage, for instance, Nim said *eat Nim*, while the three-sign list contains elaborations like *more eat Nim* and *banana eat Nim*. This begins to look like structure, but the four-sign combinations are not only very rare, they are all of the redundant *eat drink eat drink* variety. Most of Nim's signing had to do with eating, drinking and playing, but from time to time we are given a glimpse of the young chimp paging through a book and softly signing to himself the names of the things he sees.

Nim at work with one of his teachers

Nucleic Acids Synthesis: Applications to Molecular Biology and Genetic Engineering.

Proceedings of the International Symposium on Chemical Synthesis of Nucleic Acids. Held May 1980 in Egestorf, West Germany. Nucleic Acids Symposium Series No. 7

In the fields of molecular biology and genetic engineering, synthetic nucleic acids and their constituents have proved to be valuable tools and their uses appear to be infinite. In the present era of 'synthetic biology' it is not surprising that the chemical synthesis of nucleic acids is experiencing a tremendous renaissance. This symposium, which has brought together the experts from all over the world, centres around recent synthetic improvements and their numerous applications.

Circle No. 17 on Reader Enquiry Card

In the end, the author concludes that there is no evidence that chimps can produce sentences. Moreover, analysis of the project's videotapes indicated that most of his signed utterances were prompted by a teacher and contained major constituents of the teacher's previous utterance. Only 10% of Nim's utterances were spontaneous. Furthermore, he showed little ability to hold a conversation; he tended to interrupt his teachers frequently and to be unaware of the notion of taking turns.

Terrace carried his argument further by analysing films from other ape language projects and arriving at the same conclusions. Like the turn-of-the-century horse prodigy, Clever Hans, who appeared to do sums in his head and tap out the answers with his hoof, the signing apes appear to be responding at least in part to subtle cues from their trainers.

Reports of Terrace's work have been widely disseminated. Understandably, they have added to the ape-language controversy, and counter-arguments from other researchers have begun to appear. The author himself, at the end of the volume, explains why he thinks Nim's full linguistic potential may not have been realized, and he outlines a million dollar plan that he believes would produce greater success in a future project.

Language is the central issue, but the book also offers some rare insights into the personality of a bright young chimp. There are some fine photographs, and an informative appendix devoted to sign language. While the definitive work on language in apes has yet to appear, this is certainly both a scholarly and well-written one. ☐

Jean Berko Gleason is Professor of Psychology at Boston University.

Eclipsing binary light curve analysis

Joel A. Eaton

Language of the Stars: A Discourse on the Theory of the Light Changes of Eclipsing Variables. By Zdeněk Kopal. Pp. 280. (Reidel: 1979.) Hardback Dfl. 120, $63; paperback Dfl. 55, $28.95.

THIS book is written for an exceedingly small audience of specialists, or would-be specialists, involved in eclipsing binary light curve analysis. Contrary to the publisher's claim on the back cover, it is not a suitable book for amateur astronomers — other than those with doctorates in theoretical physics. Likewise, it would be inappropriate as a text for a university course about double stars as its content is too narrowly defined, while the references are almost completely restricted to the work of Kopal and his associates.

Throughout the book, Kopal seems to be re-fighting his traditional battle against the Russell model for calculating light curves. In doing this he has for the most part ignored the important work on the synthesis of light curves in the past decade, in which electronic computers have been used to integrate numerically over the visible surfaces of the components of a model binary system the light received at a distant point. This approach, developed by Leon Lucy, Robert E. Wilson and Graham Hill, to mention but a few of the more important contributors, has practically superseded the Russell model for application to tidally distorted binaries. Yet it rates only a few sentences of disparagement from Kopal.

The subject of this book is a method for determining the geometry of an eclipsing binary star by the Fourier analysis of its light variation, a technique already used extensively by others, Sławek Ruciński for example (*Acta Astronomica* **23**, 79; 1973), in studies of the light curves of W Ursae Majoris binaries. The classical method of analysing such light curves is to calculate a theoretical light curve for an assumed set of geometrical and photometric elements, compare these calculations with the observations of brightness as a function of orbital phase, and modify the elements to produce a better fit.

Kopal has devised a scheme for relating the geometrical elements of the model to certain properties of the Fourier transform of the light variation. Specifically, he has derived complicated algebraic equations relating geometrical elements and certain Fourier coefficients. However, after roundly criticizing the Russell model for basing a light curve solution on only three fixed points on the light curve (as was done in the early days), Kopal goes on to base his Fourier-analysis solutions on the power at only four frequencies in the Fourier transform. Indeed, nowhere in the book does he illustrate the Fourier transform of a light curve. ☐

Joel A. Eaton is a Research Associate at the Dyer Observatory of Vanderbilt University, Nashville, Tennessee, who specializes in studies of eclipsing binary light curves.

Inspec have just published *Ion-Solid Interactions: A Comprehensive Bibliography*, compiled by Walter M. Gibson and Henry H. Teitelbaum. The bibliography, which consists of three volumes — *Bibliography, Permuted title index* and *Author-title index* — and contains more than 12,000 references, is available from Inspec, Nightingale Road, Hitchin, Herts, UK, price £95, $195.

Archaeological chemistry for the curious

Robert Hedges

Archaeological Chemistry. By Z. Goffer. Pp. 376. (Wiley-Interscience: 1980.) £15.20, $33.

THIS book should appeal most to those wishing for a quick canter around the field of applications of chemistry to archaeology. The first 75 pages give a crash course in chemistry — atoms and molecules in one page, analytical techniques in about 30 — so that, having learnt to sit in the saddle and keep his eyes open, the reader is briskly shown all the major 'sights' of archaeological chemistry.

With research in this area flourishing at present, the scenery is rich indeed. Topics range from ancient cement-making to amino-acid racemization dating; from metal corrosion and its conservation to the identification of dyes used in antiquity. As might be expected, most space is reserved for accounts of ceramics and of metallurgy, but room is also found for such less-common subjects as palaeotemperature measurement, soil surveys and authentication. Faced with all this, inexperienced readers will be grateful that the treatment of each topic is, perhaps inevitably, superficial. However, they will obtain a clear idea of the extent to which scientific definition can be imposed on the material with which the archaeologist deals, and a notion of some of the surprising results that can follow from the careful use of analytical techniques. References to original literature are frequently cited, although to benefit from them would demand a deeper knowledge than is provided by this book. The style is relaxed, but never unscientific, and the few mathematical hurdles that have not been avoided are taken easily.

Nevertheless, I doubt that the reader will finish the book with any specific knowledge of the kind of research being conducted now, either in terms of individual work or as more synoptic problems (for example, the geographical exploitation of tin during the Bronze Age, the invention of glazing technologies or the dissemination of iron smelting techniques). Nor would I expect an archaeologist reading this book to be much better able to evaluate critically the results of his colleagues' work. For example, in an area where such cooperation is particularly active — the determination of pottery provenance from the comparison of trace element distributions — the subject is treated in just four pages, has no mention of the statistical problems and only a hint of geochemical difficulties.

The subtitle, *A Sourcebook . . . ,* makes claims that are not lived up to. Important books and journals are omitted in the bibliography, and comparatively few references are given beyond 1975. To cover such a field with authority would require a much more penetrating book. However, no other single volume attempts to cover such wide ground, and this one can be recommended to those whose interest is based on curiosity rather than knowledge. ☐

Robert Hedges is at the Research Laboratory for Archaeology, University of Oxford.

Will we use the ocean wisely?

Henry Charnock

Opportunities and Uses of the Ocean. By D. A. Ross. Pp. 320. (Springer-Verlag: 1980.) DM39.50, $21.80.

ONCE upon a time and a very good time it was oceanography was the profession of a small number of (almost all) men. They devoted their energy, skill and persistence, and sometimes their money, to exploring, measuring and seeking to understand the complicated structure and motion of the sea. Not, one supposes, in the hope of immediate financial gain; apart from pioneers like Maury and Fitzroy, who realized that an understanding of winds and currents could shorten sailing-ship passages and improve their owners' profits, most of the early marine scientists seem to have had only the most general notion that knowledge of the sea would prove useful.

Energy from under the sea — a natural-gas rig in the North Sea

Much more effort has been devoted to marine science since the Second World War, and even more money has been poured in since the great powers decided to deploy their nuclear weapons in submarines instead of aircraft. A vast amount of money is now spent in studying the ocean but with changed and more explicit motives — science is increasingly linked with technology and oceanic exploration has given way to exploitation, to the winning of food, minerals and energy and to the dumping of waste.

Not all of the proposed uses of the ocean are compatible and divergent views are strongly held by a range of interested groups. Dr Ross has set himself the question: "Where is the truth — what are the real problems and opportunities associated with the ocean?" He has attempted "to present some basic information about the ocean in a form that will be understandable to people who are not oceanographers, but who are interested and concerned about the marine environment". So the problems he is concerned with are not so much about the science as about the politics and legalities, while the opportunities are not to understand how the system works but how it can be exploited in a sensible (sustainable?) way.

An objective assessment needs the basic facts, so he gives 30 pages or so on "how the ocean works". It is difficult to compress such a broad subject into so little space — three pages to physical oceanography, for example — so it is not surprising that some of the explanation seems fluent rather than exact.

With finance as the only criterion, the most important users of the ocean are the navies of the world. Figures are hard to come by but it seems clear that a vast sum is spent each year on a range of activity and equipment mainly concerned with the detection of submarines. Anti-submarine warfare is a multi-billion dollar industry.

So the opacity of the ocean to electromagnetic radiation, which makes it dark, cold and mysterious, has led to a huge expenditure of scientists' time and taxpayers' money. Fortunately, perhaps, even though the (mainly acoustic) detection systems are complex the modern submarine is relatively safe in the ocean. Ross quotes a comparison between anti-submarine warfare and a game of baseball with the fielders blindfolded. And it is increasingly a game played between only two players, USA versus USSR, both of whom use the ocean as the location of their major weapon systems, their so-called 'second strike' capability. Because both nations have nearly undetectable submarines with frightening nuclear weapons, Ross argues that the opacity of the ocean deters them from starting a nuclear attack — an optimistic view.

If the opacity of sea water is important to submarines its combination of high density and low viscosity is fundamental to merchant shipping; surface ships remain the only practicable way of transporting heavy and bulky cargo over intercontinental distances. Next to military activity the shipping industry spends most on marine affairs (about 10^{11} dollars/year is said to go on building, maintaining and repairing ships). Ships and shipping have changed a great deal in recent decades: passenger liners are no more and cargo ships have become much more specialized, especially as regards the handling and stowage of their loads. They now need far smaller crews and in spite of much improved navigational aids collisions and other accidents still happen. Such catastrophes may lead to acute pollution of the *Torrey Canyon* type and one sympathizes with Ross's advocacy of "clear and positive control of ships, especially near or within coastal waters". But a comparison of aircraft and marine traffic control shows that this will need significant changes in the education and attitude of seafarers: this is a sociological problem which badly needs study.

The resources of the ocean with which most people are familiar are animal and mineral (it seems unlikely that the vegetable phytoplankton will be harvested in bulk, though seaweed is an important product and its cultivation a new and growing industry). There is much argument about the total amount of fish and related creatures that could be safely harvested — perhaps 2×10^8 tons/year is an optimistic figure. But it seems clear that marine biological resources are not the answer to the basic food problem posed by half the world's population being short of protein. Poorly understood and rather ineffectively controlled, fishing is perhaps the classical example of a non-profit industry. There may be an opportunity to exploit hitherto untaken species (krill is the obvious example); one can improve processing so as to convert trash fish into palatable products; one can develop and improve aquaculture techniques. All these will help supplement the world's protein requirements but seem unlikely to make a major contribution.

Mineral, as distinct from biological, marine resources provide a clearer problem. Most are not renewable so the problem is to find them, extract them and process them, without harming the environment. Here Dr Ross is on home ground, giving a clear account of the probability of exploiting the sediments of the Red Sea brine pools and of the possibility of using the better known manganese nodules. In shallower water offshore hydrocarbons are already a major industry, and will be for decades. Their yearly value (about 4×10^8 dollars) already exceeds that of fisheries.

Marine pollution is a diffuse and ill-defined subject. There is a great lack of information on sources, cycles and sinks of chemicals in the sea. Much of the most objectionable material comes from industrial sources, mainly in developed countries (the degree of marine pollution correlates closely with gross national product). So it would be possible, at a price, to control it at source. This is one of the points made strongly by the developing nations at the UN Conference on the Law of the Sea, and one can readily sympathize with their point of view. Not much interested in the military and shipping aspects, they are concerned to ensure that the industrialized nations do not gain a disproportionately large share of the (perhaps over-stated) marine resources. The scientific study of the ocean comes relatively low on their list of priorities (after agriculture, roads, hospitals, literacy and such) so they see little harm in the pace of marine research being slowed down. Even the so-called developed nations prefer to gain control over as much of the ocean and seabed as possible rather than to make it free for oceanographers to study the basic phenomena.

Ross ends with a chapter "Innovative Uses of the Ocean", including energy from the sea; climate and the ocean; fresh water from the sea; drugs from the sea; disposal of nuclear waste; research on satellite oceanography; the prospects for offshore islands. Again the chapter is too short to do justice to the variety of topics and the author has not been able to polish his writing sufficiently. Altogether the book, though superficially attractive, gives the impression that it would have been much improved by more attention to detail, both in text and illustration. The photographs are good but some of the map projections unfortunate; the text has confusing expressions and rather a lot of minor misprints, even in the prefatory poem (*The Sea and the Hills,* from Kipling's *The Five Nations* — and a good example of his sound and fury style it is).

No one could possibly disapprove of the author's motives — it would be marvellous if politicians and lawyers and admirals and (perhaps especially) multi-national moguls knew and cared more about the sea. But I fear it will need more than a book like this.

Henry Charnock is Professor of Physical Oceanography at the University of Southampton.

Soil sugars for the soil scientist

M. Schnitzer

Nature and Origin of Carbohydrates in Soils. By M. V. Cheshire. Pp. 216. (Academic: 1980.) £15.80, $36.50.

ABOUT 10% of the organic matter in soils occurs as carbohydrates — mainly in the form of polysaccharides comprised of at least seven neutral, two acidic and two basic sugars — which originate from plant and animal remains and from microbial syntheses. From an agricultural point of veiw, their most important functions are to supply microorganisms with readily available food and to bind soil particles into stable aggregates which improve soil aeration, root development and ease of cultivation, and prevent erosion.

The first four chapters of this book deal with the composition and analysis of carbohydrates and polysaccharides in soils. Especially useful are recommended procedures for the hydrolysis and analysis of freed sugars, uronic acids and amino sugars by colorimetric, gas chromatographic and enzymatic methods. A problem in such analyses is that polysaccharides in soils appear to be chemically linked to proteins and humic materials; so far separation from humic materials has been more successful than from proteins.

The next section is concerned with the metabolism of carbohydrates in soils. Incubation experiments with ^{14}C-labelled glucose show that while microorganisms can synthesize soil sugars, the overall composition of microbial polysaccharides differs from that of soil polysaccharides as a whole and can only account for a part of it. It is estimated that the live biomass constitutes only 2.5% of the weight of soil carbohydrates.

The author has made a very useful contribution by bringing together the essence of widely scattered literature published over a period of 85 years. To the best of my knowledge this is the first book to deal with carbohydrates in soil; its appearance will be welcomed by those interested in the chemistry, biology and management of soil organic matter. ☐

M. Schnitzer is Program Leader of soil chemistry and biology research at the Chemistry and Biology Research Institute, Agriculture Canada, Ottawa.

ANNOUNCEMENTS

Awards

Three Royal Medals, known also as The Queen's Gold Medals, of the Royal Society are to be awarded to: **Sir Denys Wilkinson** (Vice Chancellor of the University of Sussex); **Professor Henry Harris** (Regius Professor of Medicine in the University of Oxford); **Dr J. P. Wild** (chairman of CSIRO).

The Council of the Royal Society has made the following award of medals: The Copley Medal to **Sir Derek Barton** (L'Institut de Chemie des Substances Naturelles, Gilf-sur-Yvette France); The Rumford Medal to **Professor W. F. Vinen** (University of Birmingham); The Davy Medal to **Professor A. W. Johnson** (University of Sussex); The Darwin Medal to **Professor S. Wright.** (University of Winsconsin); The Hughes Medal to **Dr F. J. M. Farley** (Royal Military College of Science, Shrivenham); The Mullard Prize and Medal to **Sir Edward Abraham** (University of Oxford). The Council has awarded the Royal Society Wellcome Foundation Prize for 1980 to **Dr C. Milstein** (University of Cambridge).

The 1980 Paul-Martini-Prize has been divided between **Dr Winfried Gunselmann** (Institut für Medizinische Dokumentation und Statistik der Universität Erlangen-Nürnberg) and **Professor David Grahame-Smith, Dr Jeffrey Aronson** and **Dr Alan Ford** (University of Oxford).

The recipients of the Wolf prizes — 1980 are: in agriculture, **Professor Karl Maramorosch** (Rutgers University, New Jersey); in mathematics, **Professor Emeritus Henri Cartan** (Université de Paris) and **Professor Andrei N. Kolmogorov** (Moscow State University); in chemistry, **Professor Henry Eyring** (University of Utah); in physics; **Professor Michael E. Fisher** (Cornell University, Ithaca), **Professor Leo P. Kadanoff** (Brown University, Providence) and **Professor Kenneth G. Wilson** (Cornell University, Ithaca); in medicine, **Dr César Milstein** (Medical Research Council), **Professor Leo Sachs** (The Weizmann Institute of Science) and **Dr James L. Gowans** (Medical Research Council).

The Wellcome Trust have awarded the following Senior Lecturerships in medical and veterinary science: **Dr J. K. Aronson** (University of Oxford); **Dr B. Burchell** (University of Dundee); **Dr M. J. Doenhoff** (London School of Hygiene & Tropical Medicine); **Dr S. E. File** (University of London); **Dr S. L. Lightman** (St Mary's Hospital Medical School); **Dr S. Tomlinson** (University of Sheffield); **Dr R. D. Ward,** (Liverpool School of Tropical Medicine); **Dr I. K. Welsh,** (Royal Postgraduate Medical School).

The next prize of the Foundation de Physiopathologie Professeur Lucien Dautrebande for work on human or animal clinical physiopathology, will be awarded during 1982. Further information from: The Office of the Foundation, 35, chaussée de Liège à 5200 Huy, Belgium.

Appointment

Alan R. Katritzky, former Professor of Chemistry in the University of East Anglia, has been appointed from 1 August, to the new Kenan Chair of Organic Chemistry at the University of Florida, Gainesville.

Meetings

20-21 October **Waste Utilization,** Chicago (S. A. Bortz, ITT Research Institute, 10 West 35th St, Chicago, Illinois 60616).

27 October, **Enzyme Mechanisms and the Design of Enzyme Inhibitors,** London (Conference Secretariat, Society of Chemical Industry, 14 Belgrave Square, London SW1, UK).

27-28 October, **Managing Periodicals Profitably,** London (Benn Business Promotions Ltd, Press House, 25 High St, Edenbridge, Kent, UK).

28 October, **The Resources and Resourcefulness of Agriculture,** London (PA to the Director, The Ciba Foundation, 41 Portland Place, London W1, UK).

27-31 October, **1980 Photovoltaic Solar Energy Conference,** Cannes (Mr D. Nicolay, Commission of the European Communities, DGXIII A, Kirchberg, Luxembourg).

29 October, **Food Science and Technology in Developing Countries,** Glasgow (Institute of Food Science and Technology, 105-111 Euston St, London NW1, UK).

29-30 October, **The Manipulation of Genetic Systems in Plant Breeding,** London. (The Royal Society, 6 Carlton House Terrace, London SW1, UK).

2-5 November, **Applications of Accelerators in Research and Industry,** Texas (Conference on Application of Accelerators, PO Box 5368, NTSU Station, Denton, Texas 76203).

4-5 November, **Planetary Exploration,** London (The Royal Society, 6 Carlton House Terrace, London SW1, UK).

6 November, **Is It a Virus?** London (The Royal Society, 6 Carlton House Terrace, London SW1, UK).

7 November, **Nutrition and Diabetes,** Edinburgh (Dr M. I. Gurr, Shinfield, Reading, UK).

11-13 November, **The Food Industry and its Effluents: Treatment and Conservation,** Norwich (Mrs H. Gibbons, AHS, Owles Hall, Buntingford, Herts, UK).

12-13 November, **The Perception and Assessment of Risk,** London (The Royal Society, 6 Carlton House Terrace, London SW1, UK).

20-21 November, **Interaction of the Platelets and the Vessel Wall,** London (The Royal Society, 6 Carlton House Terrace, London SW1, UK).

24 November, **The Physics of Microwave Devices,** London (The Meetings Officer, 47 Belgrave Square, London SW1, UK)

24-28 November, **Combination Processes in Food Irradiation,** Colombo (PO Box 100, Vienna International centre, A-1400 Vienna, Austria).

25 November, **Memory Its Function, Technology and Impact,** London (The Royal Society, 6 Carlton House Terrace, London SW1, UK).

26 November, **Instrumentation and Analysis — Remember the Burette?,** London (Society of Chemical Industry, 14 Belgrave Square, London SW1, UK).

27-28 November, **Gamma ray Astronomy,** London (The Royal Society, 6 Carlton House Terrace, London SW1, UK).

10-12 November, **Automated Instrumentation for the Analytical laboratory,** Central New Jersey (The Centre for Professional Advancement, East Brunswick, New Jersey 08816).

17-19 November, **Practical Mass Spectrometry,** Central New Jersey (The Centre for Professional Advancement, East Brunswick, New Jersey 08816).

2-4 December, **Offshore :Environment in the 80s,** St John's Newfoundland (Information and Public Relations Officer, Killam Labrary, Dalhousie University, Nova Scotia B3H 4HB).

3-5 December, **Practical Colorimetric Chemical Analytical Methododology,** Central New Jersey (The Centre for Professional Advancement, East Brunswick, New Jersey 08816).

9-12 December, **Industrial Membrane Technology,** Central New Jersey (The Center for Professional Advancement, East Brunswick, New Jersey 08816).

15-17 December, **Applied Absorption Technology,** Central New Jersey, The Center for professional Advancement, East Brunswick, New Jersey 08816).

15-19 December, **Genetic Engineering,** Washington (Battelle, Memorial Institute, 505 King Avenue, Columbus, Ohio 43201).

7-9 January, **Plastics Additives,** Central New Jersey (The Center for Professional Advancement, East Brunswick, New Jersey 08816).

27 January, **New Forms of Silicon for Use in Semiconductor Devices,** London (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1, UK).

3-6 February, **Industrial Membrane Technology,** San Fransisco (The Centre for Professional Advancement, East Brunswick, New Jersey 08816).

8-15 February, **Immunoglobulin Idiotypes and their Expression,** Salt Lake City (ICN — UCLA Symposia, Molecular Biology Institute, University of California, Los Angeles, California 90024).

15-20 February, **Differentiation and Function of Hematopoeitic Cell Surfaces,** Keystone (ICN — UCLA Symposia, Molecular Biology Institute, University of California, Los Angeles, California 90024).

22 February — 1 March, **Mechanisms of Chemical Carcinogenesis,** Keystone (ICN — UCLA Symposia, Molecular Biology Institute, University of California, Los Angeles, California 90024).

1-8 March, **Cellular Recognition,** Keystone (ICN — UCLA Symposia, Molecular Biology Institute, University of California, Los Angeles, California 90024).

8-12 March, **Genetic Variation among Influenza Viruses,** Salt Lake City (ICN — UVLA Symposia, Molecular Biology Institute, University of California, Los Angeles, California 90024).

9-13 March, **Structure and DNA Protein Interactions of Replication Origins,** Keystone (ICN —UNCLA Symposia, Molecular Biology Institute, University of California, Los Angeles, California 90024).

15-20 March, **Development Biology using Purified Genes,** Keystone (ICN — UCLA Symposia, Molecular Biology Institute, University of California, Los Angeles, California 90024).

30 March-3 April, **The Theory and Practice of Solid Dosage Form Manufacture,** London (Mr R. E. Marshall, Dept of Pharmaceutical Sciences, The Pharmaceutical Society of Great Britain, 1 Lambeth High St, London SE1, UK).

30 March-2 April, **Viral Hepatitis, New York** (New York University Postgraduate Medical School, 550 First Ave, New York, New York 10016).

5-11 April, **The Sea in the Service of Man,** Monaco (International Bureau, 16 Regency St, Westminster, London SW1, UK).

5-10 April, **2nd European Congress of Biotechnology,** Eastbourne (ECB2 Secretariat, Society of Chemical Industry, 14 Belgrave Square, London SW1, UK)

6-10 April, **Time and Space in the Emergence of the Atmosphere,** London (R. W. Simms, Dept of Zoology, British Museum (Natural History), Cromwell Road, London SW7, UK).

7-9 April, **Assessment of Imaging Systems,** Reading (Sira Institute Ltd, South Hill, Chislehurst, Kent, UK).

7-10 April, **Properties of Oriented Polymers,** Leeds. (The Institute of Physics, 47 Belgrave Square, London SW1, UK).

8-10 April, **Spring Meeting — Association of Radiation Research,** Dundee (Dr I. V. Chapman, Dept of Medical Biophysics, University of Dundee, UK).

13-16 April, **Electroanalysis in Clinical, Environmental and Pharmaceueutical Chemistry,** Cardiff ((Short Courses Section Electroanalysis Symposium), UWIST, Cardiff, UK).

29 April-1 May, **Energy Storage,** Brighton (BHRA Fluid Engineering, Cranfield, Bedford, UK).

2 June-3 July, **Advanced Training of Foreign Participants in Remote Sensing — Geologic Interpretation,** Flagstaff (John A. Reinemund, US Geological Survey, National Centre — M/S 917, 12201 Sunrise Valley Drive, Reston, Virginia 22092).

7-12 June, **International Leucocyte Culture Conference,** Heidelberg (Dr H. Kirchner, Instiut für Virusforschung, DKFZ Im Neuenheimer Feld 280, D-6900 Heidelberg, FRG).

22-26 June, **Affinity, Chromatography and Related Techniques,** Nijmegen (Dr T. C. J. Gribnau, Kathlieke Universiteit, Nijmegen, The Netherlands).

22-27 June, **3rd European Symposium for Stereology,** Ljubljana (Prof. Dr M. Kalisnik, Institute for Histogy and Embryology, PO Box 10, 61105 Ljuljana, Yugoslavia).

19-24 July, **Chemotherapy,** Florence (Secretariat, 12th International Congress of Chemotherapy, Via della Scala, 10, Florence, Italy).

21-30 July, **General Assembly of IASPEI,** Ontario (Prof. A. E. Beck, Dept of Geophysics, University of Western Ontario, London, Ontario, Canada N6A 5B7).

11-12 August, **Open Symposium on Remote Sensing,** Washington (Dr D. L. Croom, Rutherford and Appleton Laboratories, Ditton Park, Slough, Berks, UK).

17-22 August, **Earth Tides,** New York (J. T. Kuo, Columbia University, New York, 10027).

23-28 August, **Solar World Forum,** Brighton (UK ISES, 19 Albemarle St, London W1, UK).

23-29 August, **7th International Biophysics Congress and 3rd Pan-American Biochemistry Congress,** Mexico City (Cerrada de Popocate-petl, México 13 D.F. Mexico).

31 August-3 September, **Computer Applications in Fermentation Technology,** Manchester (Society of Chemical Industry, 14 Belgrave Square, London SW1, UK).

9-11 September, **Radiopharmacology,** Chicago (Dr L. G. Colombetti, Pharmacology Dept, Loyola University, Stritch School of Medicine, Maywood Ilinois 60153).

Essential information at your fingertips

Every month!

The British Journal of Clinical Pharmacology is the leading authoritative journal presenting results of clinical pharmacological research.

Published monthly on behalf of the British Pharmacological Society the journal:

★ Bridges the gap between medical professions, clinical research and the Pharmaceutical industry.

★ Contains papers and reports on all aspects of drug action in man, in both health and disease.

★ Prints letters and short communications which allow immediate discussion of urgent observations.

Subscribers to British Journal of Clinical Pharmacology receive, free of charge, the proceedings of selected symposia on new methods, new drugs, and new approaches to treatment. Some past symposia have been on narcotic antagonists and antagonist analgesics, labetalol, clobazam mianserin, temazepam and the relationship between angina pectoris and hypertension.

Why not join the growing number of clinical pharmacologists, clinicians and others who rely on the British Journal of Clinical Pharmacology as their information medium.

What is wrong with US engineering?

To many of those outside the United States, the recent wave of anxiety about the quality of engineering in the United States, and the rate of industrial innovation in American industry, will seem curiously self-indulgent. How can it be, the question will be asked, that the industrial state which, since the turn of the century, has been the dominant source of new technology, and whose people now enjoy unprecedented and unparalleled prosperity largely as a result of past innovation, should so suddenly take fright? Is there something real to worry about? Or is it just another election stunt? What can be learned from experience elsewhere? And what, in any case, can be done?

The speed with which public concern has blown up is breathtaking, almost bewildering. The trigger appears to have been the recognition that the rate at which automobiles imported into the United States, especially those from Japan, may not be halted by the launching of the new indigenous products of the three principal automobile manufacturers, apparently more resolute than before to market vehicles that people are likely to want to buy as gasoline prices keep on increasing. The discovery, or rather the recognition, that the American car industry is less productive, man for man, than its Japanese competitor seems to have helped dramatize more problems of wider long-term significance — the weakness of the dollar, itself dependent on the continuing deficit of overseas trade and, to some extent, on the federal government's own domestic deficit.

In truth, this process of the discovery of crisis in the United States puts the cart before the horse. There have been signs of trouble for much longer than a decade. Since the early 1960s, and before the monetary rot set in, productivity (measured on a man by man basis) has been growing less quickly in the United States than in most other industrialized countries (the United Kingdom and, more recently, Italy excepted). Between 1955 and 1977, the annual growth of productivity in the United States has been an average of 2 per cent per year, only a third of the annual increase of productivity in Japan during the same period. More recently, there have been signs that the rate of investment in manufacturing industry has been declining (as a proportion of national wealth) as consumers have kept on spending, or providing funds for the federal government to spend on their behalf. Where, people are beginning to ask, will it all end?

The first need is not to take fright. There are some respects in which the relatively poor record of recent years is a consequence of earlier success. Thus the displacement of a large part of the labour force from manufacturing industry to the service industries, whose potential productivity is inherently less, implies that the rate of growth of productivity is likely to decline. In this respect, the rate of growth of productivity in the United States has been traded for the availability of health services, education and the like, which Americans have come to think of as essentials, which they would indeed prefer to see improved — and which they are well-heeled enough to afford. The concern in the past decade about environmental quality, and the regulations and restrictions which have followed, have similarly been bought with diminished growth of productivity. (This is not to say that environmental regulations should be swept away but merely that environmental quality is a public purchase; Dr Barry Commoner, the presidential candidate for the People's Party in November, is after all forever saying that "there is no such thing as a free lunch".) Success and prosperity spawn problems in other ways. It is necessarily harder to break new ground, as the United States has been doing for the past century, than to follow a path already trodden. In a world in which international trade is acknowledged to be an important stabilizing influence, and in which attempts to bend the rules are relatively infrequent, it is inevitable that countries at the top, like the United States, will find their industrial supremacy in traditional fields from time to time eroded. Whole industries, footwear for example, have disappeared in the past; others (steel?) will do so in the future. If the automobile industry should find, next spring, that it cannot keep imports at bay, that will not mean that the world has come to an end but merely that the pattern of industrial production is being shared out internationally and economically.

That, at least, is what the textbooks say. The message will bring very little comfort to a Detroit in greater trouble even than at present. But there is a sense in which the pattern of industrial change cannot indefinitely be postponed, or can be forfended only at enormous and increasing cost. Several European countries have learned this lesson the hard way. British shipbuilding is merely the most obvious. In the United States, however, as elsewhere in the industrialized world, the record of the past few years has been confused by the consequences of the curious mixture of deflation and inflation ushered in by the first dramatic increases of the price of oil in the second half of 1973. By now there is ample evidence that, in circumstances like these, industrial investment grinds almost to a halt. The long-term consequences for productivity are plain enough. If worn-out and obsolete machinery is not replaced, and if new kinds of enterprises are not begun, then the growth of productivity must inevitably be diminished. No palliative exists. The only remedy is to avoid inflation and create circumstances in which industries (and people) respond rapidly to changing circumstances.

Last month's package of economic proposals from the White House is in this respect not especially relevant. To the extent that some expected tax revenue is to be forgone, people will have more to spend and some industries may begin to feel cheerful again. But the federal government's deficit and, possibly, the inflation rate, may be increased. By the time that Congress has finished with these proposals, the outcome may not be the stimulus to industrial recovery that President Carter is planning. More directly relevant, but again of dubious consequence, are the proposals that there should be more or less instant tax credits, paid in cash if need be, when manufacturers invest in new equipment. For what it is worth, a very similar proposal is a central part of the French budget for 1981, made public two weeks ago. The objective is laudable, but the results will not necessarily be those intended. If, for example, the chief beneficiaries are those manufacturers who are struggling to preserve industries whose economic foundations have long since disappeared, the cause of productivity will be hindered, not helped.

This is the background against which to judge the concern of the National Science Foundation with research in engineering, and with the training of engineers. The central issue is whether it will be possible, within the $1,200 million budget of the foundation, to make a decisive change in the pace of industrial innovation. For the past several months, the foundation has been searching for a form of internal organization that will enable it to function more effectively in this respect (see *Nature*, 11 and 18 September). It also shares with other federal agencies ambitions to found cooperative research centres that will carry out research on behalf of groups of industries judged to be in need of technological innovation (and prepared to share the cost). The proposed reorganization looks like a leaf out of the book of the

0028-0836/80/400377-02$01.00

UK Science Research Council, which has long since used its Engineering Board as an explicit means of fostering and improving engineering research in British universities. Even the admirers of the Engineering Board acknowledge that it has had an uphill struggle, however. The National Science Foundation may have better luck, given the stronger tradition of research (as distinct from external consultancy) among engineering faculties in the United States. But nobody should think that the cooperative research centres will have a decisive effect. Many will no doubt be useful, but the funds available do not bear comparison with what the mission agencies spend on development contracts.

By the same tests, the proposal that there should be a National Engineering Foundation, with terms of reference similar to those of the National Science Foundation, is likely to fly like a lead balloon. Representative George Brown, the chief sponsor of the scheme, sees it chiefly as a way of goading existing institutions into action. But what action? As long as nobody is sure, a National Engineering Foundation would be simply a cosmetic device, a monument to the common Washington view that any problem can be solved by throwing money at it.

Yet there are constructive things that could be done. In the past twenty years, the character of engineering has changed enormously (especially in the United States), but the engineering schools remain much as they were. The best of them are prestigious places, and have adapted their teaching to changing needs. Elsewhere, teaching and the evolution of the curriculum have been hampered as much by the lack of teachers as money. If the eager beavers in Washington really seek to help, they would be well advised to concentrate on the education of engineers.

The consequences (so far) of the Finniston Inquiry into British engineering education may have been meagre, but the more flexible American university system could well benefit from taking stock of how it educates engineers. Why, for example, should not some engineering schools follow most medical schools in recruiting intending engineers from among people with good first degrees in relevant fields of study? These and other innovations deserve a fair hearing. Some useful ideas are, by all accounts, included in the report of the Secretary of Education and the Acting Director of the National Science Foundation, submitted two months ago but not yet published. Congressmen urging that something should be done about engineering might do worse than demand a sight of that document. But in the long run they must know that the health of the engineering profession depends intimately on the health of the economy, which is Congress's chief responsibility.

Poor outlook for British universities

One thing is certain about the future of the British university system — if it collapses, or if some parts of it collapse, these events will be recorded in the appropriate Annual Survey of the University Grants Committee (UGC) with decorum and gentility. These are the hallmarks of the latest document in this series, published last week (HMSO, Cmnd 8031) and covering the turbulent academic year 1978–79. The UGC records the successive chops and changes of public support for the universities under its wing, and does not in even the mildest language protest that this is not the way in which a motley collection of universities such as the British can be run sensibly, even economically. In the same way, the latest survey tells how the UGC responded to the decision a year ago that the recurrent grant to the universities would be slightly reduced in the academic year now starting by "advising universities . . . that their admission arrangements for 1980 should be so conducted that, if necessary, they could restrict the number of entrants in a way which would restrict the rate of increase in the total numbers of home undergraduates". The survey notes that the UGC "subsequently learned" of the proposals to increase the fees of students from overseas and says that "the unpredictable results of these new arrangements are causing universities much anxiety". The UGC as such stays on the fence, not adding even a mild expression of opinion such as "which we share". They order things differently in France (see page 381).

The truth is that the upshot of government decisions about British university finances in the past two years amounts to the most serious perturbation of the system since the onset of rapid expansion in the early 1960s. The bursars' departments of British universities have become almost as concerned to know what cheques will be in the next post as the most insecure small businesses. The comfortable quinquennial system of financing will not be revived in the foreseeable future, but even the system of rolling budgets offered as a substitute four years ago is vulnerable, from day to day, to quite minor changes of government policy. The UGC itself, in the course of distributing funds to the universities in its charge, frequently finds it necessary to keep back funds for dealing with unexpected problems (a sudden pay award, perhaps). The result is that individual universities sometimes do not learn until towards the end of an academic year whether they will finish up in the black or the red.

The coming academic year will be worse than ever, for the rules have been changed. The UGC's own recurrent grant has been reduced by the estimated cost of educating new students from overseas. Individual universities hope to make good the difference by the increased fees they will recover. It is too soon to known how successful they will be — not all the overseas students offered places have turned up as yet, while it remains to be seen how many will actually have the cash required of them. Some universities, a little surprisingly, seem confident that they will not be much worse off than last year. Others are despondent. It is, however, agreed that total income will decline. The UGC's own reaction is familiar, and understandable. Again it will keep some money up its sleeve, with the intention of helping out universities in trouble. As so often in the past, the successful universities will no doubt be penalized to help those that cannot recruit their expected quota of students from overseas. In the meantime, many university finance officers will be literally unable to make their budgets balance for the coming year. So they will skimp wherever they can, even on the quality of teaching.

Few outside the university system appreciate the debilitating consequences of this way of carrying on. The UGC no doubt regrets the way it has to keep its supposedly autonomous universities on tight and unpredictable purse-strings — but there is not a flicker of regret or even sympathy in the latest annual survey. This omission, tactful though it may be, is important and potentially damaging because there are already many in the universities who question the utility of the long-term survival of the UGC. For several decades, the committee has been held up as a shining example of public administration, a buffer between the government (first the Treasury, now the Department of Education and Science) and the universities. There may be no truth in the suspicion that the UGC is now less staunch a buffer, but its ready compliance with each tiny shift of public policy has given a different impression. That is merely one reason why it should seize what chances come its way to say where it stands. Another is that in the upheavals that lie ahead, some at least among British universities will look to the UGC for protection, not just from penury but from the structural changes there will be if the research councils eventually decide to concentrate their research grants on a smaller number of institutions (as the Merrison committee may well suggest). If the UGC persists in its present passive ways, however, it will be less able to offer help than the circumstances require. The larger and more successful universities will be able to look after themselves — and some would prefer to do so even as things are. There is no unalterable law that all universities must indefinitely survive. The UGC, however, seems well set to let them go without a struggle.

NASA budget falls foul of contracts

Washington

The National Aeronautics and Space Administration (NASA) has been caught in crossfire between the US Congress and the Office of Management and Budget (OMB) over whether the federal bureaucracy is spending too much money in employing private consultants to carry out its work. This has resulted in a demand from the Senate that NASA cut $14 million from a budget for consultant services which NASA claims totals only $4.3 million, but which the Senate Appropriations Committee, using a broader definition disputed by both the agency and the OMB, claims to be more than $90 million.

Unless it is reversed during negotiations with the House, the extra cut in NASA's budget, coming on top of a proposed two per cent reduction (approximately $100 million) in its budget request, will mean further pressure on space research projects as efforts are made to protect the space shuttle programme.

The pressures are already beginning to bite. For example, NASA is planning a reduction in the scope of experiments to be carried out by the spacecraft which will take part in the international solar polar mission, due for launch in 1982. Scientists from the European Space Agency, which is providing the second spacecraft in a dual mission, argue that the omission of instrumentation from the US craft could reduce the value of their own findings.

The proposed cuts in NASA's consultancy contracts reflect a general unease in Congress about the way in which federal agencies have come to rely increasingly on outside contractors to meet their responsibilities.

However, the agencies face a dilemma. On the one hand, Congress is continually increasing their work-load while, on the other, the Administration is keen to keep down the cost and size of government. The inevitable result is that the agencies contract work out. This, in turn, provides ample scope for disputes over rigged bidding for contracts, favouritism towards contractors, duplication of work and conflicts of interest.

Several instances of such practices have come to light in the past year. Last week, for example, officials from the Department of Energy admitted before a congressional oversight hearing that they had failed to check up on a consultancy firm employed to help draw up clean air regulations and were therefore unaware that the firm had also been working for companies engaged in a campaign to oppose the Clean Air Act of 1977.

In debating the 1981 budgets for a number of independent federal agencies, the Senate agreed to a proposal from Senator Warren Magnusson, chairman of the Appropriations Committee, to make a 15 per cent cut in the consultancy budgets of three agencies — NASA, the Environmental Protection Agency and the Department of Housing and Urban Development.

In opposing the proposed cuts, NASA complained that the analysis on which they had been calculated did not reflect the difference between narrowly defined contracts for advisory services and service contracts essential to a range of space programmes, including the shuttle.

Strong support for NASA's activities came from Senator Adlai Stevenson and ex-astronaut Senator Jack Schmitt, chairman and ranking minority member of the Senate Science and Space Subcommittee. Mr Schmitt proposed as an alternative that the 15 per cent reduction be according to NASA's own definition of what constitutes a consultant — this would reduce its budget by only $640,000.

However, Mr Magnusson and fellow Appropriations Committee member Senator William Proxmire remained firm. Mr Magnusson quoted a recent report from the General Accounting Office citing OMB's apparent failure significantly to reduce excessive waste, and its abuse of consultants' contracts over a 20-year period, as well as a statement from Admiral Hyman Rickover that "the use of consultants often impedes, rather than facilitates, action by government agencies". Mr Schmitt's amendment was lost by 27 votes to 66.

NASA is not the only agency in trouble about consultants. The Environmental Protection Agency (EPA) announced last Friday the cancellation of a $285,000 contract offered to a research worker at the California Institute of Technology to study the health effects of radon gas because of charges that the contract had improperly been awarded to the university without competitive bidding.

Dr David M. Rosenbaum, head of EPA's Office of Radiation Programs, had offered the contract to the university without seeking other bids on the basis that Caltech was the only contractor qualified to carry out the work involved. However, a university research worker told a Senate committee last Thursday that there were other contractors who could have carried out the same work.

Dr Rosenbaum also justified his actions on the grounds that it would have taken nine months to secure the services of a consultant through competitive bidding, and that because radon was a "serious health problem", fast action was needed.

However, his superior at EPA said that Dr Rosenbaum may have violated the agency's procurement regulations in making the award. And the agency's inspector general said that she had found "serious and troublesome" problems in the contracts procedures used by the radiation office.

David Dickson

Einstein Observatory in trouble

Washington

Equipment problems on board the National Aeronautics and Space Administration (NASA)'s second High-Energy Astronomical Observatory (HEAO 2) — also known as the Einstein Observatory — are causing concern that the mission may have to be brought to a premature end.

Initially the satellite, which was launched in 1978 and has provided the first X-ray telescope as sensitive as ground-based optical telescopes, was planned to operate only for one year. But after its initial success in generating new scientific data, the mission was extended, and until the recent setback NASA scientists hope the satellite would continue to send back data well into next year, when atmospheric drag would take it out of orbit.

How long the satellite goes on operating, however, will now depend on the behaviour of the gyroscopes used to position it. Three weeks ago, the transmission of scientific data had to be temporarily shut down after the failure of two of the six gyroscopes to switch on after a temporary black-out.

The satellite needs three functioning gyroscopes to position itself. One is already dead, and another has been working erratically for some time. The latter, however, has now had to be brought back into service in the hope that its performance will be adequate. If not, NASA officials said last week that they are developing software instructions for a back-up control system which would use the two gyroscopes that are still functioning, as well as either a sun sensor or a star tracker on the satellite.

At Harvard University, whose Center for Astrophysics is responsible for collecting the data transmitted from the Einstein Observatory, scientists also fear that even if the observatory continues to operate satisfactorily — as they are now hoping — the extra fuel consumed during recent manoeuvring to keep solar power cells facing the sun will shorten its lifetime by a couple of months.

The trouble on HEAO 2 started when one of the thrusters on the satellite started to burn for longer than it should during a repositioning manoeuvre. The gyroscopes were subsequently turned off with other equipment, but two failed to start when power was switched back on.

The gyroscopes have given trouble once before at the start of the mission in 1978,

0028-0836/80/400379-02$01.00

but this was resolved by NASA engineers. Ironically, while the problems with HEAO 2 were being worked on, gyroscope problems also developed in its successor HEAO 3, which was intended merely for a six-month mission.

In this case, a command sent to HEAO 3 caused it inadvertently to start drifting from its proper position, leading its control computers to switch the satellite into a "safe" mode. However, this problem is again said by NASA engineers to have been solved.

The HEAO satellites are not the only space activities encountering technical problems. Thus NASA officials are now carrying out an in-depth review of the space telescope programme and are concerned about the possible combined effects of cost overruns and schedule slips.

The critical design review of the telescope has been put back from this summer until January 1981, partly because of the need to redesign the wide-field planetary camera to save weight. In addition, the fine-polishing of the primary mirrors for the telescope is behind schedule; and various contractors for the space telescope project, due to be launched from the space shuttle in early 1984, are complaining that they have been allocated insufficient manpower and funds to keep the programme on schedule.

NASA is soon expected to announce the results of a competition for the location of the Space Telescope Institute, which will collect and analyse data from the telescope. The three main contenders are Johns Hopkins University in Baltimore, Princeton University and the Fermi National Accelerator near Chicago. Two groups — Associated Universities Inc. and Universities Space Research Association — have drawn up separate plans for locating the institute at Princeton. The Baltimore site is being proposed by the Association of Universities for Research in Astronomy and Fermilab by the Universities Research Association Inc., which already operates the laboratory's accelerator for the Department of Energy.

David Dickson

Radiation safety

X-ray survey

A plea for more effective steps to reduce the radiological dose to the gonads of patients from X-ray diagnosis has been put out by the National Radiological Protection Board (NRPB). The board is especially concerned about young adults, and says that if they were protected as well as children usually are, then the genetically significant dose to the British population from diagnostic radiology could be reduced by 40–50 per cent.

The NRPB set out to investigate whether the lessons from a similar study in 1957 under Lord Adrian had been learnt. That study concluded that the dose to the gonads of individuals could be reduced by the use of better radiological techniques, such as narrower beam widths. It also found that gonad dose from the same types of examination varied considerably, sometimes by as much as a factor of three or four between different parts of the United Kingdom.

The new study has found that the genetically significant dose — the average gonad dose per head of population weighted for child expectancy data — has remained approximately the same over the past 20 years despite a 50 per cent increase in the annual number of radiological examinations, suggesting that techniques have indeed improved. But it has also found that local variations in dose for the same examinations are as great as they were in 1957, suggesting that the use of gonad protection varies from place to place.

With this said, the NRPB is not alarmed. The "genetically significant dose" in Britain is still considerably less than in most other industrialized countries and could be responsible for a total of 100 genetic defects a year compared with a rate of 20,000 cases of genetic birth damage each year. Nevertheless, according to one of the reports, a reduction of only 10 per cent in the contribution to the genetically significant dose from diagnostic radiology would be the equivalent of the present contribution from nuclear power. As techniques for reducing the radiological contribution are easily available and relatively inexpensive compared with those needed to achieve a similar reduction from nuclear power, the NRPB says they should be implemented.

The study, based on data about radiological investigations in 1977, measured the gonadal dose in a sample of patients undergoing different types of examinations. The genetically significant dose is inferred from child expectancy data.

A breakdown of examinations into type reveals that most have increased in frequency whereas a few have decreased. A substantial factor in keeping the genetically significant dose down to its 1957 level is the large reduction in the number of obstetric radiological examinations. Their contribution to the genetically significant dose has fallen from 4.5 mrad in 1957 to 0.6 mrad now.

Although the NRPB study claims that there is probably room for further reductions of the genetically significant dose, it has few practical suggestions as to how this might be done. Nor does the NRPB fully understand the large differences of gonadal doses for the same examination in different parts of the country. It also acknowledges that gonad shields cannot be used in all cases, especially where they would obscure organs to be investigated. The plan is to discuss the findings with radiologists later in the year in the hope of finding ways to reduce the genetically significant dose.

Judy Redfearn

DNA guidelines

More relaxation

Washington

The National Institutes of Health (NIH) are expected shortly to reduce the burden of recombinant DNA regulations on research workers. This follows the recommendation of the institute's Recombinant DNA Advisory Committee (RAC) that details of virtually all experiments covered by the current safety guidelines need no longer be submitted to NIH for review.

At the same time, RAC has decided that NIH should limit their attempts to oversee recombinant DNA activities carried out in the private sector. In particular, the committee has proposed a procedure for checking on the biological aspects of large-scale experiments, but is suggesting that it should now restrict itself to general comments on the physical aspects of the fermentation and containment technology rather than reviewing each proposal submitted.

RAC has not gone as far as some would like. At a meeting in Bethesda, Maryland, last week, it decided to defer action on a proposal that clearance from local institutional biosafety committees (IBCs) should no longer be required before a research worker carries out an experiment in containment conditions specified in the guidelines.

The proposals for a procedural change in the guidelines were put to RAC by Dr Maxine Singer, head of the National Cancer Institute's biochemistry laboratory and a prominent participant in the 1973 Gordon conference which first drew attention to the need for caution in recombinant DNA research.

Dr Singer told the committee that many scientists felt that there was unnecessary delay in waiting for the Memoranda of Understanding and Agreement, required by NIH, to be approved by IBCs before research was allowed to begin. Also, there was impatience with the requirement for central review of experiments where the safety procedures to be followed were relatively straightforward.

On the latter point, committee members readily accepted Dr Singer's proposal that central registration be eliminated. Such registration is already no longer required for the bulk of recombinant DNA experiments, those carried out with the disabled K12 strain of the bacterium *Escherichia coli*. The new proposal would chiefly affect experiments being conducted in P2 and P3 physical containment conditions; the status of experiments now requiring the NIH director's explicit approval would not be altered.

More controversial was the proposal to remove the requirement for prior review of experiments by IBCs. Debate on this was coloured by a report presented to the committee on the performance of 19 IBCs

0028-0836/80/400380-02$01.00

studied in the state of California. This revealed, among other things, considerable differences in the rate at which IBCs accepted or rejected proposals for experiments in particular containment conditions, raising questions about the consistency with which research workers are interpreting the guidelines.

The report was prepared by Dr Dianna Dutton of Stanford University School of Medicine, under a grant from the National Science Foundation. She pointed out that IBCs established by private companies in particular had a high acceptance rate of proposals, and also claimed that the fact that none of the IBCs contacted publicized their regular meetings, even though attendance was unrestricted, reflected an apparent reluctance to involve the public in IBC decision-making.

A nationwide study of IBCs is now being planned by NIH, and will be discussed at a meeting of IBC chairmen in November. In the light of this proposed review, and the result of the Stanford study, RAC agreed that consideration of the elimination of pre-review of experiments should be deferred "until the frequency of principal investigator error in selecting containment levels is determined".

In another step designed to lessen the burden of regulation — this time primarily on the private sector — the committee agreed that its review of proposals for large-scale experiments should be focused chiefly on aspects of biological safety.

This decision was the culmination of a lengthy debate over how far NIH should go in regulating recombinant DNA research in the private sector. As there is no legislation, private companies are at present unregulated, although all companies involved have agreed to observe the NIH guidelines voluntarily.

A major stumbling block to this has been disagreement over procedures for evaluating experiments involving more than 10 litres of culture, at present requiring special permission from the director of NIH regardless of the genetic material being used. Some committee members have argued that RAC lacks the technical expertise to evaluate the safety of large-scale fermentation techniques, others that regulation in this area is the responsibility of the Department of Labor's Occupational Safety and Health Administration (OSHA).

Dr Eula Bingham, however, the head of OSHA, has now written to NIH saying that although her agency can act on complaints from workers or on suspicion of a potential hazard, it lacks the statutory powers to require the certification of facilities where no hazard is suspected.

Committee member Dr Sheldon Krimsky of Tufts University proposed that, in the light of OSHA's reply, a subcommittee of RAC should be set up with representatives of other federal agencies to comment on proposed containment procedures for large-scale experiments. He pointed out that although the pre-review of industrial technology might be a radical departure for regulatory agencies in general, it was within the spirit of the scientific and public concern which had originally led to the development of NIH guidelines.

Other committee members, however, were not convinced. Having earlier passed a motion agreeing to procedures for evaluating the biological classification of proposed large-scale experiments — and therefore the level of physical containment that would be required — they amended Dr Krimsky's proposal suggesting a new subcommittee primarily to advise on the proper procedures and design of such operations. The proposed subcommittee would review the effectiveness of local IBCs, including industrial IBCs, but it would not have to approve specific containment procedures for particular experiments; and its creation has still to be approved by the director of NIH.

David Dickson

Biotechnology

UK company gells

Britain's new biotechnology company, Celltech, is beginning to take shape. Sir Michael Stoker, foreign secretary of the Royal Society and former director of the Imperial Cancer Research Fund, has been appointed chairman of the board of directors and it is thought that Norman Carey of G. D. Searle Limited is in line for the scientific directorship. Most of the other members of the board have also been appointed. Offers of senior posts have been made, although it is not yet clear how many of them will be taken up. A full statement is promised later in the month.

Since the National Enterprise Board's announcement in July (*Nature*, 24 July, page 321) that it was to provide 40–50 per cent of the initial £12 million to set up the company, the managing director, Mr G. Fairtlough, has been looking for a site for administrative offices and a laboratory as well as appointing his board and senior posts. The most likely site, as was rumoured earlier, is Cambridge, although other possible sites are also being considered. The plan now is to buy existing offices and laboratories near to each other, which could be adapted easily to the company's needs.

The timing of the start of the company's operations will depend to a large extent on the suitability of the laboratories it acquires, but Mr Fairtlough is hopeful that operations could begin early next year. An older building needing extensive alterations would obviously delay the start.

As soon as the senior post have been filled, Fairtlough plans to start looking for candidates for other posts. The company hopes to build up a staff of 75–100 over the next two years. Initial products will be for medical diagnosis, but the company hopes to expand into other fields later and to cooperate with larger pharmaceutical companies on production of items beyond its scope.

Judy Redfearn

Going and coming

Sir William Henderson, chairman of the Genetic Manipulation Advisory Group (GMAG), responsible for the administration of the UK guidelines on recombinant DNA, will be giving up as chairman at, or soon after, the end of 1980. His original appointment, at the end of 1978, was for a term of two years, but it is understood that he is prepared to stay on for a month or so if his successor cannot take over at the beginning of the year.

In the past few months, there has been some confusion among GMAG members about the future chairmanship of the committee, which has apparently not yet been decided.

GMAG is also in the throes of a debate about its own future. At its next meeting, GMAG will debate a proposal by one of its members that the group should recommend its own demise. The proposal is likely to be resisted by the government departments and agencies concerned, at least until the Dangerous Pathogens Advisory Group (in limbo since the smallpox accident at the University of Birmingham two years ago) is reconstituted.

It has also become known in the past week that the search committee of the European Molecular Biology Organization (EMBO) has nominated as the next director-general of EMBO Dr L. Philipson of the Department of Microbiology of the Biomedium Centre at Uppsala. If appointed by the EMBO council, Dr Philipson will succeed Sir John Kendrew, whose term of office ends next year.

French universities

Trouble behind

Paris

French universities are still recovering from a series of attacks and retreats by the government which have left the universities strictly on the defensive.

In July, the minister for the universities, Mme Saunier-Seïté, vetoed the granting by the universities of the long-standing "engineer PhD", the Docteur-Ingénieur, and cancelled 200 first degree (deuxième cycle) and 600 postgraduate (troisième cycle) courses which were due for reapproval by her ministry.

Last month, the Prime Minister, M. Raymond Barre, intervened in the resulting row, but his action was more cosmetic than real. He restored the freedom to create Docteur-Ingénieurs at 25 of France's 78 universities, and approved a further 22

0028-0836/80/400381-02$01.00

courses at first degree and 39 at postgraduate level, after energetic lobbying by the Conference des Présidents d'Université during the summer.

According to the vice-president of the Conference, Professor Jacques Latrille (president of the Université de Bordeaux II), these concessions are "nothing like enough". Last year some 2,000 Docteur-Ingénieurs qualified and 25 universities cannot cope with the demand, which comes largely from qualified students of the Grandes Ecoles wishing to do research. Although the Grandes Ecoles, sometimes described as the crack training grounds of the French establishment, have a highly selective entry, they offer relatively few opportunities for research.

The scrapping of a net 178 first degree courses will — by government design — chiefly affect the new universities, the score of institutions, such as the universities of Chambéry and Pau, which have been established in the French provinces since the reorganization of 1968 and which tend to have 3,000–5,000 students. The social sciences, educational science, psychology, philosophy, history, geography, foreign languages and the performing arts have all been hit hard, with the result that teaching in these disciplines will be concentrated in the major cities and Paris. There may be further cuts next year, when the other half of the 1,917 undergraduate diplomas will be up for renewal.

The postgraduate cuts, on the other hand, affect mainly the bigger, older universities (15,000 to 20,000 students each), where most research is done; but again the cuts fall mostly in the humanities.

M. Barre, in his recent speech, gave his support to the broad emphasis of Mme Saunier-Seïté's policy — the restoration of "the vigour and quality" of the universities after the "rude shock" of 1968. It was clear, said M. Barre, that an increasing number of postgraduate (troisième cycle) proposals were ill thought-out and sustained by too few professors, libraries and laboratories.

A survey of deuxième and troisième cycle courses by Mme Saunier-Seïté had revealed a single management professor requesting the establishment of three postgraduate courses; six professors of belles lettres proposing ten senior undergraduate courses; and five biology professors proposing three postgraduate courses in life sciences.

M. Barre mentioned the notion of autonomy, but it is unlikely that the state will easily relinquish its vast power to approve all courses as well as appointment of professors and lecturers. On this point, the Prime Minister contrived to sound more like a benevolent dictator, offering democracy to his people "when they were ready", than a man committed to granting independence.

Neither does Mme Saunier-Seïté offer many crumbs of consolation. Although she is president of the Conference des Presidents d'Université, she has attended none of its meetings for more than a year. Academics are not asking for revolution. The government, says Professor Latrille, is entitled to make its own policy for the universities: but the universities should at least be consulted, through existing mechanisms, to give advice on how it is applied.

Robert Walgate

Non-proliferation

India gets fuel

Washington

Last week was a good one for the US nuclear industry, and a disappointment for its critics. On Tuesday, voters in the state of Maine rejected a proposed law which would have banned nuclear power from the state. The next day the US Senate failed to prevent the export of nuclear fuel to the Tarapur nuclear power station in India despite India's continued refusal to submit its nuclear facilities to international inspection.

Both votes had been closely watched as pointers to nuclear policy in the 1980s and both had, in consequence, been the focus of intense lobbying. In the lobbying in Maine, for example, supporters of a bill which would have closed the state's single nuclear power station and forbidden the construction of further nuclear plants were outspent by five to one by pro-nuclear forces, who raised financial support from utility companies around the country.

Although the vote in Maine supports the development of nuclear power, anti-nuclear voters did turn out in strength, and 40 per cent of those voting supported the proposed ban. After the vote, a spokesman for the local utility company admitted that the result demonstrated the substantial public concern that exists about the safety of nuclear power.

In the Tarapur case, the Administration's victory was even closer, and the lobbying even more intense. Shaken by a defeat by three to one in the House of Representatives of its attempts to permit the export of the nuclear fuel and a subsequent defeat in the Senate Foreign Relations Committee, the Carter Administration pulled out all the stops to prevent what was seen as a major challenge to its foreign policy.

Many key senators received telephone calls from the President, and Secretary of State Edmund Muskie even pleaded at length with the Senate Republican Conference. The result was that a resolution to disapprove the export of the fuel was defeated by just two votes, 46 to 48, with a majority of Democrats voting against the resolution and the majority of Republicans — with a significant number of liberal Democrats — voting for it.

India's request for the export of 38 tons of fuel for its Tarapur reactor was the first major test of the Nuclear Non-Proliferation Act of 1978, which forbids the export of nuclear fuel to countries which have not accepted international safeguards on their nuclear facilities.

Earlier this year, the Nuclear Regulatory Commission (NRC) decided unanimously that, since India had not met these requirements, the sale of the fuel could not go ahead. President Carter, however, invoked broader foreign policy considerations to overrule the NRC's decision, and the President's move could only have been overturned by Congress if both houses had voted against it.

The dispute over the export licence resulted from a conflict of strategy about whether non-proliferation objectives should be pursued single-mindedly, as implied by the Non-Proliferation Act, or whether they are as likely to be achieved through more conventional economic and diplomatic channels.

Senator John Glenn, the leading supporter of the resolution opposing the export, said that India, which had conducted a nuclear test in 1974 using components from Canada which had led to the current legislation , had "the worst history of any of our trading partners".

He warned that to back down at this stage would damage the credibility of the whole US non-proliferation policy, and after the result of the vote was known he commented that it would now be "practically impossible" for the United States to try to convince other countries that they should accept nuclear safeguards.

This view, however, was directly challenged by Senator Frank Church, chairman of the Senate Foreign Relations Committee. Reflecting the Administration's own position, Mr Church said that not permitting the export of the nuclear fuel would abrogate an agreement reached in 1963 to supply the fuel. This would permit India to disregard other safeguards built into the agreement and could postpone indefinitely further negotiations with India on nuclear issues.

After the vote, a spokesman for the Carter Administration said that the result would help discussions with India about bringing all India's nuclear facilities under international safeguards, but there was some scepticism in New Delhi. A spokesman for the Prime Minister, Mrs Indira Gandhi, said that her government had not changed its position on comprehensive safeguards, which it still regarded as discriminatory since the major nuclear states — including the United States — were not required to open all civilian and nuclear facilities to international inspection.

This debate is not likely to go away. The Indian Foreign Ministry announced two weeks ago that it had applied earlier in September for a new export licence for 19.8 tons of enriched uranium for the Tarapur plant — a move which could stir up the whole stormy debate again.

Information technology

Cheering on UK

The past week has been remarkably active for British thinkers on government policy on information technology, the technology which interfaces computers and telephones, and for some of the designers of the technology itself. The Advisory Council on Applied Research and Development (ACARD), an advisory body to government and counted amongst the thinkers, published a report on the subject; the government announced some changes in the organization of responsibility for it; and British Telecom's research centre at Martlesham Heath, a designer of information technology, opened up its laboratories for more or less public scrutiny.

Central to this activity seems to be an awareness that Britain needs to put more coordinated effort into adopting information technology if it is to be competitive among the industrialized nations not only in the technology itself but also in many aspects of industry and business. This feeling certainly seems to be the basis of the ACARD report, which is more an exercise in publicity for information technology than a detailed analysis of its potential. Written by six industrialists, a trades unionist and a member of ACARD, it is an exhortation to government to take note of information technology rather than a guide to how policies might be implemented.

The report's main recommendation, that one minister and government department should be responsible for coordinating information technology policy, has to some extent been pre-empted by the government's announcement. The former computer systems and electronics divisions of the Department of Industry is to become the information division. It will assume responsibility for government policy formulation on information technology, under one deputy secretary who also has responsibility for the Post Office and satellite communications. In future, responsibility for coordinating government policy will lie with an official committee of the Cabinet Office especially set up for that purpose.

In making an international comparison of the development and uptake of information technology, the ACARD report is not very encouraging for Britain. It finds that the French, West German, Japanese and American governments are spending more than Britain on research, development and promotion. It is particularly nonplussed by the French government which, it says, has succeeded in creating considerable public awareness of information technology through one or two innovative public demonstration projects and at the same time has successfully promoted in other countries the idea that it leads the world in the field on the basis of projects that are not yet operational. This impression has been achieved, says the report, through the skillful use of publicity.

The report does not suggest that Britain should follow suit by committing more public funds to research. However, it does suggest that a leaf could be taken out of France's book by setting up demonstration projects to increase public awareness. Suggestions for doing this include putting telex and facsimile transmision machines in Post Offices, putting Prestel receiving machines in schools and public libraries and providing telephone subscribers with black and white Prestel-like video terminals for directory information.

The government could also help develop information technology industries by buying equipment for its own departments — a move which would need to be carefully implemented to avoid creating artificial markets. The report does not mention this possible pitfall, but it does recommend that the government should help stimulate closer cooperation between users and supplies.

Despite the lack of public funds spent on information technology, Britain is by no means behind on all counts, a fact which was evident at last week's open days at British Telecom's research centre. In such an international business, however, there is strong competition between countries to have their own systems adopted as standard and Britain, says the ACARD report, has been particularly bad at promoting its own interests. It says that Prestel is suffering because extensive negotiations over viewdata standards have failed to get it accepted as an international standard despite its technological lead.

Moves should be taken, it says, to encourage pupils at school to enter this field and to encourage industry to provide its own training schemes. **Judy Redfearn**

Bulgarian science

Reaching out

Varna

An unusual approach to international cooperation lies behind the Third PCITRRA International Colloquium (Physical and Chemical Information Transfer in the Regulation of Reproduction and Ageing), now taking place in Varna, Bulgaria. By presenting the work of young Bulgarian researchers side by side with papers by leading international experts in the field, the organizer, Dr Julia Vassileva-Popova of the Laboratory for Rapid Spectroscopy and Biological Physics of the Bulgarian Academy of Sciences, hopes to stimulate fruitful international working visits.

The theme of PCITRRA, as an international and interdisciplinary colloquium, was selected by Dr Vassileva-Popova in the early 1970s on the grounds that to compete in genetics would be to attempt to break into a very crowded field. She felt there would be more elbow room in the area of non-genetic information transfer, the first stages of hormone action, and bioreceptor and neurotransmitter processes. Since her laboratory is more than self-financing, exporting sophisticated rapid-spectroscopy equipment primarily to the USSR, the funding of basic research is a smaller headache to her than to some other Bulgarian laboratory directors. Accordingly, Dr Vassileva-Popova has been able to gather together a large and keen team. Since East European etiquette normally calls for the laboratory head or research supervisor to be cited as a co-author, this meant that out of the 117 scheduled communications, Dr Vassileva-Popova was named as co-author of 23.

The third PCITRRA colloquium (they have been held at three-year intervals since 1974) was formally part of the celebrations of next year's 1,300th anniversary of Bulgarian statehood, and was in part supported by the State Committee for Culture — the first time apparently that this body has sponsored an international scientific event. Yet Dr Vassileva-Popova is adamant that she is not trying to found a "Bulgarian school" of biophysics/biochemistry. In her opinion, it is scientists and not their countries which matter. Indeed, had it not been for a small organizational error, she said, the participants' badges would not even have shown their countries' names. She even suggested to the international organizing committee that the fourth PSITRRA colloquium might be held outside Bulgaria — a proposal which they emphatically rejected.

Certainly, Dr Vassileva-Popova has been able to attract to Varna an impressive international gathering — including Henry Arnstein and J. R. Tata from the United Kingdom, Oscar Hechter and Elwood Jensen from the United States, Friedrich Jung from the DDR, Rostislav Sovicka from Czechoslovakia, Pushpa Bhargava from India and Andrei Tchernitchin from Chile. And this in spite of the relatively long duration of the colloquium (seven days, with working sessions of up to ten hours a day) — Dr Vassileva-Popova eschews poster sessions, and insists that all papers from her young collaborators which reach the required standard are read in full. In addition, all those foreign visitors who could spare the time were invited to stay on for a new feature of the PCITRRA colloquia, a summer school for young scientists at Burgas, further down the coast.

One notable figure was absent — Sir John Kendrew, who was detained at an EMBO meeting in Heidelberg. His encouragement of Bulgarian biophysics and biochemistry was, however, recognized earlier this year, when he was given the highest award of the Bulgarian People's Republic — the Order of the Horseman of Madara.

CORRESPONDENCE

DNA X-ray data

SIR — We have recently suggested[1] that the available X-ray diffraction data from B DNA are consistent with a model for the structure of DNA which we have called the "side-by-side" model and in which DNA strands are linked together in pairs of the Watson–Crick type but are not wound into a continuous right-handed helix. Our model has however been alluded to[2,3] in terms that suggest that alternatives to the double-helix model have been finally disposed of. We wish now to emphasize that existing X-ray data on B DNA are not in themselves sufficient for an unambiguous decision for or against either model.

Naturally occurring specimens of B DNA do not form single crystals of good quality, and the resolution of available X-ray data is very limited. For these reasons, and because there is rotational disorder in all specimens of B DNA so far reported, the only standard crystallographic quantity that can be immediately calculated from the X-ray data is some cylindrical average of the Patterson function, which must in practice be compared with the corresponding function calculated from molecular models.

We have shown[1] that in the analysis of B DNA data, there are advantages in using what we call the axial Patterson function (essentially the cylindrically averaged Patterson function with the radial coordinate zero) Briefly, the axial Patterson function is less sensitive than the Patterson function itself to imperfections of diffraction data. Of necessity, the axial Patterson function, which averages out much of the fine detail inherent in the observed diffraction patterns, can only be used for preliminary tests of the agreement between model structures and the X-ray data.

The nub of our argument is that the axial Patterson function computed from the data agrees (within the apparent experimental error) with that calculated from the side-by-side model but not with that computed from the double-helix model refined by Arnott and Hukins[4]. We do not of course claim that the double-helix model can therefore be dismissed — the quality of the data is so poor. But in the circumstances one wonders about the value of sophisticated refinements of the double-helix model (for example, ref. 4).

We are also surprised at the recent claim by Greenall *et al.*[5] that the double-helix model is in much better agreement than the side-by-side model with the diffraction patterns measured from paracrystalline B DNA specimens. We find roughly equal disagreement for both models. (We do not wish to make too much of what we feel is an anomaly of the double helix on the tenth layer line, because it could well be an artefact of excessive refinement based on inadequate data.)

For such reasons, it must be concluded that available X-ray data are at best an equivocal means of deciding between alternative DNA models. So much is acknowledged by Crick *et al.*[6]. For X-ray analysis to provide unambiguous distinction between different models of DNA, it will be necessary for much better crystals to be prepared from well characterized polynucleotides. In the meantime, while no doubt the merits of alternative DNA models will be assessed by considerations other than those deriving from X-ray data, it is prudent that the present insufficiency of the latter should be widely and openly acknowledged.

Andrei Sakharov

SIR— The Olympic games are over; the hopes that Academician Andrei Sakharov might be allowed to leave his internal exile in Gorky and return to Moscow are over now too Professor Sakharov has been exiled for over nine months and has no contact with his scientific colleagues, is not allowed to take part in seminars or lectures, has no access to scientific information so crucial for his research. (Books and journals have to be brought to him by his relatives from Moscow, which usually takes weeks or months. Since January, his colleagues from Lebedev Institute have been allowed to visit him only three times!)

In spite of this, he has managed to write three scientific papers in Gorky, and English translations have been published at SLAC, Stanford University (Estimate of the Quark-Gluon Coupling Constant; Cosmological Models of the University with Rotation of Time's Arrow; Mass Formula for Mesons and Baryons).

I am convinced that it is time now for the world scientific community to escalate the efforts to help our distinguished Soviet colleague. From Andrei Sakharov's last communication it is obvious that he is mainly missing the information about what is going on in physics.

It should be very easy for the physicists to break down this information barrier Let the theoretical institutes, laboratories and groups from all over the world begin sending to Professor Sakharov their preprints, lecture notes, reports. Send them by *registered* mail with the red "Avis de Reception" card to·

Professor Andrei Sakharov
Prospekt Gagarina 214, kv.3
Scherbinka 2, Gorky, USSR

Don't hesitate to ask your local post office to investigate if the red card is not returned to you with Andrei Sakharov's signature within about a month Your local post office is obliged, according to international postal convention, to make the investigation and, if unable to provide proof that the mail was delivered, to pay you compensation

There is no doubt that such world-wide action will not only provide Professor Sakharov with necessary scientific information but will also represent considerable moral support for him. It will be important for Soviet authorities too· they will see that Andrei Sakharov's case is not at all forgotten by the world scientific community

Preventing plagiarism

SIR — The article "An outbreak of piracy in the literature" (*Nature* 12 June, p.429) shocked me deeply. In December 1978 Dr Alsabti sent manuscripts to us also, with the headed paper of the M.D. Anderson Tumor Institute. Again, he gave a private address in Houston for correspondence and made acknowledgement to the Jordan Royal Family. Fortunately for us, he grossly overdid it, sending five manuscripts within a month. A call to M.D. Anderson helped us in taking the decision to reject the five manuscripts.

An old custom in the Italian universities called for the approving signature of the professor on the front page of a manuscript. Although I do not agree with a system which may impair scientific freedom, the present incident should teach us how important it is to ascertain directly from the host institution the credentials of an intended author, particularly when complex international relationships are apparent.

Pesticides as poisons

SIR— Peter Clarke (*Nature* 18 September p.184) defines a poison, but fails to note that "the dose alone determines the poison" (Paracelsus, 1564), a point that was emphasized correctly in *Nature* 28 August p.832. He says high blood levels of DDT in Guatemala were "the corollary" of an "aggressive marketing campaign" by a transnational corporation, and that cigarettes and pesticides are "harmful products". Cigarettes are harmful to human beings, pesticides to pests The use of DDT in Guatemala was started by the World Health Organization and the United Nations International Children's Emergency Fund to control endemic malaria in 1,500 Guatemalan communities. A reduction in malaria was achieved

THOMAS H. JUKES

*Department of Biophysics and
Medical Physics,
University of California,
Berkeley, California*

SIR — Of necessity, I have had to become something of an "applied toxicologist".

The only still-unfalsified definition of a poison is that of Paracelsus *"Dosis facit venenum"*, the definition offered by your correspondent Peter Clarke (*Nature* 18 September, p.184) contains less of the essential nature of a poison, and therefore fails. *Nature*, consequently, has avoided polemic (unlike your correspondent), and has indeed abandoned prejudice. Dr Clarke's letter is a brilliant piece of special pleading on behalf of a political stance — and I congratulate *Nature*, Sir, on your stand for true objectivity.

I am about to retire from full-time employment as a scientist, but I hope to maintain an attitude of 'informed scepticism'.

NEWS AND VIEWS

Myths, models and human evolution

What on earth can safely be said in public about human evolution? The charitable among those who heard Dr J. R. Durant's Darwin lecture to the British Association this year will have been worrying at this question for the past three weeks. The title of Dr Durant's address — The Myth of Human Evolution — tells the tale sufficiently: the stories that people tell, he argued, and which have been used for various purposes by people as different as Freud and Galton, Lorenz and E.O. Wilson, are but myths; "theories of human evolution have come to embody contemporary hopes and fears about the society in which we live". Specifically, the accusation goes, since the time of Raymond Dart until quite recently, the story told of human evolution has involved a model of human nature which is consistent with the doctrine of Adam and Eve, the Garden and the Fall, the doctrine of Original Sin, the notion that each contemporary human being is a battleground between civility (in the strict sense) and the primitive and powerful Beast within. The notion that primitive men were not merely successful hunters of other species but killers of each other, Durant says, fitted well with contemporary views of society at war within itself. But now, says Dr Durant, the fashion is changing. In making the public legend of human evolution, people have taken to describing primitive humans or hominids as creatures whose survival depended on cooperation between individuals and among groups, whose behaviour was shaped by an implicit recognition of the benefits of the division of labour in a hunter-gatherer society which Adam Smith first clearly described, and whose distinctive attribute — that of language — predisposes towards communality. What view, it might innocently be asked, is right? Neither, said Dr Durant. Each is a myth. Tell us instead, he asked of palaeoanthropologists, palaeoarchaeologists and the rest, the truth. Or at least acknowledge that your data are insufficient to say very much at all.

Stirring stuff like this is certain to evoke some kind of a response. Dr Durant will not have been surprised that, to begin with, the British daily newspapers were hesitant in knowing where he stood. Was he an anti-Darwinist, a Lamarckian or perhaps even a Creationist? When the fine print showed that he is none of these things, the tide of excitement ebbed. Mr Ronald Reagan, running for President of the United States, had in any case captured more attention with his aside in Dallas, Texas on the teaching of evolution in American schools (and may yet capture the Creationist vote in the United States with a sufficiently well-calculated goof.)

Durant's complaint, in any case, was a complaint against a style of argument. His targets were writers such as Lorenz (in the old school) and E.O. Wilson (in the newer fashion). His audience, given its provenance, may not fully have appreciated that Durant had selected pushovers for his attack. "Criticize Lorenz's concept of innate aggression" must now be a standard essay topic in undergraduate biology courses in most universities. Before long it will be joined by topics such as "What is the evidence (if any) for the belief that genetically determined altruism has played a part in human evolution?". He was entirely within his rights to complain that, in much of what passes for a general account of the evolution of human beings and of human nature, people who should know better are too fond of making too much of far too little evidence. Their common error is to take a living primate species as a model for earlier — and even contemporary — human (or hominid) society. Human nature being what it is, it is not surprising that these reconstructions reflect their prejudices or their hopes of wish fulfillment.

So far, so good. Dr Durant must have been well satisfied with his attack on such a variety of false prophets. Yet there is more than this to say and to ask. Why, for example, does the question of human evolution evoke such powerful interest, and such passion? What is to be said with confidence in such a field, where the data are likely always to be insufficient? And how should an account of human evolution be constructed — and made immune to the attentions of the myth-makers?

Nobody should be surprised that these issues excite deep and general interest. Long before Darwin made it possible to talk about the issues in concrete terms, people at large were understandably preoccupied with the subject matter of *Genesis*. All writers on the human condition have found it necessary to tackle the same questions — although it remains a puzzle that the Greeks, typified by Plato in the *Laws*, contemplated a past more or less indistinguishable from their present. For the past century, however, the public interest in human evolution has mostly been guided by Darwin's terms of reference. It would have been charitable of Dr Durant to have acknowledged that that is a step forward, and away from myth. But there is, as he complained, some way to go.

The lack of evidence is the chief stumbling block. The palaeoanthropologists may not really agree, but they are fortunate among those who work on human evolution. They have bones and other objects to measure, but past behaviour has left no fossils, only occasional artefacts from which behaviour must be inferred. In the circumstances, it is remarkable how much has been accomplished with the fossils uncovered in the past half-century. The time-span of human and earlier hominid evolution has been pinned down more accurately than could have been hoped a decade ago: 3.25 million years, give or take the usual ten per cent, will span the earliest australopithecine so far known (*A. afariensis*) and the present. Anatomical evidence appears to make possible the distinction between potential ancestors of hominids and apes among the contemporaries of late-Tertiary *Ramapithecus*. The palaeoanthropologists have been helped along by pieces of unexpected good luck — such as the way in which genetic differences between extant primate species will increasingly be used as evolutionary clocks. Even so, the reconstruction of this relatively tangible part of human evolution is full of uncertainty. Was *Homo habilis* an ancestor, or a dead end? Which of the specific names which the palaeoanthropologists have put into circulation will survive discoveries not yet made? Calculated scepticism — which jibes uneasily both with the temperament of the practitioners and the expectations of the public — is clearly essential.

So how, with such caveats, can progress be made towards a robust understanding of how early people, and hominids, behave? Most of Dr Durant's complaints were levelled at those who have embellished fossils with patterns of behaviour for which there is no evidence. He may have unfairly overlooked the opportunities that do exist for tackling these questions empirically — for example, by constructing models of the coordinated evolution of anatomy and behaviour, using data gathered not merely from the fossil beds but from analyses of the structure of, say, intelligence, observations by psychologists of the acquisition of specified skills in infants and other primate species and even the evolutionary implications of, say, protein biochemistry.

The trouble, of course, is that models are easily misunderstood. The safeguard, in this field as in, for example, cosmology, is that their function should be widely understood. A model is but a hypothesis to be tested. To regard it otherwise is to make a myth of it.

Infrared astronomy comes of age

from R. D. Wolstencroft

A recent conference* provided the first opportunity to discuss the contributions to astronomy being made by the new infrared telescopes on Mauna Kea, Hawaii. Infrared observations, both of cool clouds of interstellar gas and of the infrared sources within them, give vital information on the conditions under which star formation occurs. A wealth of new information is being obtained by a range of sophisticated instruments and the first studies are being carried out in regions of star formation outside our Galaxy.

Interstellar clouds exhibit a wide range of size, mass, density and temperature. They are observed over a wide range of wavelengths, from the optical to the radio, and with a variety of techniques which emphasize regions of differing density and temperature in a given cloud. The synthesis of such observations to give an overall picture of a cloud are still at a rather rudimentary stage. Because of this and also because of the continuous nature of the cloud — inter-cloud medium no completely logical classification for clouds has yet been derived. Thus the terms in use such as 'molecular cloud', 'dark cloud' or 'globule' do not necessarily define objects with similar physical properties. R. J. Evans (University of Texas) summarized the properties of molecular clouds and discussed the problems of classification. A typical giant molecular cloud is 100 pc across with a mass, up to half of which may be molecular hydrogen, of about 10^5 solar masses. Stars tend to form in the densest and hottest parts of the cloud, usually in clusters. Massive stars form preferentially in the larger clouds whereas the low mass stars form in clouds of all sizes. The infrared sources found in the molecular clouds may be either embedded stars or protostars; they are very luminous, typically in the range 10^3 to 10^5 times the solar luminosity.

Clouds at the low end of the mass and length scale are the Bok globules which were discussed by A. R. Hyland (Mount Stromlo Observatory). A promising new approach was described for studying the short wavelength infrared extinction by looking at background sources seen through a globule. The technique has been applied to a relatively symmetric globule in the Coalsack dark cloud. From the canonical relation between infrared colour excess, visual extinction and molecular hydrogen column density, a mass of 11 solar masses and a radius of 0.25 pc can be derived. Thermal emission from the dust at far infrared wavelengths can yield the typical temperature (about 15° K) and mass (about 0.1 solar mass) of the dust in a globule. It is probable that most globules are not undergoing gravitational collapse.

The Orion Molecular Cloud (OMC) is a well studied region which received much attention at the symposium. N. Z. Scoville (University of Massachusetts) described a model of an expanding envelope of gas centred on the Becklin-Neugebauer (BN) and Kleinmann-Low complex of infrared sources: the expansion velocity, based on CO mm line measurements, is 50 km sec^{-1} at 0.1 pc from the centre. A quite different view is held by R. Genzel (Center for Astrophysics) who proposed a model based partly on a VLBI proper motion study of maser sources: the source IRC 2, rather than the BN object is the centre of a low velocity (18 km sec^{-1}) outflow with a higher velocity outflow in the surrounding region. IRC 2 is an unusual source: it has a very strong 10µm absorption feature, possibly a greater luminosity than the BN source and it is the only SiO maser in a star-forming region. Other evidence of energetic motions in OMC comes from observations of molecular hydrogen emission in the 2.1µm vibrational quadrupole line and other rotational lines: this emission may be due to shocked gas at a temperature of about 2,000 K.

Results from a variety of sophisticated instruments were presented, notably those in the field of far infrared spectroscopy and speckle interferometry. As an example, infrared speckle interferometry by R. R. Howell and colleagues (Steward Observatory) has shown that the source W3 IRS 5, previously thought to be one source, is in fact a double source with a one arc second separation. If many sources prove to be double or multiple and if the components were to have different temperatures this could significantly affect our interpretation of source temperatures. F. Sibille and P. Lena (Meudon Observatory) have measured upper limits to the angular size of several sources, including 0.08 arc s for BN at 2.2µ. There is a strong possibility that proto-planetary disks will eventually be resolved by this technique.

Evidence for the presence of magnetic fields in molecular clouds comes from recent studies of the polarization of infrared sources in the clouds, a topic reviewed by H. M. Dyck and C. J. Lansdale (University of Hawaii). The generally large linear polarization, the approximately constant ratio of circular to linear polarization and wavelength dependence are consistent with a model of aligned grains in the vicinity of the source. An alternative explanation for the observed polarization in terms of scattering by grains in a bipolar nebula or similar geometrical configuration appears to be ruled out. A twist in the grain alignment along the line of sight near the source is implied by the circular polarization: twists of between 20 degrees and 80 decrees can be deduced for the nine sources so far studied. The grains are most probably aligned by an enhanced Galactic magnetic field permeating the cloud. Questions concerning the strength of the field, the origin of the twists in the grain alignment and the location in the cloud of the polarizing region, are of great interest and should be answered by further careful polarimetric observations in the infrared.

The latest observational results concerning the galactic centre were reviewed by I. Gatley (UKIRT, Hawaii) and E. Becklin (University of Hawaii). Outside the central few parsecs an expanding ring of molecular clouds has been identified from CO mm line measurements. The far infrared luminosity (30 to 100µm) in the region can be explained by thermal emission from dust heated by a large density of late type stars. Within the central few parsecs are a number of 10µm sources which appear to be objects a fraction of a parsec across with about one solar mass and 10^5 solar luminosities. A preliminary analysis of the observations suggests that they may be losing mass at a high rate: the nature of these objects is quite uncertain, but it is tempting to think of them as analogues of the BN object. Another important finding, based on 30 to 100µm observations, is the low abundance of dust within the central parsec. A black hole may be needed to explain the variety of observational results now available.

Star formation in the nuclear region of external galaxies was reviewed by G. H. Rieke (University of Arizona). About 40 percent of galactic nuclei so far studied show a large infrared excess at 10µm: whenever this excess is seen a very large infrared luminosity (10^9 to 10^{10} solar luminosities) is also seen within a few hundred parsecs of the centre. The 10µm silicate feature is also present in these same galaxies. Rieke argues that thermal radiation by dust is the immediate source of the observed radiation with the ultimate origin of the high luminosity being rapid star formation in the nuclear region. The nuclear infrared source is resolved in all cases. For example C. T. Telesco (University of Hawaii) reported that the 10µm emitting region of M51 has a diameter of about 3 kiloparsecs. Rieke posed three important questions which should be addressed in the near future: (1) What is the initial mass function (IMF) for star formation in nuclear regions? From a study of M82 it appears that there may be a bias against the formation of stars with masses below 2 or 3 solar masses relative to

Hurricane Allen destroys Jamaican coral reefs

from J. D. Woodley

HURRICANE Allen, which traversed the Caribbean in early August, was the second strongest ever recorded with wind speeds approaching 300 kph (185 mph). Fortunately, its track was mostly over the sea but, while the islands were spared the impact of extreme winds, they were exposed to enormous storm-generated waves. In the small hours of Wednesday 6th August, Allen passed within 50 km of the north-east coast of Jamaica. Severe wind damage occurred to the forests of the Blue Mountains and the banana plantations of the adjacent lowlands. Huge waves beat upon the eastern and northern shores, claiming several lives. Houses built on cliffs 12m above the sea were destroyed. Beneath sea-level, the spectacular fringing coral reefs suffered considerable damage.

The Discovery Bay Marine Laboratory of the University of the West Indies is at a site is in the middle of the north coast and not in the area hardest hit but, after the hurricane waves subsided, the water was turbid with fine sediment and pulverised tissues; there was a smell of dead corals, gorgonians and sponges. Death and injury to these and other organisms have now been assessed. Branching corals have been smashed, massive corals toppled or split, and plate-like ones fractured or torn off the reef slopes. Gorgonians and sponges have been ripped away or broken, echinoids destroyed and many fishes injured too. Physical damage varies with exposure and submarine profile, but in some places extends below –50m. Tons of sediment have been removed from the reef slopes and terraces. Sand-blasting and flying missiles have caused extensive abrasion, especially in the shallowest zones, where almost total destruction prevails. Before the storm, luxuriant stands of elkhorn coral (*Acropora palmata*) dominated the breaker zone from 0 to –6m (Fig. 1). This species is well able to resist the forces of ordinary breaking waves, but evidently not those generated by a severe hurricane. It has been reduced to rubble (Fig. 2) and some of this flung on to the reef flat, forming islands where none was before.

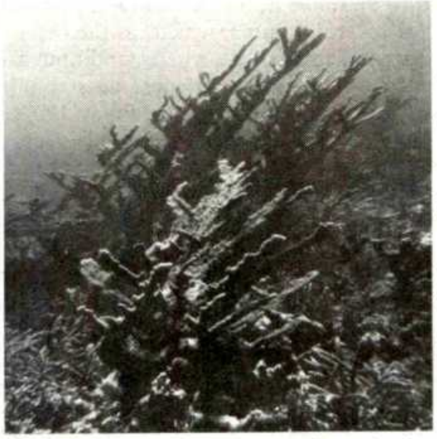

Fig 1 A stand of *Acropora palmata* in the breaker zone before the hurricane.

Photographs by J.W. Porter, University of Georgia

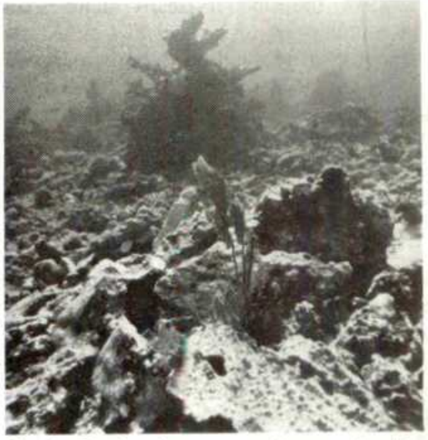

Fig 2 The breaker zone at the same locality after Hurricane Allen.

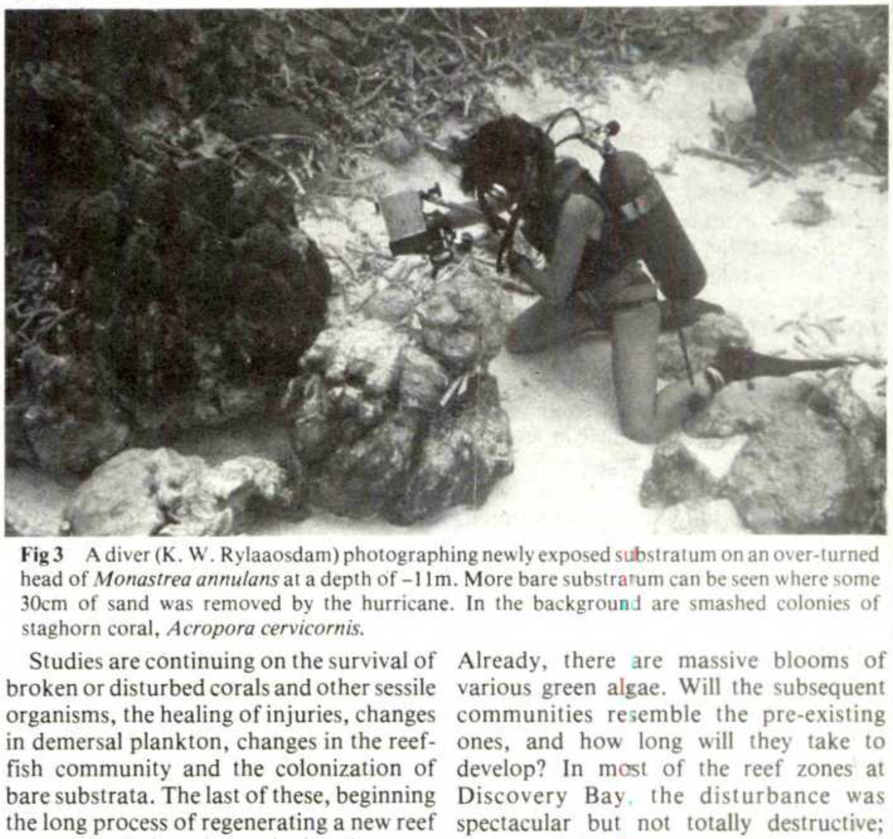

Fig 3 A diver (K. W. Rylaaosdam) photographing newly exposed substratum on an over-turned head of *Monastrea annulans* at a depth of –11m. More bare substratum can be seen where some 30cm of sand was removed by the hurricane. In the background are smashed colonies of staghorn coral, *Acropora cervicornis.*

Studies are continuing on the survival of broken or disturbed corals and other sessile organisms, the healing of injuries, changes in demersal plankton, changes in the reef-fish community and the colonization of bare substrata. The last of these, beginning the long process of regenerating a new reef community, is of particular interest. Abrasion, fracture and sediment removal have exposed large areas of new surface for colonization throughout the reef profile (Fig. 3), but especially in shallow water. Already, there are massive blooms of various green algae. Will the subsequent communities resemble the pre-existing ones, and how long will they take to develop? In most of the reef zones at Discovery Bay, the disturbance was spectacular but not totally destructive; recovery is likely to occur within a few years. Where extreme damage has occurred, that is, in shallow water and progressively deeper on reefs further east, it is possible that 'recovery' will take decades.

J. D. Woodley is Director of the Discovery Bay Marine Laboratory, Discovery Bay, Jamaica.

---

the IMF for the solar neighbourhood. (2) Are there any galaxies intermediate between the high and low infrared luminosity galaxies? (3) What mechanism starts and sustains the star formation activity?

The correlation between neutral hydrogen velocity width and integrated magnitude for galaxies (Fisher–Tully relation) can be used to determine the Hubble flow velocity, H_0, and hence the extragalactic distance scale. M. Aaronson (Steward Observatory) discussed his latest results using infrared magnitudes which give a tighter correlation than the optical magnitudes used in earlier studies. With the exception of galaxies in the Virgo cluster the value of H_0 is 95± 4 km sec^{-1} Mpc^{-1}. Judging from the reaction to Aaronson's talk at the meeting this new value of H_0 is being treated very seriously. Since the canonical value of 55km sec^{-1} Mpc^{-1} by Sandage and Tamman is very much less, it is clear that the origin of the discrepancy between these values must be urgently sought. For Virgo $H_0 = 65$ km sec^{-1} Mpc^{-1} which can be interpreted as an infall of the local group of galaxies towards Virgo at a radial velocity of 480 km sec^{-1}.

The vigorous growth of the subject makes it likely that this first symposium devoted to all major fields of infrared astronomy may well be the last with such a wide compass. The direction this expanding field of research will go in is not easy to predict. However it is clear that infrared observations of redshifted galaxies will play a vital role in the solution of many of the most important cosmological problems, a point stressed by M. Longair (University of Cambridge) at the end of the symposium. □

Industrial biopolymers

from Paul Calvert

THE term biopolymers really includes all macromolecules of biological origin but, for industrial application, biopolymers can be divided into two categories: those to be used in aqueous solution and those to be used as solids.

The first category contains a wide range of polysaccharide thickeners, emulsifiers and gelling agents used in the food industry and in a wide range of printing and coating applications. These materials can be extracted from trees, seeds and seaweeds or can be manufactured by modifying starch or cellulose. A variety of microorganisms also produce water soluble extracellular polysaccharides and it was a microbial product — Xanthan gum — that was the centre of attention at a recent meeting in Birmingham*. Xantham gum is produced commercially by Kelco from *Xanthomonas campestris* and consists of a glucose main chain with three-unit side chains (mannose-glucoronic acid-mannose) on every other glucose residue. It was picked for its unusual gelling properties from a survey of microbial polysaccharides carried out by Allene Jeanes at the US Department of Agriculture in the 1950s. It is pseudoplastic, that is it forms a gel or high viscosity solution which thins when the solution is stirred. The viscosity is stable to changes in temperature, pH and salt concentration but can be modified by adding other vegetable gums. This gives it a wide range of uses, for example in 'instant' desserts and in salad dressings that flow out of the bottle but not off the salad.

One very important possible application for water soluble polymers is in the secondary recovery of oil. A normal oil well only produces about 40 per cent of its oil content in the combined processes of primary recovery, where the oil comes out under its own pressure, and secondary recovery where it is forced out by water or gas pumped down a series of holes surrounding the oil reservoir. The extraction is limited by the failure of the water to displace oil from porous rock and by the tendency of the water to follow cracks in the rock directly to the central well rather than sweeping the oil before it. There are a variety of ways to enhance oil recovery (for a review see Arnold, C.W. in *Microbial Polysaccharides and Polysaccharases* ed. Berkeley, Gooday, & Ellwood, SGM/Academic Press, 1979) but a possible new approach is through a combination of surfactants, to allow the water to displace the oil from rock, with water-soluble polymers to increase the water viscosity and prevent it by-passing the oil. The requirements for such a polymer are that it gives a high viscosity increase at low concentrations but is shear-thinning for ease of pumping. It should also be stable at the bottom of an oil well for several months, which, in the case of deep North Sea wells where conditions are most severe, means it must be stable in saline at temperatures of about 120°C. Polyacrylamides have been used successfuly in the US although the cost was high compared to the value of the oil produced. For general use, polyacrylamides are too unstable and too easily absorbed and every known water soluble polymer has been considered as an alternative. Xanthan gum or a similar microbial polysaccharide seem to be suitable but current fermentation methods of production make them expensive. Also, at a rate of one pound of polymer used per barrel of oil produced there may not be sufficient production capacity for the polysaccharides to satisfy the potential demand even if all fermentation plants were employed for this one product.

In the light of the increasing price of oil and the current interest in fermentation methods of producing industrial chemicals it seems natural to seek an industrial plastic made by microorganisms. For a biopolymer to be used as a plastic it should be a linear uncross-linked molecule insoluble in hot water but soluble in organic solvents or, better, capable of melting and processing without decomposition. Given that natural structural polymers like cellulose and collagen tend to be made from polar monomers and derive their insolubility from strong intermolecular hydrogen bonding it is not surprising that suitable examples are rare. One example is poly (β-hydroxybutyrate) which is an optically active thermoplastic polyester with a melting point around 175°C produced as an intracellular storage compound by various bacteria inlcuding *Azotobacter vinelandii* and *Pseudomonas solanasearum*.

If a suitable naturally produced thermoplastic were available it may still not be practicable to manufacture it. Any fermentation process leads to products which must be separated and purified and this may be considerably more expensive than a simple catalytic polymerisation, (for example, ethylene to polyethylene) although it may be competitive with the more expensive condensation processes leading to nylons or polyethylene terephthalate.

Thus while the traditional biopolymers, cellulose and rubber, are still the most important and water soluble biopolymers are in production, a solid polymer, the plastic microbe, has yet to come. □

Essential fatty acids and prostaglandins

from Michael Crawford

IN 1930 at the University of Minnesota in Minneapolis, George and Mildred Burr made the remarkable discovery that dietary linoleic acid was essential for growth, development and normal function in rats. At this time, pharmacological activity of a group of uncharacterised substances from semen and male accessory glands was also being studied by U.S. von Euler at the Karolinska Institute in Stockholm. He characterized the material as a biologically active hydroxylated unsaturated fatty acid and named it 'prostaglandin'.

World War II interrupted research on the 'essential fatty acids' (EFA) and 'prostaglandins' (PG), and it was not until the 1950s, with the introduction of radioisotopes, gas-liquid chromatography and mass spectrometry that further progress was made. During the 1950s and 1960s EFAs were shown to be required by several species, including man, and linoleic acid was found to be metabolized to longer chain polyunsaturated acids. In 1964 these were established as the precursors for the PGs by Van Dorp and colleagues of Unilever in Holland and by Bergström and colleagues at the Karolinska Institute in Sweden.

In spite of this evidence establishing a link between EFA and the PGs, work in both fields remained separate. Pharmaceutical companies became excited by the potential of PGs, their analogues and inhibitors in the fields of reproductive physiology, inflammation and thrombosis. Meanwhile in the EFA camp, advances were made in establishing the role of EFA in cell membrane function, brain growth and the prevention of atherosclerosis and thrombosis. At the time, however, benefits of high linoleic acid diets to the cardiovascular system were largely attributed to reduction in blood cholesterol. The important role of EFAs and PGs may well be in the integrity of vascular membranes, the stability of platelets and in modulation of vascular tone.

A recent Congress* was held to bring the two fields together. Both Burr and von Euler attended the Congress as guests of honour. The sessions were designed to highlight the precursor-product relationship between EFAs, PGs and other biologically important EFA metabolites.

A number of different speakers independently supported the idea that nutritional management of dietary precursors should affect biosynthesis of PG and other oxygenated products. The practical applications of this include the reduction

*The Golden Jubilee Congress on Essential Fatty Acids and Prostaglandins was held at the University of Minnesota, May 4-7, 1980.

0028-0836/80/400388-02$01.00

of hypertension and of atherosclerosis and the prevention of retinopathy in human diabetics by a diet rich in linoleic acid over a six-year period. In cardiovascular disease also, EFA aspects of nutrition emerged as a positive contribution to health in contrast to the negative effects of saturated fats and cholesterol.

It was suggested that conventional descriptions of EFA deficiency as a scaly skin and an elevated triene/tetraene ratio may be inadequate because different disease states were described in which conversion of linoleic acid to the PG precursors were impaired. Psoriasis is one example of EFA deficiency in which supplies of the linoleic and arachidonic acids are adequate but in which there is a block in the enzyme cyclooxygenase necessary for PG formation. In addition, the conversion of dihomogammalinolenic and arachidonic acids to the spectrum of leukotrienes, thromboxanes and prostacyclins may need to be similarly considered. In this context, present recommendations for linoleic acid intake of 1-2% of dietary energy may have to be revised upwards, especially when one considers our present high consumption of saturated fatty acids and their competition with EFAs for the enzyme systems. It is possible that the health of the vascular endothelium and the prevention of atherosclerosis should be a criterion by which one measured EFA requirements.

New leukotrienes were described bringing to three the families of leukotrienes. Within each family two compounds have pro-inflammatory and bronchoconstrictor roles making them possible mediators of inflammation and asthma. Probably these account for the biological activity of the slow reacting substance in anaphylaxis (SRS-A). There were also reports on chemical synthesis of novel leukotrienes and of the biosynthesis of leukotriene-like substances from 18-carbon fatty acids possessing Δ 5-unsaturation.

In the prevention of thrombosis and control of the immune system, there was renewed speculation that PGE_1 and/or other derivatives of the EFA precursor (8, 11, 14-20:3) may play previously hidden roles. Alteration of PG metabolism induced by the therapeutic use of lidocaine in endotoxin shock in baboons indicated that prostacyclin might be involved in protection against shock. This finding, for the first time, provided a rational link between adequate nutrition and susceptibility to stress and shock.

Columbinic acid proved to be of great importance. Derived from the seeds of the Columbine, its structure is similar to linoleic acid with a *trans* double bond at the five position. This acid was found to express many EFA functions associated with linoleic acid, but it cannot be converted to prostaglandins. Columbinic acid thus provides an experimental tool for separating PG-mediated functions from the structural lipid functions of essential fatty acids. For instance, columbinic acid could restore skin lesions of EFA-deficient rats, but could not normalise the response to inflammation.

Other exciting topics included a report suggesting that arthritis may be alleviated by dietary means involving 6, 9, 12-18:3. This result was found in an animal model of immune-mediated arthritis, the leukocytes from such animals were not able to take part in chemotaxis. With this and the other reported examples from the immune response and cardiovascular areas, the distinct impression was given that we may be on the verge of new and exciting developments in dietary control or prevention of major chronic disease states.

The Congress banquet ended with two historic speeches from two remarkable men — Burr and von Euler — remarkable not only for their work but for their great insight and natural humility. As scientists we were reminded to "expect the unexpected" and to realise that original discoveries often only become important after development by others whose contributions are forgotten.

The unique formula for this Congress worked in a very special way. It was the first meeting of two branches of science which have been distant acquaintances for many years; the knowledge each offered the other fused them into one. It is to be hoped that the new links and friendships it created will help to expand the new and permanent dimension that was added to biology in Minneapolis.

Neural communication and control: facts and theories

from D. M. MacKay

Everyone would agree that the interaction between theory and experiment should ideally take place in one and the same head. This is doubly true in a field such as brain research, where we are often in doubt as to the categories in which our problems should be expressed, let alone resolved. Present-day education being what it is, however, few of those most productive in experimental neuroscience are ideally equipped to do their own theorising; and all too many theorists show a lack of that sense of proportion that comes from long exposure to experimental fact.

Perhaps because of its close kinship with problems of engineering, the study of neural communication and control has enjoyed more than its share of theoretical attention over the past three decades. Can we learn anything from the history of those exceptional theories that have succeeded in catalysing experiments on new lines with useful results? Conversely, which current experimental findings (if any) seem likely to set theoretical speculation off in fresh directions? These were the kinds of question faced at a recent Symposium*.

T. H. Bullock (University of California, San Diego) set us off with an impressive survey of the diversity of physical changes that might serve to represent information or to control function in a single neuron, and therefore should not be overlooked by theorists of neural communication. Field potentials can be causative (for example, at the Mauthner cell axon cap). The relative timing of impulses may be as important as their mean frequency, especially if central 'clocking' occurs. Even physical movement of fibres cannot be discounted. Much of the ensuing discussion sought to narrow the range over which these alarming complications may be significant; but there was general agreement that at least in plexiform tissue the representation of neuronal interaction by means of 'circuits' was too simple to be safe.

Simultaneous recording from multiple microelectrodes, described by G. L. Gerstein (University of Pennsylvania) and others, offers a particularly promising new line of data for theorists of local network function. With tungsten microwire bundles, for example, Gerstein has found much greater similarity in the patterns of coincident firing of a group of visual cortical neurones than in the responses of a single neuron to two successive stimuli. This suggests that sensory information may be represented with lower variance in ensemble statistics than in single-unit histograms. A host of theories of neural network function in other areas may become testable as this technique develops.

A beautiful preparation for the study of neuronal interaction was described by P. Andersen (University of Oslo), who has succeeded in maintaining isolated slices of hippocampal cortex in functional condition for recording *in vitro*. Among many important results, he finds remarkable equipotency of synapses on the inner regions of pyramidal cell dendritic trees, and virtual simultaneity of excitation of a row of pyramidal cells by parallel afferents. Summation of simultaneous EPSPs from neighbouring inputs is perfectly algebraic, with no sign of conductance interference even at synapse separations below 50μm. Andersen's recordings identify GABA-containing interneurones as important modulators of pyramidal function.

D. M. MacKay is Head of the Department of Communication & Neuroscience, University of Keele, UK.

---

*A Satellite Symposium of the 1980 Physiological Congress, co-sponsored by the Commission on Communication and Control Processes of the International Union of Pure and Applied Biophysics, was held between July 20 and 24 at the University of Debrecen in Hungary. The organizers were S. Damjanovich & G Szekely (Hungary), P I Johannesma (Netherlands) and D. M MacKay UK.

An elegant experiment was described by M. Constantine-Paton (University of Princeton), on the tectal innervation from a third eye implanted in the developing frog. This shows that stereotypic segregation into alternating bands of ocular dominance can develop from an initial state of overlap between the two projections, and is superimposed upon a retinotopic representation of visual space. R. M. Gaze (National Institute of Medical Research, Mill Hill), working with compound (double-nasal, double-temporal, double-ventral) eyes in *Xenopus,* reported data supporting the "tea-trade" model of connection-formation developed by Willshaw and von der Malsburg[1].

The cerebellum has long invited theoretical modelling by the regularity of its geometry. Another highlight of the meeting was the study by M. Ito (University of Tokyo) of adaptive changes in the flocculo-vestibulo-ocular system of the alert rabbit, which has for the first time yielded a detailed and nearly complete functional picture of a cerebellar subsystem. Mossy fibre impulses from the labyrinth are transferred across the flocculus and elicit signals from Purkinje cells that adjust the vestibulo-ocular reflex. 'Retinal slip' error signals, sent to climbing fibres via the inferior olive, modify the efficacy of mossy fibre synapses on the Purkinje cells until the adjustment is accurate. Conjoint stimulation of mossy and climbing fibre afferents reduces the efficacy of parallel-fibre synapses. Although the synaptic changes found are opposite to those postulated in Marr's theory[2], being rather in the direction assumed by Albus[3], the general framework of Marr's original conceptualisation of cerebellar function appears to be supported by these findings.

At the theoretical 'whole-brain' level V. Braitenberg (Max-Planck-Institute, Tübingen) challenged us to consider the implications of some neuroanatomical statistics. With pyramidal cells making up perhaps three quarters of the neuronal population, synapses at a density of 10^9 per mm^3, and fibres perhaps 3×10^9 per mm^3, he argued that more than 100 axons must cooperate in order to excite one pyramidal cell. Hence the influence of any one pyramidal cell on another might be relatively small, despite their proximity. He favoured a view of the cerebral cortex as an array of associative cell assemblies rather than of feature-classifying units, with co-operative state–transitions representing specific 'decisions'.

Finally, D. M. MacKay (University of Keele) described recent experiments, based on his earlier information-flow analysis of cognitive agency[4], which gave evidence of goal-conflict between the two 'halves' of split-brain patients only at the executive level. The inference suggested was that the direct physical correlate of cognitive agency is not cortical activity as such, but rather the cooperative activity of a 'supervisory system' whose dominant evaluative level is embodied in diencephalic or other structures not divided by the splitting operation.

One's impression from the meeting as a whole (from which the above are only samples) is that the working relationship between experimentalists and theorists of neural function is entering on a new and remarkably fruitful phase. ☐

Chopping and changing in immunoglobulin genes

from Miranda Robertson

A concluding speaker, summarizing one of the 19 themes of the 4th International Congress of Immunology*, remarked that immunological research seems not so much to rush forward like a river, as to advance and retreat by turns like the tide. While there may be some truth in this assessment for cellular immunology, it clearly does not apply to the molecular biology of immunoglobulin genes, which has been advancing with gathering momentum ever since Tonegawa and his colleagues announced the first V region sequence in 1978[1]. Yet even in this field, there were signs at the Congress, if not of a retreat, at least of a significant change in orientation. Many of the molecular biologists who have been seeking an explanation for the diversity of antibody molecules have now clearly shifted their attention from somatic recombination of DNA to somatic point mutations.

The data which have led to the recent emphasis on recombination were reviewed by E. Kabat (Columbia University), and can be recapitulated as follows (see also ref. 2). It is known that the antigen-binding variable region of the immunoglobulin light chain is constructed from two separate genes: a V gene and a J gene. During the differentiation of an immunoglobulin-secreting B cell, one of a set of between 100 and 1,000 germ-line V genes combines at random, and with slight variations in the precise site of recombination, with one of a set of 5 germ-line J genes. The site of recombination coincides with the third hypervariable region. The heavy-chain variable region is constructed by a similar process with one additional complication. The V genes of heavy chains do not join directly to the J genes, but to a third set of genes, the D genes, which join in turn to the J genes. The D region of the heavy chain, which may vary considerably in length, corresponds to the third hypervariable region.

Given that each of the two immunoglobulin chains is constructed by such random recombination of substantial sets of germ-line genes, and that the light and heavy chains assort independently, it has been argued, here[3] and elsewhere, that there are enough germ-line immunoglobulin genes to account for the entire antibody repertoire without any need to postulate further diversification by mutation.

But whether or not these mechanisms could in principle account for all antibody diversity, there was general recognition at the Congress that in practice they do not. Kabat pointed out how little evidence there is that sequence changes brought about by V-J recombination have any effect on antigen-binding specificity, which depends not only on hypervariable region 3 but on hypervariable regions 1 and 2 as well. He himself, on the basis of an extensive survey of amino acid sequence data, adopts the minority view that the entire V region is constructed from mini-genes separately encoding each of the four framework regions and three hypervariable regions — a view that has been partly vindicated by the discovery of the separate D and J genes encoding the third hypervariable and fourth framework regions in the heavy chain. But while it is undeniable that, historically, amino-acid sequences have been rather good predictors of otherwise surprising properties of immunoglobulin genes, the balance of opinion is heavily against the mini-gene hypothesis in its extreme form. This is because of the evidence at the DNA level that only one rearrangement takes place between sperm and adult, and that that rearrangement results in transposition of a continuous sequence of DNA containing all three of the first three framework regions with the first two hypervariable regions *in situ.*

The majority view therefore is that any antibody diversity not generated by known recombination mechanisms cannot be explained by recombination at all; and an accumulation of evidence, some of it by no means new, has led to a pronounced switch in emphasis from recombination to somatic mutation as the main generator of antibody diversity.

Ontogeny and diversity

The data that are now recognized as pointing to somatic recombination are

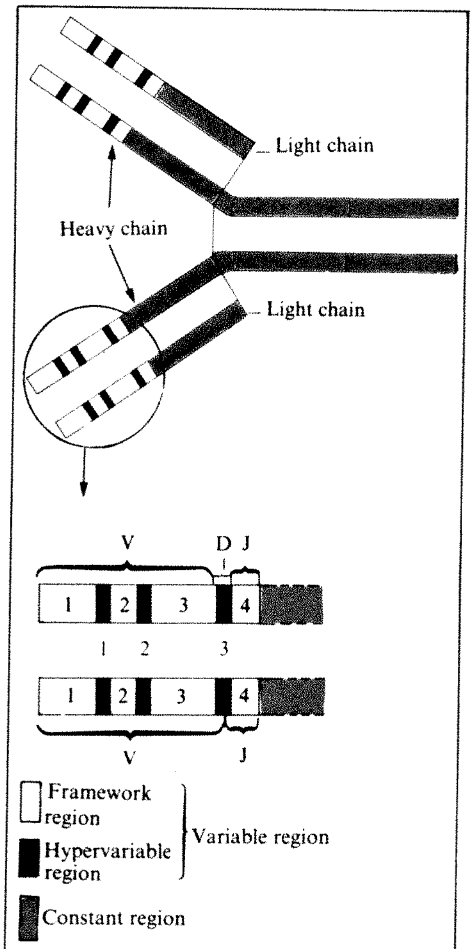
0028-0836/80/400390-03$01.00

those showing that isolated amino-acid substitutions occur not only in the hypervariable regions but also in the framework regions of secreted immunoglobulin chains. Such substitutions were reported in mouse V_L chains some years ago by Weigert *et al.*[4], and were in fact apparent from a comparison of the first sequenced germ-line V_L gene with the myeloma gene which had provided the probe[1]. A more systematic investigation of departures from germ-line sequences is now under way in a collaboration between K. Rajewsky's laboratory (University of Cologne) and A. Bothwell in Baltimore's laboratory, where 10 germ-line genes have been sequenced for comparison with immunoglobulin genes from a panel of hybridomas secreting antibodies against nitrophenol (NP). This comparison is still in progress, but in the meantime both Rajewsky and P. Gearhart (Carnegie Institute) reported a highly suggestive relationship between immunoglobulin diversity and B cell ontogeny.

This relationship is revealed in a comparison of antibodies of different classes directed against the same antigen. The first class of antibodies to be expressed in an immune response is always IgM, followed by IgG and later perhaps by IgA or IgE, the different classes of antibody being defined by the constant region of the heavy chain, which may be μ, γ, δ, or ε. It is believed that the sequential expression of different classes of antibody recognizing the same antigen (the heavy-chain switch) reflects the sequential recombination of a single V-D-J combination with the different C_H genes, by a process known to involve DNA deletion[2].

Gearhart reported an initial comparison of anti-phosphorycholine (PC) antibodies that suggests, indirectly, that the heavy-chain switch may be associated with somatic mutation in the V region. Partial sequences of 15 hybridoma proteins showed that while all four IgM proteins examined had identical N-terminal sequences, those of eight out of nine IgG proteins had amino-acid substitutions. Seven myeloma IgA anti-PC proteins were also partially sequenced and substitutions were found in 5 of those. Rajewsky has found a similar pattern of substitutions in a preliminary comparison of hybridomas secreting anti-NP IgM and IgG. One important incidental point to emerge from these investigations is that the same idiotype was expressed on the different immunoglobulin classes, which invalidates the use of anti-idiotypic antisera for monitoring changes in the V region during B cell ontogeny[3].

At present, the evidence in favour of such changes is necessarily indirect, and there is clearly an urgent need for a B cell clone in which a class switch can be induced so that comparison of V regions is possible within a single cell line. (Cell lines that undergo class switches do exist, but they are tumour cell lines of suspect ploidy.)



Immunoglobulin molecules are made up of four chains: one pair of heavy chains and one pair of light chains. Each chain is divided functionally into two regions: the variable region, which mediates antigen recognition, and the constant region, which in the case of the heavy chains mediates the effector function of the molecule.

The variable region can be further subdivided into four regions which vary only slightly from one antibody molecule to another, and are known as the framework regions, and three regions (the hypervariable regions) which are very much more variable and in the folded protein form the actual antigen-binding site.

Each light chain is now known to be coded by three separate genes: a C gene coding for the constant region, a J gene coding for the fourth framework region and part of the third hypervariable region, and a V gene coding for the first three framework regions including hypervariable regions one and two and part of hypervariable region three.

Each heavy chain is coded by four separate genes: a C gene coding for the constant region, a J gene coding for the fourth framework region, a D gene coding for the third hypervariable region, and a V gene coding for the first three framework regions including hypervariable regions one and two.

Ig genes of T cells

While the immunoglobulin molecule steadily yields its secrets to the combined onslaught of restriction enzymes and sequencers, the T cell receptor continues to elude molecular and cellular immunologist alike. This is particularly tantalizing in view of the evidence at the cellular level that the antigen binding sites of T cell receptors are encoded by immunoglobulin V_H genes. The original evidence for the expression of V_H genes in the T cell receptor was the demonstration that T cell help in antibody production could be induced or inhibited by anti-idiotypic antibodies[5]. Since then both suppressor (T. Tada, Tokyo University; M. Taussig, ARC Babraham; A. Nisonoff, Harvard University) and helper (E. Mozes, Weizmann Institute) cells have been found to bind anti-idiotype antibodies and to release idiotype-bearing factors which suppress or induce the production of antibodies to a specific antigen.

Progress on the biochemical characterization of these factors has however been slow, and in the meantime the appealing prospect of unifying T and B cell responses to antigen within a regulatory network based on idiotypic determinants of a single repertoire of V_H regions has become fogged with complications. C. Janeway (Yale University), discussing the variable consequences of attempts to manipulate the immune response with anti-idiotypic antibodies, pointed out that there is evidence that T cells have a more restricted repertoire than B cells, since an anti-idiotypic antibody that suppresses only a part of the B cell response to an antigen (the idiotype-positive part) can completely eliminate the T cell response to the same antigen. In the light of recent developments, this could simply mean that T cells use the same germ-line V genes but do not subsequently diversify by mutation. However a more serious problem arises in a result reported by H. von Boehmer (Basel Institute of Immunology) who has used an anti-V_H antiserum raised by D. Givol (Weizmann Institute) and his colleagues to stain cytotoxic T cells. To circumvent the problem of antigen specificity and the T cell repertoire, Givol produced an antiserum directed against common V_H framework determinants. This antiserum has been used successfully to isolate T cell factors but von Boehmer finds that it does not stain cytotoxic T cell clones.

Meanwhile, molecular biology laboratories have been competing in the attempt to by-pass the biochemistry altogether and reach for the receptor DNA with heavy-chain probes. Tonegawa, as reported at the Congress by von Boehmer, has used a J_H probe to explore a cloned cytotoxic T cell line and found V genes either in their germ-line arrangement, or rearranged aberrantly, but never rearranged to produce a V-D-J join as in a differentiated B cell.

In spite of the overwhelming evidence that none of the known immunoglobulin C regions is present on T cells, D. J. Kemp (Walter and Eliza Hall Institute of Medical Research) and T. Rabbitts (MRC Laboratory, Cambridge) have used a C region rather than a V region probe and shown, surprisingly, that the gene encoding the μ chain is rearranged both in T lymphoma cells[6] and in cloned T cells[7]. Kemp's colleagues have however gone on to show that although the μ gene is transcribed it is not translated[8].

What, then, is the significance of the apparently futile rearrangement of immunoglobulin genes in T cells? The answer suggested by Kemp is that they reflect the operation in T cells of the same enzymes that mediate the recombination events accompanying differentiation in B cells; and that T cell differentiation, therefore, is probably dependent on the same enzyme system, not necessarily operating on the same genes.

Abortive rearrangements in B cells

Abortive rearrangement of immunoglobulin genes is in fact an extremely common feature of B myeloma cells, in which it was first reported by Lenhard-Schuller *et al.*[9]. It has since been shown that in a large proportion of immunoglobulin-secreting myelomas, rearrangement of both light and heavy chain genes has occurred on both chromosomes, although only one directs the synthesis of immunoglobulin[10,11]. (The other may however give rise to protein fragments, which have occasionally been reported in biochemical investigations of myeloma cells.)

There are three ways of looking at these rearrangements. One possibility is that they are a peculiarity of myeloma cells and would not be seen in normal B cells if it were only possible to clone one and look at its DNA. This view is increasingly disfavoured. The second, which was emphasized by P. Leder (US National Institutes of Health), is that they may be a part of the price the immune system pays for antibody diversity. For example, one obvious consequence of the variable site of V-J joining is that in some recombined genes the reading frame may be shifted; and detailed investigations at the DNA level have now shown that this indeed accounts for an abortive rearrangement in myeloma MPC 173[12] in which a frame shift resulting from the V-J join on one chromosome produces a stop codon within the J sequence.

Similarly detailed investigations on another myeloma, MPCII, have revealed[13,14] a rather different kind of abortion, in which the V region on one chromosome recombines with a 'pseudo-joining' sequence, closely homologous to the V-J recombination sequence but falling within the intron between the J regions and the C region. This gives rise to a primary transcript from which the J region is missing and in which the splice signals in the RNA are altered in such a way that the V region sequence is spliced out during RNA processing and the final product of translation is a curious little fragment consisting of a hydrophobic leader sequence attached to the constant region of the κ chain. For abortive rearrangements of this sort however M. Weigert (University of Philadelphia) does not accept an explanation in terms of necessary sacrifices to the generation of diversity. He adopts the third possible view of abortive rearrangements, which is that they are the mechanism of allelic exclusion[11].

One of the numerous problems posed by B cells is that of how they contrive to express the immunoglobulin genes on only one of the two homologous chromosomes of a diploid cell. Once it was realized that immunoglobulin gene expression involves rearrangement of the DNA, an obvious possibility was that the DNA remained in the germ-line configuration on the excluded chromosome. However, restriction digest data on that point were conflicting. The conflict is now resolved: in some myelomas the immunoglobulin genes on the excluded chromosome remain in the germ-line configuration, in others they do not; and furthermore rearrangement cannot be the prerequisite for immunoglobulin gene transcription, since C_L (though never V_L) fragments may be transcribed in some myelomas from an unrearranged chromosome[11].

The important point is that in no case has a myeloma cell been shown to express more than one functional chain of each type. Weigert takes the view that this is because immunoglobulin genes have evolved so as to prevent such an occurrence by making functional rearrangements highly improbable. This accounts, he argues, for the survival of the 'pseudo-joining' site described by Leder, and for the conservation of 'pseudo-J' genes, originally described in κ light chains and now for λ light chains and for heavy chains (O. Bernard, Walter and Eliza Hall Institute). 'Pseudo-J' genes are J genes which do not lead to expression after recombination with a V segment. The conservation of such genes in the repertoire of the three different kinds of chain must imply that they have an important function: namely, to ensure that functional rearrangements are so unlikely that they almost never occur on both chromosomes. It follows from this that a large number of B cells probably undergo abortive rearrangements on both chromosomes and die without ever expressing immunoglobulin.

Further support for this general scheme is to be found in recent evidence on the fate of the κ light chain genes in B cells secreting λ light chains. For B cells have to decide not only which of two allelic sets of λ or κ light chains is to be expressed, but whether they are to be λ or κ in the first place. That the two decisions may be made on a similar basis was first suggested by the discovery[9] that, just as the genes for the unexpressed allele have been found to be rearranged, so the genes for the unexpressed κ class are rearranged in myeloma cells secreting λ chains. This discovery has now been confirmed and extended by Alt *et al.*[15] who have shown that in two out of four λ-secreting mouse myeloma cell lines, the κ genes are not only abortively rearranged but transcribed and translated into protein fragments. Similarly, Leder and his colleagues have shown that κ genes are rearranged in human B cell lines secreting λ chains.

These data are consistent with the general idea that abortive rearrangements may be the rule rather than the exception. However, preliminary investigations in Leder's laboratory on the converse question of the fate of λ light chain genes in human B cell lines secreting κ chains casts some doubt on whether light-chain class exclusion is really exactly analogous to allelic exclusion within a light-chain class. For in κ-secreting lines, the λ genes seem to remain in the germ-line configuration. The implication of this is that chromosomal rearrangements may take place in a predetermined order, so that only if recombination of the κ genes fails to produce a functional light chain will the λ genes be rearranged. It is already clear that there is some hierarchy in the rearrangement of genes for different immunoglobulin chains since it is established that heavy-chain genes are expressed before light-chain genes. As soon as a functional light chain is expressed, it can combine with the heavy chain to form a complete cell surface receptor. Alt *et al.* suggest that it is this event that shuts off further rearrangements of immunoglobulin genes so as to exclude the formation of λ chains in cells already expressing κ chains.

According to the evidence so far, then, there is a pecking-order for the DNA-recombining enzyme such that V_H genes are rearranged first, followed by the $V_{L\lambda}$ genes and finally, but only in the absence of existing surface immunoglobulin, the $V_{L\lambda}$ genes.

What is conspicuously missing from this picture is its context. While the ambitions of molecular biologists run to the possibility not only of isolating clones of B cell precursors, but even of dispensing with the cell altogether so as to examine the recombination mechanism without interference, there is on the other hand a real need to understand the events of lymphocyte differentiation in general in the context of the physiological signals that trigger them.

REVIEW ARTICLE

Insulating ground state and nonmetal–metal transitions

B. K. Chakraverty

Groupe des Transitions de Phases, CNRS BP 166, 38042 Grenoble Cedex, France

For over a decade there has been intense activity in the field of nonmetal–metal transitions in condensed systems in general and in solids in particular. The object of this review is to pinpoint the nature of the insulating ground state and to outline recent trends in our understanding of the metallic state and related phase transition.

ALL condensed systems can be considered as belonging to essentially three canonical states which in their simple limits are: metals, Mott insulators and covalent insulators (P. W. Anderson, personal communication). It is easy to define the metallic state in the simple limit—here the kinetic energy of the electrons dominates all relevant interactions whether between electrons and electrons or between electron and ion cores. The simple metals from the first columns of the Periodic Table especially those of the second, third and fourth columns are well described by this limit (r_s is small, where r_s is electron–electron distance and is a measure of electron–electron repulsion $\sim 1/r_s$ as well as of their kinetic energy $\sim 1/r_s^2$). As the kinetic energy of the electrons (their bandwidth) becomes smaller as we go away from this limit, two distinct types of symptoms usher the transition to the two other canonical states before the system becomes insulating: the characteristic large susceptibility and specific heat of almost magnetic metals such as Pt (ref. 1) which indicate strong repulsive interaction between electrons (henceforth called Mott–Hubbard U)[2] and on the other hand superconductivity which results from electron–ion interactions (henceforth called λ).

The decreasing bandwidth is achieved in principle by increasing the atom–atom distance which would obviously result if the process is continued until it results in systems of well separated atoms. Individual atoms are in general magnetic when their electrons are in open shells. This limit is represented by the paramagnetic 'Mott' insulators, which include a wide variety of transition metal oxides and sulphides, such as NiO and V_2O_3; their magnetic properties show that these cations retain unpaired spins and in spite of their open shells show no metallic conduction. This is because the repulsive energy U needed to put an extra electron on the same orbit is higher than the kinetic energy (bandwidth W) gained in delocalizing the electron resulting the electron preferring to remain in a localized state on every atom. This is the second canonical limit of $U > W$, which we have designated as 'Mott insulators'. In this limit, the system will permit two classes of excitation: (1) those involving the reversal of a spin in place of the type

$$S_i^+ = C_{i\uparrow}^+ C_{i\downarrow}, \quad Si^- = C_{i\downarrow}^+ C_{i\uparrow}$$

where S_i are the spin-operators on site i and Cs are the creation and annihilation operators. And (2) those involving the actual creation of a free pair of carriers of the form $C_{i\sigma}^+ C_{j\sigma}$, $i - j \rightarrow \infty$. The latter requires the excitation energy U, whereas the former does not (if the spins are not ordered) and for $U \gg W > kT$ we will have a paramagnetic insulator. As long as $W \neq 0$ but remains smaller than U, mixing of the spin-states through electron tunnelling between sites will occur so that the ground state will order antiferromagnetically ($J_{aF} \sim W^2/U$), although we may note that the resulting doubling of the lattice periodicity has nothing to do with the insulating Mott ground state: most Mott insulators remain nonconducting above the Néel temperature. One must point out that the Mott transition to a metallic state at zero temperature is, by definition, a phase transition of first order due to many-electron screening of U (and an electron must necessarily suddenly change from localized to itinerant behaviour) and this has nothing to do with the polemic whether the Hubbard hamiltonian generally used to describe interacting electron system in a narrow band gives a first or a second order phase transition or not.

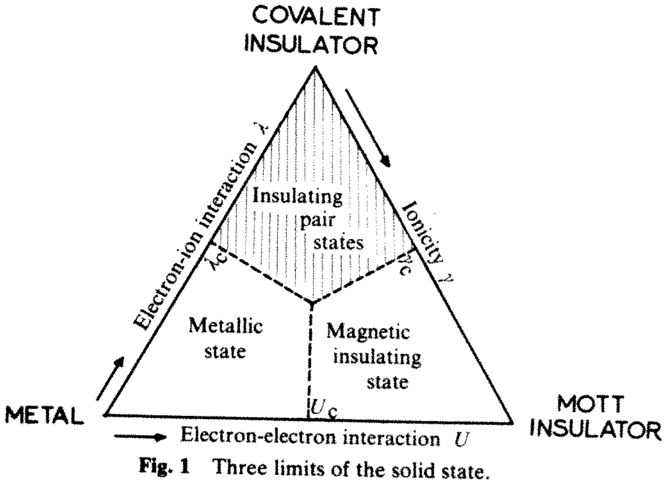

Fig. 1 Three limits of the solid state.

The third canonical limit of the solids is reached when the electron–ion interaction λ far exceeds the electron bandwidth W. As we approach from the side of a perfect metal ($\lambda = 0$, since by definition free electrons do not see the perturbing potential of the ions), a non-zero λ makes itself felt by phonon-induced resistivity $\sim T^5$ in the low temperature region. In the ground state, however, this non-zero λ has two strikingly related behaviours, both related to λ-induced attractive interaction between two electrons: if $\lambda \ll W$, this results in electron pairing and superconductivity, while for $\lambda \gg W$, we find ourselves in localized pair ground states which are diamagnetic singlet states, the covalent insulators being their extreme canonical limit (their essential diamagnetism differentiates them from the Mott insulators) of this class of solids. It is essential to realize that a purely local one electron–ion interaction results in a non-local two-electron attractive interaction sufficiently strong to overcome the repulsive mutual Coulomb interaction so that paired ground state can occur. The tendency to pairing is quite evident as we look into the Periodic Table. The fifth column semimetals provide an excellent example—Bi, As, Sb. These metals have an outer s-shell completely full leaving three electrons in their p-orbitals, along x, y and z directions. In a tight-binding theory of the cubic structure (all these metals at high pressure are cubic) as developed by Labbé and Friedel[3], the dominant hopping

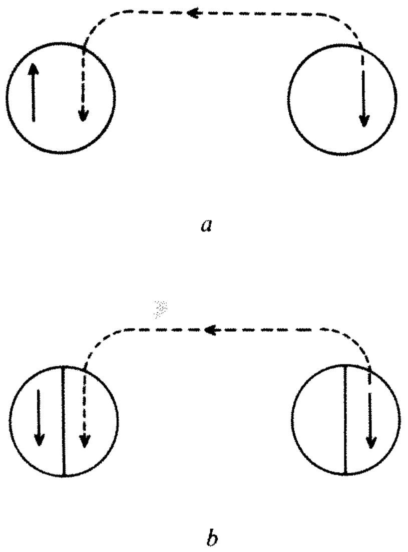

Fig. 2 *a*, Kinetic interaction, antiferromagnetic ground state. *b*, Kinetic interaction, degenerate orbitals, ferromagnetic ground state.

integral is the p_σ-type which gives simply three one-dimensional tight-binding bands each of which will be half filled. The effect of λ would be essentially a lattice distortion, known as 'Peierl's distortion' leading to pairing up of the electrons along x, y and z orbitals and thus one expects a layered structure in which each Bi atom will have three close neighbours in the x, y and z directions, which is what one observes in the actual metals. Note that in these semimetals, the Peierl's distortion leads to a Fermi surface with incomplete gaps, hence very large dielectric constants and small effective mass of the carrier which explain their semimetallic behaviour. The pairing phenomenon leading to Peierl's distortion is a process which competes with superconductivity and if for example Bi or As or Sb can be kept simple cubic, either by pressure or by quenching in impurities, they develop a remarkably high superconducting transition temperature ~10 K. Similarly, the A_{15} high T_c transition metal superconductors are equally subject to the martensitic structural instability often before the superconductive transition. This shows that the effects of λ on the metallic ground state are (1) superconductivity, (2) covalent-pairing leading to incomplete gaps at the Fermi surface in some cases—as in the semimetals or uniform distortion as in the A-15 compounds and (3) for larger λ, the tendency to covalent-pairing becomes so great that we get bipolaronic insulating state[4] (counterpart of the superconducting ground state) and eventually a covalent insulator like Ge or Si, where one can think of the pseudo-potential interaction λ as having eaten up the whole of the Fermi surface making a complete energy gap all around the Brillouin zone. These three canonical states of the solids—metals, Mott insulators and covalent insulators—are depicted in Fig. 1, in an 'alchemical' triangle (at $T=0$) which shows clearly the metal–nonmetal transition boundary to be expected as we move away on U-axis or λ-axis from the simple metal limit. The third axis that ties up the covalent insulator with the Mott insulator is the ionicity parameter γ (Pauling–Phillips–Van Vechten[5]) or the Madelung energy contribution that increases as we approach the Mott-insulation limit. On the Mott insulator side, anions are completely diamagnetic (unlike the cations), filling up the closed rare-gas shells. Approaching the boundary towards covalency, the outermost anionic wave functions spread out into the cationic orbitals. On the other side of the covalent ionic boundary as the ionicity decreases, we start building up the pair states like H_2, O_2 or N_2 or larger groups like benzene, where internally within the molecule we have mobile pair of electrons, but overall a molecular insulating crystal. For the rest of the article, we shall not elaborate any further on this third axis of the alchemical triangle.

Mott insulators

The transition from a metallic to Mott-insulating ground state is by definition accompanied by no change of lattice symmetry. The states on either side of the transition remain paramagnetic (from Pauli to Curie–Weiss behaviour) and is brought about as the lattice parameters are expanded such that diminution of W leads to U/W exceeding some critical value ~1. A rough idea of this critical value can be obtained from elementary arguments. Assume that U is small and the system is in the metallic state with one electron per atom. If we now remove one electron from its site and let it travel around the system, it will on each site have an energy ε_0+U due to repulsive interaction of the electron already sitting there. If the electron on its tour through the crystal happens to catch the hole it left, it will have an energy ε_0 at the side where it happens. This means the electron will recognize the hole as a potential well of depth U (and radius R). We can easily find out when these two body scattering events start to form a bound state. This is an elementary problem in quantum mechanics and gives us the binding condition as

$$\frac{8}{\pi^2}\frac{m^*U}{h^2}R^2>1$$

where m^* is the effective mass of the electron. Fitting the density of states to a rectangular density of states function and a bandwidth W, we can rewrite the bound-state condition as

$$\frac{U}{W}>\frac{\pi}{4}\left(\frac{4\pi}{9}\right)^{1/3}\sim 0.88$$

which is not very different from the Hubbard solution.

Are there any experimental systems that show the Mott ground state? Unfortunately the paramagnetic insulating ground state at $T=0$ is not the lowest energy state due to exchange effect between the electrons and is thus unobservable. This exchange effect can be essentially of two kinds: if the orbitals are non-degenerate and we have one electron per atom, the exchange is a so-called kinetic exchange and is antiferromagnetic, as seen in Fig. 2*a*. The hopping of electron from one site to another is only possible if they have opposite spins; (for identical spins, the Pauli principle prevents all electron transfer) so that the lowest energy state is antiferromagnetic, with a $J_{AF}\sim W^2/U$. Thus in the ground state, we will find an insulating and antiferromagnetic material. On the other hand, suppose the lowest energy orbitals are degenerate (say doubly degenerate) and we have one electron per atom. We expect the system to be metallic as the band will be 1/4 full but it will be a ferromagnetic

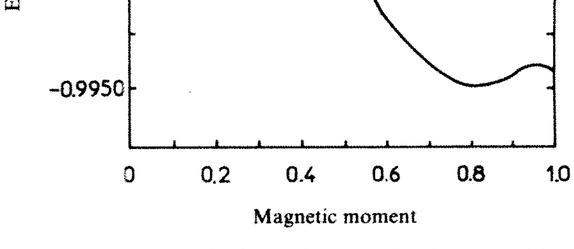

Fig. 3 Total energy at the first order metal–insulator transition as a function of the magnetic moment in the unit cell at $r_s = 2.84$. The inset shows an enlargement of the double-well structure. The arrow indicates that value of M for which the bottom of the upper spin band crosses the top of the lower spin band.

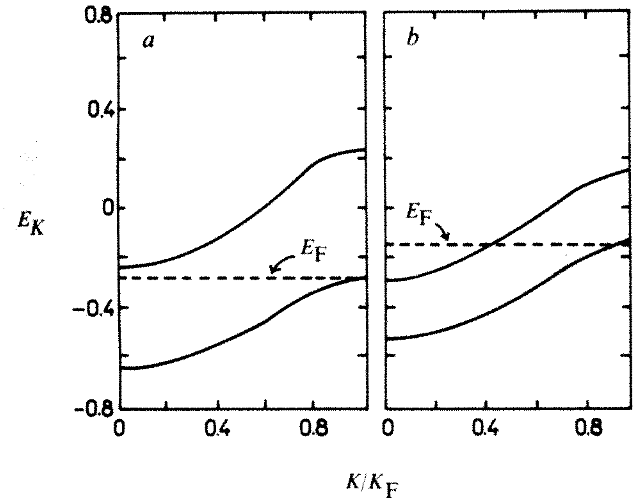

Fig. 4 Spin-split bands at the first order phase transition. *a*, The bands and the existence of an energy gap when the electrons are completely spin aligned ($M=1$). *b*, The overlapping bands which occur at the second energy minimum (see Fig. 3) for $M=0.82$.

metal due to the following simple argument[6] (Fig. 2*b*). If the two electrons on the adjacent sites have identical spins but on different orbitals, they can profit from Hund's rule coupling when one hops, as shown, to give

$$J_{\text{ferro}} \sim -\frac{W^2}{U-J_0}$$

where J_0 is Hund's rule coupling energy, while

$$J_{\text{AF}} \sim \frac{W^2}{U}$$

These two behaviours are very nicely illustrated in the transition metal dichalcogenide crystals of pyrite structure as we go from $CoSe_2$ to NiS_2. In CoS_2, the doubly degenerate e_g orbitals has one electron per atom; CoS_2 is metallic and ferromagnetic. In NiS_2, the same e_g orbitals now have to accommodate two electrons per atom; NiS_2 is insulating and antiferromagnetic. Thus NiS_2 (refs 7, 8) is a very good candidate for a Mott insulator. And under pressure at ~30 kbar, NiS_2 does go to a metallic ground state. A pure Mott transition has also been claimed[9] for V_2O_3 and its Cr-doped alloys, at its high-temperature transition to the insulating paramagnetic state. This is one of the most completely studied system; controversy remains, however, because the paramagnetic insulating state is reached as temperature is increased and the antiferromagnetic insulating ground state is accompanied by lattice symmetry change considerably complicating the implication of correlation 'only' in this system.

Recently, more quantitative calculation of the Mott–Hubbard transition had been performed by Rose *et al.*[10] For the system of one electron per atom, they have obtained as a function of r_s the ground-state energy (Fig. 3) energy dispersion (Fig. 4*a*, *b*) as well as magnetic moment per site (Fig. 5). We see very nicely the first-order metal–nonmetal transition at an $r_s=2.84$ predicted by Mott (this corresponds to Mott's universality criterion of $n^{1/3}a_0=0.22$). The double-well structure of Fig. 3 is the signature of the first-order phase transition. Considering Fig. 4*a* drawn for $r_s=2.84$, we see the band occupation when magnetization per site $M=1$, that is, complete spin polarization of the system. Consider taking a few electrons out of the lower band and putting them in the upper band. We must pay an energy ΔE to do this as Fig. 3 shows. However, there is a second effect which causes this energy increase to stop and leads to the formation of the second minimum at $M=0.82$. This effect results from the fact that the electrons and holes created by the transfer interact and reduce the energy gap between the two bands. In fact this effect is sufficiently large so that when we put enough electrons in the upper band, the bottom of the upper band crosses the Fermi surface of the lower band and energy is gained by transferring electrons to the upper band. The result is the minimum at $M=0.82$ (Fig. 4*b*). The qualitative behaviour is exactly as described by Mott's original arguments for the first order nature of the metal-insulator transition. These calculations also show formation of a spin moment in a second order phase transition at $r_s=2.74$ (Fig. 5).

To conclude this section, we will mention a completely different class of systems that show metal–nonmetal transition and are probably closest to the spirit of the original idea of Mott—that as the atom–atom distance is decreased, the system must go suddenly to the nonmetallic state. These systems are the low-density fluids or dense metallic vapours at high critical temperatures or pressures, and have been studied extensively by Hensel and co-workers[11] over the last decade. The most thoroughly studied is mercury (critical temperature 1,760 °C, critical pressure 1,510 bar for liquid–vapour transition) and it shows a transition to a fluid nonmetal as the pressure is varied. The fluid alkali metals on the other hand like Cs or Rb (ref. 12) show Mott transition at their critical points of gas–liquid transition with anomalous increase of the magnetic susceptibility as the Mott localization limit is approached (for Cs this occurs at around 1,800°C).

Bipolaronic insulators

In complete contrast to the Mott insulators, the bipolaronic insulators are characterized as a ground state of localized pairs of electrons in singlet state. Such an insulator is thus completely diamagnetic and is obtained as we go along the λ axis of Fig. 1, until a critical λ_c is reached at which the Fermi surface is unstable to the formation of these pair states. Unlike Mott insulators, the bipolaronic insulators are actually seen experimentally as a ground state[13] in a wide variety of solids and have opened up quite a new field of investigations.

The idea behind the formation of a bipolaron is really quite simple: in order for two electrons otherwise itinerant in an empty band to come together (either on the same site or on two nearby sites) and stay together localized, the lattice must locally deform to couple these two electrons together through a deformation-induced attractive interaction $\sim g_0^2/M\omega_0^2$ (where g_0 is an electron–lattice interaction term, M the atomic mass, ω_0 a lattice frequency) so as to compensate and exceed the instantaneous Coulomb repulsion $v(\sim e^2/\varepsilon r_0)$ of the underformed lattice. The total energy of the two-electron system is then

$$E_T=\frac{g_0^2}{M\omega_0^2}-v$$

When E_T exceeds $W/2$, the two electrons will emerge from the bottom of the band as a localized bound pair state. This situation is schematically shown in Fig. 6 where E_T is plotted against

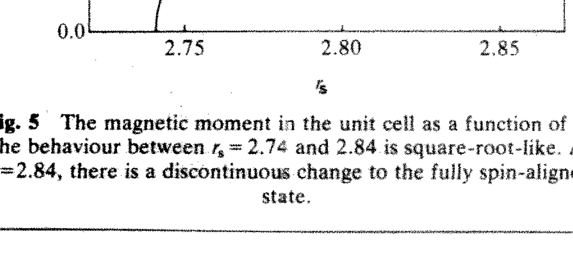

Fig. 5 The magnetic moment in the unit cell as a function of r_s. The behaviour between $r_s=2.74$ and 2.84 is square-root-like. At $r_s=2.84$, there is a discontinuous change to the fully spin-aligned state.

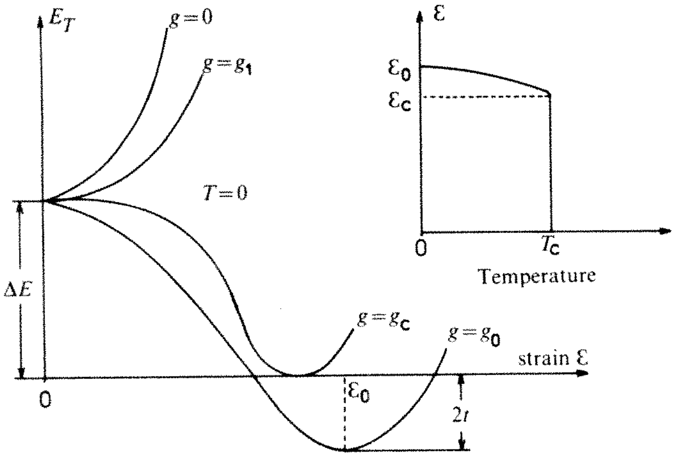

Fig. 6 Total energy of electron pair as a function of lattice deformation.

lattice deformation ε for different values of the coupling constant g_0 and we observe the critical g_0 at which the bound state for the two electrons appears. The transition to the insulating state is sudden and as we raise the temperature, the appearance of the metallic state is characterized by the vanishing of the deformation (insert Fig. 3). Such a pair is called a bipolaron in analogy with polarons. Note, however, that unlike polaronic concepts, bipolaron formation is not necessarily due to optical phonons. Ti_4O_7 (ref. 13) and its alloys remain the most extensively studied bipolaronic insulators. There are several important points that need however to be emphasized:

(1) In nature, it is rare[14] to find a $s = 1/2$ system that does not have a diamagnetic ground state.

(2) The interaction between the two electrons is really between two strain centres (two 'polarons'), that is, elastic interaction and can be long-range, highly anisotropic and oscillating in character.

(3) The bipolarons stand exactly in the same relationship to Bardeen–Cooper–Schrieffer superconducting pairs as does a localized electron to an itinerant one. A phase diagram between superconducting ground state and an insulating bipolaronic ground state has recently been suggested[15] as a function of the coupling strength λ.

(4) Formation of bipolarons is to be distinguished from the Peierl's transition[16]; unlike the latter, there is no lattice symmetry change involved in the former. In this sense, the bipolarons also differ from the insulating ground states of the so-called layer compounds due to charge density wave formation where the lattice periodicity is modulated[7,8].

We have attempted a synthesis between what we called the three simple canonical states of solids—metals, Mott insulators and covalent insulators. No attempt has been made to include all varieties of metal–nonmetal transition—for example the valence transitions[17] in rare-earth compounds, or the transitions in lower dimensionality[18] solids or Anderson transitions[19,20] in disordered systems. Each of these are in a rapidly developing state both theoretically and experimentally and it is quite impossible to include any of them in this short review. The reader is referred to specific articles dealing with these topics. *Note added in proof*: A complete calculation of the Goodenough–Kanamori rules and their relevance to Mott insulators has recently been published[21].

Improved conversion of methanol to single-cell protein by *Methylophilus methylotrophus*

The glutamate dehydrogenase gene of Escherichia coli *has been cloned into broad host-range plasmids and can complement glutamate synthase mutants of* Methylophilus methylotrophus. *Assimilation of ammonia via glutamate dehydrogenase is more energy-efficient than via glutamate synthase, thus the recombinant organism converts more growth substrate, methanol, into cellular carbon.*

A CRITICAL factor in determining the suitability of a microorganism for use in the production of single-cell protein (SCP) is the efficiency with which it converts substrate carbon into cellular carbon[1]. A major reason why the obligate methylotroph *Methylophilus methylotrophus* was selected for use in the ICI process to produce SCP from methanol was its high 'carbon conversion efficiency'. However, we have identified a potential source of methanol wastage due to its mode of ammonia assimilation. Instead of using glutamate dehydrogenase (GDH) to catalyse the conversion of ammonia and 2-oxoglutarate into glutamate, this organism uses a two-stage pathway, dependent

0028–0836/80/400396—06$01.00

on glutamine synthetase (GS) and glutamate synthase (GOGAT), to carry out the same function (Fig. 1)[2]. The latter pathway requires one extra molecule of ATP per molecule of glutamate formed.

M. methylotrophus probably uses the energetically suboptimal pathway for ammonia assimilation because of the environment in which it evolved. GS has a much higher affinity for ammonia than GDH[3] and is therefore more effective in scavenging for low concentrations of ammonia. Since ammonia concentrations are not growth-rate limiting during SCP production, exchanging the ammonia assimilation pathway used by *M. methylotrophus* should result in the organism consuming less energy for this process; correspondingly more methanol should be available for protein synthesis. We have used recombinant DNA techniques to carry out this exchange by introducing the *Escherichia coli* *gdh* gene, which codes for GDH activity, into a mutant of *M. methylotrophus* which lacks GOGAT.

Cloning the *E. coli gdh* gene

The best available strain for screening for a cloned *E. coli gdh* gene was *E. coli* CB100, which is deficient in both GDH (gdh^-) and GOGAT ($gltB^-$) and therefore requires glutamate for growth[4]. Derivatives which have received a *gdh* gene from another source should be readily selectable by virtue of their glutamate independence. However, because CB100 is λ-resistant and a relatively poor transformation host we initially cloned the *gdh* gene by *in vivo* techniques using RP4::Mu (refs 5, 6).

A $gltB^-$ *E. coli* strain (obtained from Dr J. Cole) was lysogenized with Mu *cts* and a derivative of RP4 carrying Mu *cts* was transferred into it. This strain was grown overnight at 37 °C and was then mated non-selectively at 30 °C with a derivative of CB100 which is *rec*A, rif^r and which is lysogenic for Mu *cts* (CL412). Progeny of this mating were transferred to plates of minimal medium deficient in glutamate but containing rifampicin and kanamycin. This should select for progency of CL412 which have received plasmid RP4 derivatives carrying a segment of the donor strain's chromosome containing a functional *gdh* gene (that is, an RP4'*gdh* plasmid). Several methods were used to prove that some of the progeny of this mating and selection did carry authentic RP4'*gdh* plasmids. First, the plasmids could be transferred through an intermediary host (C600 *rec*A) and back into CL412, selecting only for kanamycin resistance, and they still conferred glutamate independence on the latter strain. Second, elimination of the RP4-derived plasmid from CL412 by mating in an incompatible, trimethoprim-resistant (Tp^r), P-group plasmid, R751 (ref. 7), resulted in simultaneous loss of glutamate independence. Finally, enzyme assays showed that when glutamate independence was conferred by these plasmids it led to the acquisition of GDH and not GOGAT activity.

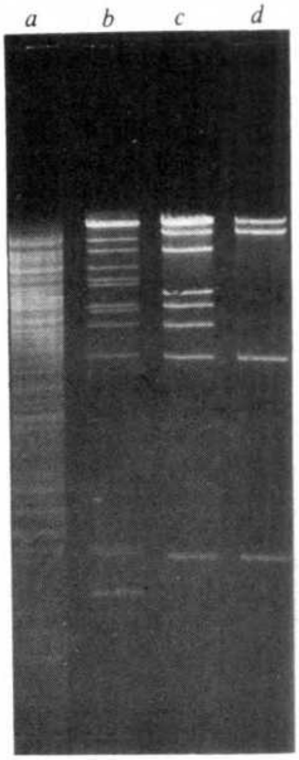

Fig. 2 Comparative *Pst*I restriction endonuclease analysis of RP4' *gdh* DNAs with RP4 and *E. coli* DNAs. RP4' *gdh* plasmid DNAs were prepared from fresh 100 ml overnight cultures of CL412 cells by a Triton X-100 (0.05%)/lysozyme lysis procedure[14], followed by 2 min vigorous vortex mixing and by centrifugation with ethidium bromide and caesium chloride[15], without a preliminary clearing spin. The closed circular DNA was collected dropwise, after preliminary aspiration of the dense linear DNA band, and was then dialysed for 2–3 h against 0.01 M Tris (*p*H 7.5); 1 mM EDTA (TE buffer) before phenol extraction, *n*-butanol extraction, ethanol precipitation and re-dissolving in TE buffer. RP4 DNA was prepared in essentially the same way and was a gift from G. S. Sharpe. *E. coli* C600 DNA was prepared as described by Marmur[16], except that the cells were lysed with lysozyme and Triton X-100. DNAs were digested with *Pst*I (MRE Porton) in 30 μl of 20 mM Tris (*p*H 7.5), 10 mM $MgCl_2$, 50 mM $(NH_4)_2SO_4$ and 100 μg ml^{-1} BSA for 60 min at 30 °C, before incubation at 70 °C for 10 min and electrophoresis on a 40 cm × 0.3 cm 1% agarose gel at 200 V overnight, under the conditions of Sharp *et al.*[17] The gel was stained in 2 μg ml^{-1} ethidium bromide for 30 min, washed in water for 30 min and photographed under UV light. *a*, *E. coli* C600; *b*, RP4' *gdh*3; *c*, RP4'*gdh*4; *d*, RP4.

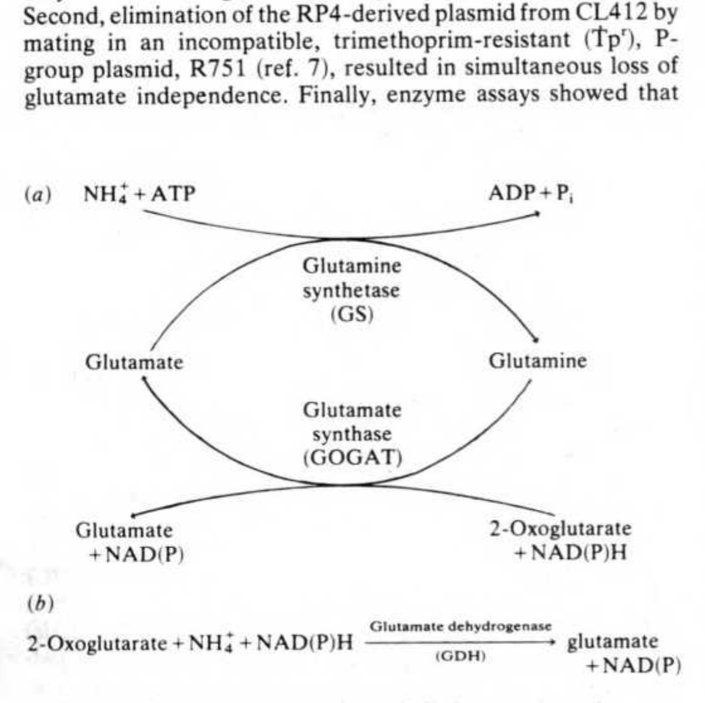

Fig. 1 Pathways of ammonia assimilation by bacteria. *a*, GS/GOGAT; *b*, GDH.

*Pst*I cleavage of plasmid DNA prepared from some of the RP4'*gdh* carrying strains gave the gel electrophoretic patterns shown in Fig. 2. Although fragments common with RP4 are clearly present, the RP4'*gdh* plasmids are much larger and give more complex restriction patterns than RP4 itself. Similarly, the plasmids RP4'*gdh*.3 and RP4'*gdh*.4 have homologous *Pst*I DNA fragments which they do not share with RP4. However, the RP4'plasmids clearly differ from each other, RP4'*gdh*.3 being substantially larger than RP4'*gdh*.4. All of these features might be anticipated because of the method of construction of the plasmids, which should have resulted in the transfer of substantial, but variably sized pieces of the *E. coli* chromosome to RP4, together with two copies of the Mu *cts* phage genome[6]. Following transfer of these RP4'*gdh* plasmids directly from *E. coli* to *M. methylotrophus*, by selection for antibiotic resistances conferred by RP4, we were unable to detect GDH activity; this could be due to the probable instability of plasmids of this structure in a recombination-proficient host[6], or to inefficient transcription of the heterologous DNA.

To isolate a more defined DNA fragment carrying the *E. coli gdh* gene, we cloned DNA from three of the RP4′*gdh* plasmids on to the vector plasmid pACYC184 (ref. 8), using the restriction enzymes *Hin*dIII, *Bam*H1 and *Sal*I. Only with the latter enzyme were substantial numbers of recombinant plasmids obtained which caused CB100 to become chloramphenicol-resistant and glutamate-independent. Plasmid DNA, isolated from four such transformants, contained in each case, a 7.6-kilobase fragment of *E. coli* genomic DNA, flanked by *Sal*I targets (Fig. 3). Enzyme analyses on CB100 strains carrying these pACYC184 derivatives, which confer glutamate independence, show convincingly that this independence is caused by the presence of high levels of GDH (Table 1*a*). The enzyme level apparently reflects the multi-copy nature of the pACYC184 vector plasmid, which indicates that increased gene dosage can cause enhanced GDH production in *E. coli*. Minicell experiments have confirmed that the principal new polypeptide, resulting from the presence of the 7.6-kilobase DNA fragment in the pACYC184 recombinant plasmids, co-migrates with purified *E. coli* GDH on SDS/polyacrylamide gels and is immunoprecipitable with anti-*E. coli* glutamate dehydrogenase antibody (T. C. Hodgman, personal communication). We are therefore confident that the *Sal*I-derived pACYC184 recombinant plasmids we have isolated carry a functional *E. coli gdh* gene and have designated them pACYC184/*gdh* plasmids.

Construction of plasmids to transfer the *E. coli gdh* gene to *M. methylotrophus*

Because pACYC184 is not transferable to *M. methylotrophus*, other plasmid vectors have had to be used to achieve *gdh* gene transfer; these are shown in Fig. 4. pRP301 is a low copy-number conjugative derivative of RP4 which has lost one of the two *Sal*I sites of that plasmid, together with kanamycin resistance (Km^r; ref. 9). Like RP4 it can transfer itself from *E. coli* to *M. methylotrophus* and maintain itself in its new host. pTB70 is a derivative of the multi-copy plasmid R300B (ref. 9), which confers streptomycin resistance (Sm^r) and sulphonamide resistance (Su^r) and into which the Km^r transposon Tn5, together with a small additional piece of DNA, has been inserted. Tn5 gives pTB70 a single *Sal*I site [10]. Like R300B, pTB70 can be mobilized by RP4 to *M. methylotrophus* and is capable of stable maintenance in this organism.

The *E. coli Sal*I *gdh* fragment was readily transferred from pACYC184/*gdh* to the pRP301 and pTB70 vectors. Donor and recipient plasmid DNAs were mixed, cleaved with *Sal*I, ligated and transformed into CB100, selecting for ampicillin-resistant (Ap^r) or Km^r transformants respectively and screening these for glutamate independence. Representative examples of the pRP301/*gdh* and pTB70/*gdh* recombinant plasmids isolated from such glutamate-independent transformants are shown in Fig. 3. Enzyme activities in CB100 cultures carrying such recombinants are consistent with the gene dosage effects noted above (Table 1*a*); pTB70/*gdh* plasmids in particular are of interest as they give rise to the highest levels of GDH in *E. coli* of any plasmids we have constructed so far.

pRP301/*gdh* recombinant plasmids could be transferred directly into *M. methylotrophus* from CB100 by selection for Ap^r. However, unlike RP4, neither pRP301 nor pRP301/*gdh* was found to be stable in *M. methylotrophus*. After growth for 11 generations on ampicillin-free medium, only about 50% of the cells remained resistant to this antibiotic. This phenomenon was not observed with *E. coli* cultures carrying the equivalent plasmid. Nevertheless ampicillin selection was routinely maintained for all strains carrying them. pTB70/*gdh* plasmids can efficiently be mobilized into *M. methylotrophus* from *E. coli* by RP4, selecting for Sm^r transconjugants. Some of these transconjugants stably acquired both RP4 and pTB70/*gdh*, others only acquired the latter plasmid, as judged by their antibiotic resistances. Plasmid DNA isolated from *M. methylotrophus* carrying either pRP301/*gdh* or pTB70/*gdh* was indistinguishable from the corresponding plasmid DNAs isolated from *E. coli* strains, as judged by restriction endonuclease analysis. To determine whether the *E. coli gdh* gene which had been transferred to *M. methylotrophus* on pRP301/*gdh* and pTB70/*gdh* plasmids gave rise to functional GDH, enzyme assays were performed on cultures which had been grown in the presence of 100 $\mu g\ ml^{-1}$ ampicillin or 15 $\mu g\ ml^{-1}$ streptomycin, respectively, to ensure retention of the plasmids in the absence of any means of directly selecting for *gdh* gene retention. As shown in Table 1*b*, *M. methylotrophus* cultures carrying either pRP301/*gdh* or pTB70/*gdh* plasmids produce significant levels of GDH as well as normal levels of GOGAT. *M. methylotrophus* itself produces only GOGAT. The *E. coli gdh* gene therefore appears to be functional in *M. methylotrophus* without further manipulation, although the efficiency of the expression is substantially reduced. The impact of gene dosage is shown in that *M. methylotrophus* carrying pRP301/*gdh* contains substantially lower levels of GDH than when carrying the multi-copy plasmid pTB70/*gdh* (Table 1*b*). The level of GDH in *M. methylotrophus* pTB70/*gdh* cultures is about 45% of that present in gdh^+ *E. coli* strains and this might be expected to be sufficient to allow efficient growth of a glutamate synthase-deficient *M. methylotrophus* strain.

Table 1 GDH and GOGAT activities in strains of *E. coli* and *M. methylotrophus*

		Enzyme	
		GDH	GOGAT
(*a*) *E. coli* strains	Cofactor:	NADPH	NADPH
C600		1010	215
CB100		ND	ND
CB100 (pACYC184/*gdh*)		4880	ND
CB100(pRP301/*gdh*)		1390	ND
CB100(pTB70/*gdh*)		6130	ND
(*b*) *M. methylotrophus* strains	Cofactor:	NADPH	NADH
M. methylotrophus	30	ND	78
M. methylotrophus (pRP301/*gdh*)	30	75	72
M. methylotrophus (pTB70/*gdh*)	30	453	75
M. methylotrophus	37	ND	229
M. methylotrophus (pTB70/*gdh*)	37	835	115
M. methylotrophus 56.2 (pTB70/*gdh*)	37	757	ND

E. coli strains used in enzyme assays were grown in M9 medium[22] supplemented with appropriate amino acids at 40 $\mu g\ ml^{-1}$ and thiamine at 4 $\mu g\ ml^{-1}$. *M. methylotrophus* strains were grown on medium containing (per litre): $(NH_4)_2\ SO_4$, 1·8 g; $MgSO_4 \cdot 7H_2O$, O . 2 g; $NaH_2PO_4 . 2H_2O$, 1 . 4 g; K_2HPO_4, 1.9 g; $FeCl_3$, 0.98 mg; $CuSO_4 . 5H_2O$, 0.02 mg; $MnSO_4 . 4H_2O$, 0.1 mg; $ZnSO_4 . 7H_2O$, 0.1 mg; $CaCO_3$, 1.8 mg. *p*H was adjusted to 6.85 and methanol added to give a final concentration of 0.5% v/v. Aliquots (500 ml) of pre-warmed media were inoculated with 50 ml overnight cultures grown in the presence of 100 $\mu g\ ml^{-1}$ chloramphenicol, 100 $\mu g\ ml^{-1}$ ampicillin or 15 $\mu g\ ml^{-1}$ streptomycin, where appropriate, to ensure selection for plasmid retention. The cultures were grown with shaking aeration at 37 °C to an A_{650} of 0.5, harvested by centrifugation, washed with 10 ml ice-cold buffer (22 mM $KH_2\ PO_4$; 50 mM $Na_2\ HPO_4$; 85 mM NaCl and 0.1 mM $MgSO_4$) and stored overnight on ice as cell pellets. Cell extracts were prepared by resuspending the pellets in 1 ml buffer, sonication and pelleting cell debris by centrifugation at 80,000 *g* for 60 min. Enzyme assays were performed at 30 °C, unless otherwise indicated. The assay mix contained (in a 3 ml cuvette): 50 mM HEPES buffer *p*H 7.5; 1 mM EDTA; 1 mM 2-oxoglutarate; 0.16 mM NAD(P)H; cell extract 0.01–0.1 ml. The reaction was initiated by the addition of substrate to give a final concentration of 10 mM, using NH_4Cl to assay GDH or L-glutamine to assay glutamate synthase. The oxidation of NAD(P)H was followed at 340 nm using a Perkin–Elmer 554 spectrophotometer and a water-jacketed cuvette holder. Enzyme activities are given in nmoles NADH or NADPH oxidized min^{-1} mg $protein^{-1}$, protein concentration being determined by the method of Lowry *et al.*[23]. ND = No detectable activity.

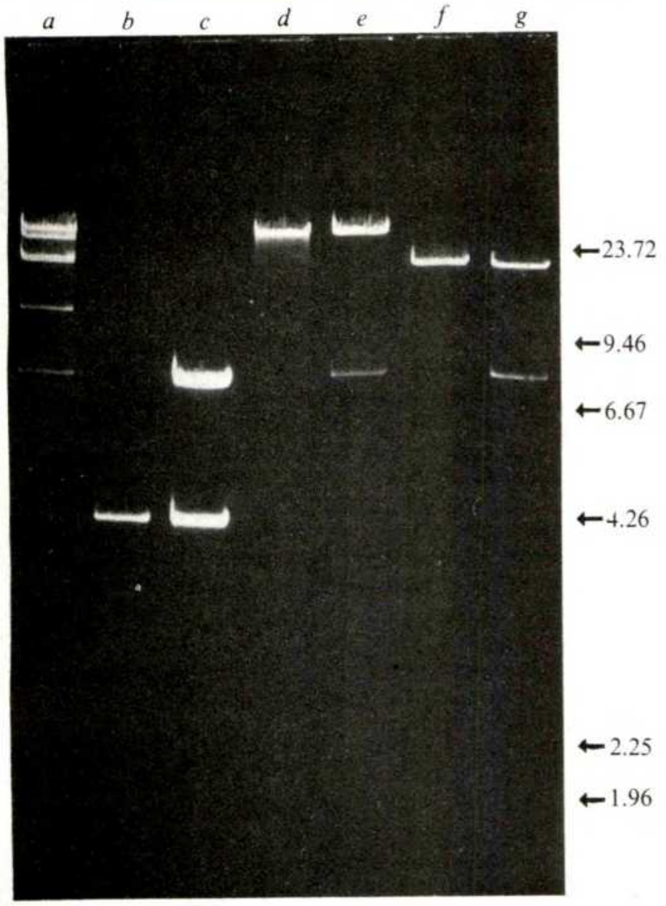

Fig. 3 Comparative *Sal*I restriction endonuclease analysis of RP4′*gdh*4, pACYC184/*gdh*, pRP301/*gdh* and pTB70/*gdh* plasmids. Plasmid DNAs were prepared from suitable CB100 derivatives as described in the legend to Fig. 2. *Sal*I digests were performed in 30 μl volumes with enzyme obtained from Bethesda Research Laboratories, under the recommended conditions. Electrophoresis, staining and photography were also as described in Fig 2. *a*, RP4′*gdh*4; *b*, pACYC184; *c*, pACYC184/*gdh*; *d*, pRP301; *e*, pRP301/*gdh*; *f*, pTB70; *g*, pTB70/*gdh*. The size markers were obtained by running a *Hin*dIII digest of λDNA in a parallel track, and are given in kilobases.

Isolation and characterization of GOGAT deficient mutants of *M. methylotrophus*

To ensure that *M. methylotrophus* carrying the cloned *E. coli gdh* gene was entirely dependent upon the GDH pathway for ammonia assimilation, it was necessary to block the existing GS/GOGAT pathway. Elimination of GS activity would result in a glutamine requirement which would not be supplemented by the presence of GDH activity; it was therefore necessary to block the GS/GOGAT pathway by isolating a mutant deficient in GOGAT.

Since GOGAT functions in the biosynthesis of glutamate (Fig. 1), through which most ammonia is assimilated into the cell, the obvious phenotype of mutants which have lost this activity would be an ability to grow on glutamate but not ammonia as sole nitrogen source[2]. However, *M. methylotrophus* cannot use glutamate as sole nitrogen source; uptake experiments suggest that this is due to impermeability to this compound (J. McNairney, personal communication). Permeability mutants which are able to use glutamate as a nitrogen source can be readily selected from *E. coli* W (ref. 11), which resembles *M. methylotrophus* in poor uptake of glutamate. However, we have been unable to isolate such mutants from the latter organism.

A search was initiated to find alternative nitrogen sources (Table 2), but of the compounds tested only glutamine gave a positive result. However, we have been unable to isolate either glutamine auxotrophs of *M. methylotrophus* or alternatively mutants able to grow on glutamine but not ammonia as sole nitrogen source. Furthermore, experiments with radiolabelled glutamine indicated that it too cannot be taken up by the cell (W. Naylor, personal communication). Since *M. methylotrophus* can grow on extremely low concentrations of ammonia, and as glutamine is rather unstable, it is conceivable that apparent growth on glutamine is due to the presence of ammonium ion impurities. Alternatively, *M. methylotrophus* may have some mechanism for breaking down glutamine extracellularly and growing on the ammonia thus produced.

These results indicated that a mutant which had lost GOGAT activity would not be able to grow on any of the nitrogen sources tested. A strategy was therefore adopted of isolating temperature-sensitive mutants and screening these for strains able to grow at the non-permissive temperature following the introduction of pTB70/*gdh* into them. Out of a total of 550 mutants, isolated after mutagenesis with *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine, four were found which could grow at the non-permissive temperature (37 °C) when they had received this plasmid. However, these mutants failed to grow at 37 °C when pTB70 was transferred into them, indicating that they were complemented by a function encoded by the 7.6-kilobase pair cloned fragment of *E. coli* DNA carried by pTB70/*gdh*. Similarly, when the mutants carried the low copy-number plasmid pRP301/*gdh*, which only gives rise to low levels of GDH in *M. methylotrophus* (Table 1*b*), they grew poorly at 37 °C. Mutants carrying pRP301 alone, failed to grow at this temperature.

Mutants of *E. coli* lacking GOGAT activity and relying on GDH for growth on ammonia are unable to grow on media supplemented with 0.075 mM NH_4^+, although the wild-type organism will grow slowly on such media[2]. This is probably due to the difference in the affinity for ammonia of the enzymes involved[3]. We therefore tested the ability of the putative temperature-sensitive GOGAT mutants of *M. methylotrophus* carrying pTB70/*gdh* to grow on plates containing 0.07 mM NH_4^+ at 30 °C and 37 °C. The results for one such mutant, 56.2, are shown in Table 3. Whereas, at 30 °C, both the wild-type and the temperature-sensitive mutants formed colonies on plates with ammonia concentrations down to 0.07 mM, at 37 °C the temperature-sensitive mutants complemented by pTB70/*gdh* would not grow on 0.07 mM ammonia. The latter strains grew well, however, on both 1 mM and 15 mM ammonia. This strongly suggests that these strains use GDH for growth and are

Table 2 Nitrogen sources for *M. methylotrophus*

γ-benzyl-L-glutamate	−

Overnight cultures of *M. methylotrophus* were centrifuged, washed in buffer and inoculated into liquid medium of the composition described in the legend to Table 1, except that the compounds to be tested were the sole nitrogen source and were assessed at both 5 mM and 10 mM. Growth was scored after 48 h incubation at 37 °C. + Indicates growth, − indicates no growth.

unable to use GOGAT for ammonia assimilation at 37 °C. Finally, enzyme assays demonstrated that temperature-sensitive mutants complemented by pTB 70/*gdh* and grown at 37 °C lack detectable GOGAT activity but have high levels of GDH synthesized from the plasmid-carried *gdh* gene derived from *E. coli*. The results for mutant 56.2 are shown in Table 1*b*.

Thus *M. methylotrophus* has now been genetically modified so that it can assimilate ammonia via the energetically more favourable GDH route. The resultant organism *M. methylotrophus* 56.2 carrying pTB70/*gdh*, was tested in continuous culture under methanol-limiting conditions at a dilution rate of 0.2 h^{-1}. Subsequent enzyme assays and plasmid analysis showed that the *gdh* gene was stably maintained even in the absence of antibiotic selection and that the modified organism gave 4–7% higher carbon conversion than its unmodified precursor.

Discussion

The isolation of a fragment of *E. coli* DNA containing a functional gene for GDH and the identification of plasmid vectors capable of transferring this DNA fragment by conjugation from *E. coli* to the obligate methylotroph *M. methylotrophus* has enabled temperature-sensitive mutants of the latter organism to be screened for those deficient in GOGAT activity. The resultant transconjugants must use the *E. coli* GDH to synthesize all the glutamate[2] and hence all the organic nitrogen they require for growth at the non-permissive temperature. The use of the energetically more efficient GDH ammonia assimilation pathway results in more methanol being converted into cellular carbon. Thus, using recombinant DNA techniques, we have been able to make a fundamental alteration in the primary metabolism of *M. methylotrophus*, inactivating one function and replacing it with a heterologous one derived from a separate microbial genus. The resulting organism is able to convert significantly more methanol into SCP than the parental strain.

One of the principal problems of gene transfer between organisms which are not closely related has been in the expression of the transferred gene in its heterologous host[12]. Although the *E. coli gdh* gene is expressed in *M. methylotrophus*, the enzyme activity produced per gene copy is 10–20-fold lower than in *E. coli*, as can be seen by comparing enzyme activities in *M. methylotrophus* carrying pRP301/*gdh* or pTB70/*gdh* with those in a *gdh* mutant of *E. coli* carrying the corresponding plasmid (Table 1). In both microorganisms, the amount of GDH activity seems to be determined largely by gene copy number. In *E. coli* the relatively wide ranges of GDH activity which can occur suggests that any mechanism of regulating the level of *gdh* gene transcription can readily be overcome and that no significant deleterious effects accrue from excess *gdh* gene expression. In *M. methylotrophus* the presence of the *gdh* gene on the high copy-number plasmid pTB70 results in an enzyme activity which is sufficient to permit efficient growth under conditions where it provides the sole pathway of ammonia assimilation.

One surprising result of this work is the apparently high frequency with which we were able to detect mutants defective in GOGAT amongst mutants isolated solely on the basis of temperature sensitivity (4 out of 550). However, in both *E. coli* and *Klebsiella aerogenes* GOGAT has been shown to be a complex enzyme consisting of two different large polypeptides[2]. Thus one might expect temperature-sensitive mutations

Table 3 Growth of *M. methylotrophus* and its derivatives on various ammonia concentrations

Growth was tested by streaking to single cells on 1.5% agar plates using the *M. methylotrophus* medium described in the legend to Table 1 except that the $(NH_4)_2SO_4$ concentration was varied as shown. Growth was scored after 48–72 h incubation. + Indicates visible colonies, – indicates no growth.

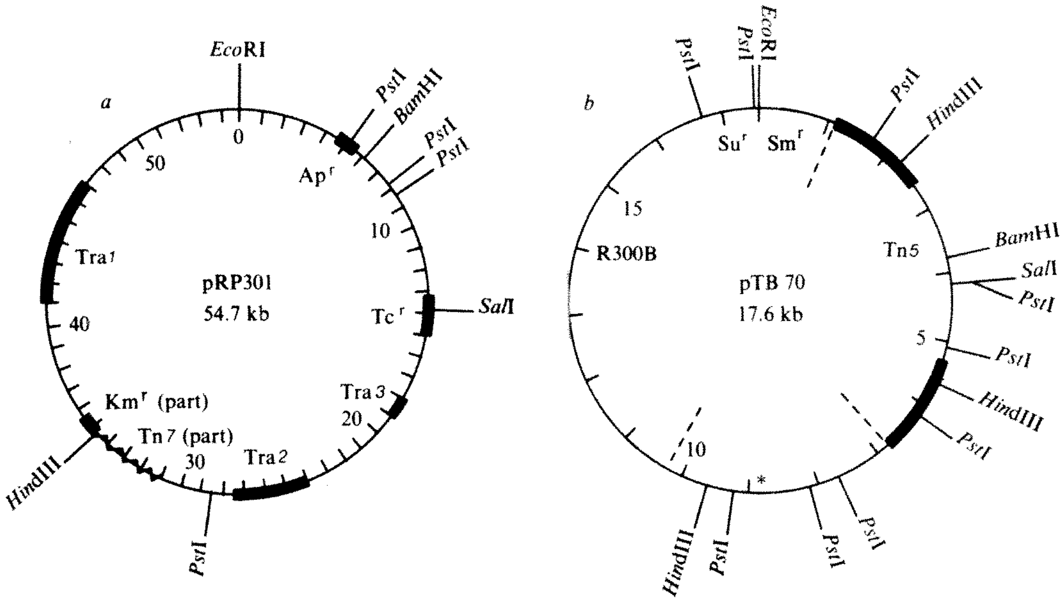

Fig. 4 Maps of the plasmid vectors used in *M. methylotrophus*. *a*, pRP301 was derived, as previously described[9], from an RP4::Tn7 plasmid (pRP3) by excision of the small *Hin*dIII fragments, followed by ligation and transformation into *E. coli*. It has lost the Km^r of RP4 and the Tp^rSm^r of Tn7. Its remaining *Sal*I site is within the gene conferring Tc^r. The blocks represent previously mapped genes on RP4 (refs 9, 18). *b*, pTB70 was derived from R300B which is a wide host-range, multicopy, 8.5-kilobase pair, Sm^r Su^r IncQ plasmid[19,20]. JR66a (*Inc*Ia, Tn5) was used to mobilize R300B from *E. coli* into *Proteus mirabilis* 13, selecting for Km^r on MacConkey agar containing polymyxin B (25 μg ml^{-1}) to counter-select the donor. *Inc*I plasmids cannot be maintained in *P. mirabilis*[21], therefore transconjugants should contain R300B::Tn5 plasmids. The restriction map of pTB70, a plasmid from one such transconjugant, is closely similar to that of R1162::Tn5, derived by Meyer *et al.*[10] (R1162 is very similar or identical to R300B[19]), but shows that it has acquired, in addition to Tn5, a 3.6-kilobase pair piece of DNA (marked *) which may also be derived from JR66a (ref. 22). The heavy lines indicate the inverted repeats in Tn5. Restriction maps were deduced from the plasmid restriction fragments seen on 0.8% and 1.5% agarose gel after electrophoresis, using *Hin*dIII fragments of λDNA as size markers. Sizes given in kilobases (kb).

affecting this enzyme to occur at a relatively high frequency. Furthermore, the genome size of an obligate methylotroph such as *M. methylotrophus* may be relatively small (*Methanobacterium thermoautotrophicum*, an obligate methanogen, only has a genome of molecular weight 1.1×10^9, as compared to the *E. coli* genome, for example, which has a molecular weight of 2.7×10^9 (ref. 13)).

For the purposes of strain improvement and modification, the alteration we have made in *M. methylotrophus* could not have been achieved either by prolonged selection under continuous culture conditions or by a conventional mutagenic approach. It represents the planned adaptation of a microorganism to a man-made environment using a combination of both mutation and intergeneric gene transfer. Effectively we have reversed the consequences of an evolutionary selection pressure which apparently demanded that the organism possessed a highly effective method of scavenging for ammonia in an ammonia-deficient environment. The evolution of many living systems must have been subject to similar pressures from environments deficient in key nutrients. Where the energy source is non-limiting, such deficiencies may be accommodated by using more energy to push equilibria in favour of the synthesis of the desired product. For industrial or agricultural use, however, this form of adaptation is contrary to efficient production and we feel there are potential savings to be made by identification of metabolic features which incur such an 'energy penalty'. It represents a new and exciting area for the application of recombinant DNA techniques.

We thank Dr B. J. Bachman for providing CB100; Dr M. Van Montagu for RP4::Mu *cts*; I. Garner, T. Hodgman and P. Burke for assistance with enzyme assays and communication of unpublished results; Dr G. M. Tonge for helpful discussions and Mr R. B. Vaisey for the fermentation work. pTB70 was isolated while one of us (P.T.B.) was working in the laboratory of Professor N. Datta.

The structure of one of the eight or more distinct chromosomal genes for human interferon-α

Shigekazu Nagata, Ned Mantei & Charles Weissmann

Institut für Molekularbiologie I, Universität Zürich, 8093 Zürich, Switzerland

The 12 interferon (IFN)-related sequences detected in a human gene bank fall into not less than eight distinct classes, indicating that there are at least eight IFN-related genes. Most, if not all, of these direct the synthesis of an IFN in Escherichia coli. *The sequence of one chromosomal gene and its flanking regions was identical to that deduced for the cDNA corresponding to IFN-α1 mRNA. No evidence was found for the existence of an intron, in either the coding or the non-coding segments of the gene.*

WE recently reported the isolation of cloned hybrid plasmids containing cDNA derived from IFN-producing human leukocytes[1]. Many of these plasmids were capable of directing the synthesis of polypeptides with human leukocyte-type IFN (HuIFN-α [ref. 2]) activity in *E. coli*[1,3]. The cDNA inserts of two such hybrids, Z-pBR322(*Pst*)/HcIFN-2h and -SN206 (Hif-2h and Hif-SN206), have been sequenced[3,4]. The amino acid sequences of the polypeptides IFN-α1 and IFN-α2, encoded by Hif-2h and Hif-SN206, respectively, differ in 17% of their positions; moreover, as deduced from the DNA sequences, IFN-α1 is one amino acid longer than IFN-α2, due to the absence of the codon for Asp 44 in IFN-α2. IFN-α1 and IFN-α2 differ in five and nine of 32 amino-terminal residues, respectively, from IFN isolated from lymphoblastoid cells and partially sequenced by Zoon *et al.*[5], designated IFN-α3.

We concluded that at least three distinct genes for IFN-α (ref. 3) exist in man. It was of interest to find evidence for the presence of several IFN-related genes in the DNA of one individual, as the cDNA clones had been derived from pooled blood samples and might reflect an extreme form of polymorphism. We therefore isolated and characterized cloned human chromosomal DNA fragments that hybridize or cross-hybridize to Hif-2h cDNA.

We report in this article the identification of eight distinct chromosomal DNA fragments which cross-hybridize with Hif-2h cDNA, most of which direct the formation of IFN in *E. coli*. We have identified and sequenced one chromosomal IFN gene which has the same coding sequence as Hif-2h cDNA. This gene for IFN-α1 lacks introns, both in the regions corresponding to the coding and to the non-coding part of the mRNA. Other than the histone genes and certain viral genes, this may be the first instance of a functional gene in higher organisms which codes for a protein and yet contains no introns.

Cloned human chromosomal DNA fragments hybridizing to Hif-2h cDNA

Lawn *et al.*[6] have prepared a collection of hybrid phage derived from fragments of fetal human chromosomal DNA, generated

0028–0836/80/400401—08$01.00

by partial cleavage with *Hae*III and *Alu*I, and joined with *Eco*RI linkers to λ Charon 4A arms. This gene bank was screened by an '*in situ*' procedure[7,8] using as probe the ^{32}P-labelled IFN-α1 cDNA insert excised from the hybrid plasmid Hif-2h[1,4]. Sixteen hybridization-positive phage clones were isolated from 240,000 plaques by repeated plaque purification[8]. Ten of the hybrid phage DNA preparations were cleaved with *Hin*dIII, *Tac*I, *Hha*I, *Bam*HI, *Eco*RI and *Bgl*II, respectively, the fragments separated by agarose gel electrophoresis, traferred to a Millipore membrane[9] and hybridized with the ^{32}P-labelled Hif-2h cDNA insert. Figure 1 shows, as an example, the patterns resulting from the experiments with *Eco*RI, *Pn*dIII and *Bgl*II; Figure 2 summarizes the total data. In each case, the positions of at least a few characteristic restriction sites were established, and the region(s) hybridizing to the IFN probe were delineated.

The hybrid ML-λCh(*Eco*)/Hchr(AH)IFN-10 (chr-10) appears to contain two separate IFN-α1-related genes, because both the 5'- and 3'-terminal Hif-2h cDNA probes (*Pst-Bgl*II fragment, nucleotides 1–315 for 5' probe; *Eco-Pst* fragment, nucleotides 685–910 for 3' probe, see ref. 4) hybridize with the 5.2- and the 20-kilobase *Bgl-Bgl* fragments (data not shown). Chr-16 clearly contains two IFN-α1-related sequences, because the two *Bgl*II fragments comprising the λ arms and part of the insert hybridize to the probe, but two internal *Bgl*II fragments from within the insert do not. Clones chr-1 and chr-23 seem to be independent isolates of the same DNA segment, as they yield identical restriction fragments. Clones chr-3 and chr-26 may represent DNA segments which overlap over much of their length because they have several *Eco*RI and *Hin*dIII fragments in common. The gene in chr-1 and one of the genes in chr-10 might be the same because the *Hin*dIII-*Hin*dIII and *Eco-Eco* fragments which hybridize with the Hif-2h cDNA probe have the same length (3.2 and 0.95 kilobases, respectively). It seems that the 'right-hand' gene of chr-16 may be identical with the gene in chr-35 (orientated in the opposite direction), as each of the two clones yields a 1.4-kilobase *Bgl-Bgl* and a 2-kilobase *Eco-Eco* fragment which hybridize with the Hif-2h cDNA probe. Therefore, the chr-16 and chr-35 inserts probably overlap. As Fig. 2 shows, all other hybridizing segments seem unique. For example, the characteristic features of the putative gene in chr-1 are: (1) *Eco*RI cleavage yields a strongly hybridizing 0.95-kilobase and a weakly hybridizing 7.8-kilobase fragment. Even if one of the hybridizing fragments has an *Eco*RI end generated by the cloning procedure, one of the two fragments must represent the chromosomal gene. (2) *Hin*dIII cleavage yields a weakly hybridizing >20-kilobase fragment, which must comprise the right-hand λ arm, and a strongly hybridizing 3.2-kilobase fragment, which must lie completely within the cloned fragment, and therefore represents the hybridizing region. (3) There is a *Tac*I site outside the hybridizing region, not further from the gene than about 5 kilobases. As mentioned above, chr-23 is identical to chr-1 in all regards, and one of the hybridizing regions of chr-10 contains a 0.95-kilobase *Eco*RI and a 3.2-kilobase *Hin*dIII fragment as does chr-1. The hybridizing *Hin*dIII fragments of chr-3, chr-12, chr-16, chr-30 and chr-35 are all completely contained in the cloned DNA frag-

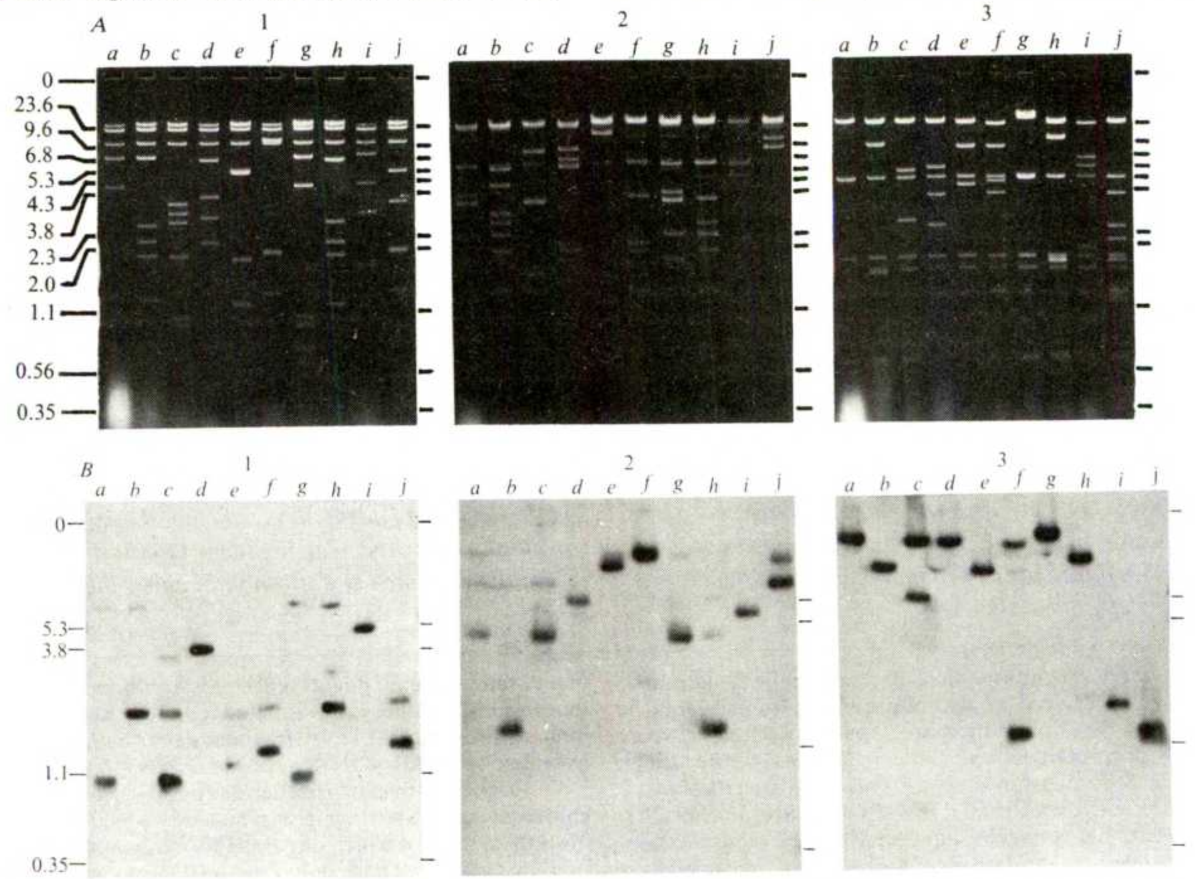

Fig. 1 Restriction and hybridization analysis of cloned human chromosomal IFN-α-related DNA. The IFN-α-related clones were selected from the λ-linked human genome library prepared by Lawn *et al.*[6]. About 240,000 plaques (about 3,000 plaques per 9.5×9.5 cm^2 filter membrane) were processed and screened by hybridization by the technique of Benton and Davis[7] as modified by Maniatis *et al.*[8]. The probe was prepared by cleaving plasmid Hif-2h[1,4] with *Pst*I, isolating the IFN cDNA insert by agarose gel electrophoresis, and labelling it by nick translation ([α-^{32}P]dATP, 250 Ci mmol^{-1}, and [α-^{32}P]dCTP, 200 Ci mmol^{-1} (NEN); specific activity of probe, 1.5×10^8 c.p.m. μg^{-1}) as described[50]. Plaques appearing to give a positive hybridization response were subjected to three cycles of plaque purification[8]. Sixteen hybridization-positive clones were isolated and 10 of these were further examined. DNA was prepared[51,52] and digested with the restriction enzymes indicated. All enzymes except *Bsp*I were purchased from New England Biolabs and used as recommended by the supplier, except that 200 μg ml^{-1} gelatin replaced bovine serum albumin in the buffers. The fragments were separated by electrophoresis in 1% agarose gels, using Tris-acetate-EDTA buffer (*p*H 7.8) containing 1.0 μg ml^{-1} ethidium bromide, and photographed in UV light. The fragments were transferred to Millipore membrane filter as described by Southern[9] and hybridized with the nick-translated Hif-2h cDNA fragment described above. Panels 1, 2 and 3, digestion with *Eco*RI, *Bgl*II and *Hin*dIII, respectively. Hybridization (600,000 c.p.m. per filter) and washing procedures are as given by Maniatis *et al.*[8]. Exposure was for 12 h. *A*, Photographs of ethidium bromide-stained gels in UV light. *B*, Autoradiogram of the hybridized filters. The lanes contain the following samples: *a*, chr-1; *b*, chr-3; *c*, chr-10; *d*, chr-12; *e*, chr-13; *f*, chr-16; g, chr-23; *h*, chr-26; *i*, chr-30; *j*, chr-35. As a marker, *Hin*dIII-cleaved λ DNA and Hif-2h (ref. 4) cleaved with *Eco*RI and *Bgl*II were run in parallel.

Fig. 2 Partial restriction maps of cloned, IFN-α-related chromosomal DNA fragments. Features of the vector λ Charon 4A DNA are shown in the bottom line. Derivation of the partial map of the chr-1 insert (*a*) was as follows: the total length of the insert, about 16 kilobases, was determined by summing the lengths of the *Eco*RI fragments. Cleavage with *Bgl*II yielded two fragments not found in the vector arms, with the lengths >20 and 4.7 kilobases. The larger fragment gave a positive hybridization response (compare with Fig. 1). As *Bgl*II cleavage of the λ arms must yield vector fragments of 1.55 (left arm) and 19.55 (right arm) kilobases linked to fragments of the insert, there must be a single *Bgl*II site within the insert, at 3.15 kilobases from the internal (*Eco*RI) end of the left λ arm. *Hin*dIII cleavage gave seven new fragments of >20, 5.6, 3.6, 3.2, 3.2, 2.1 and 1.6 kilobases, indicating six sites within the insert. The 3.2-kilobase fragment(s) gave a strong, and the >20-kilobase fragment a weak, hybridization response. As the (single) *Hin*dIII site on the left λ arm is 4.9 kilobases from the *Eco*RI site and the right arm (20 kilobases) has no *Hin*dIII site, one may conclude that the insert has a *Hin*dIII site at 0.7 kilobases from the internal end of the left arm. As the sum of all *Hin*dIII fragments derived from the insert alone is 13.7, and 0.7 kilobases of the 5.6-kilobase fragment are due to the insert, 14.4 kilobases of the insert are accounted for. Thus, about 1.6 kilobases of the >20-kilobase *Hin*dIII fragment must be due to the insert, which locates a *Hin*dIII site at about 1.6 kilobases from the internal end of the right-hand λ arm. The other four *Hin*dIII sites were not located. *Tac*I digestion of the λ hybrid (data not shown) yielded 9.2- and 5.4-kilobase fragments, the smaller of which hybridized to the IFN-α probe; the λ arms were digested to fragments of ≤0.6 kilobases, except for one 1.1-kilobase fragment which is not derived from an internal end. Therefore, *Tac*I digestion releases the insert with <0.6 kilobases of vector DNA at each end. As double digestion with *Tac*I and *Bgl*II (data not shown) yielded two 5.4-kilobase and one 3.5-kilobase fragments, the *Tac*I site must be located 5.4 kilobases to the right of the *Bgl*II site. Furthermore, the region hybridizing to the IFN probe must be located between the *Tac*I site and the junction with the right-hand λ arm. The partial maps of the other cloned DNAs were derived in similar fashion; data additional to that of Fig. 1 were obtained from digests with *Tac*I or *Bam*HI, and double digests with *Tac*I and *Bam*HI and *Hin*dIII, respectively. The accuracy of the maps is about ±10%. Parentheses around a restriction site indicate that other sites of the same kind exist but were not mapped. Hatched boxes indicate the locations of the DNA segment hybridizing to the probe. The table at the right indicates fragment length (other than those given by the λ arms alone) resulting from the cleavage with the restriction enzyme indicated. The fragments giving hybridization with the IFN-α probe are underlined with a solid line in the case of a strong, and with a dotted line in the case of a weak, response. Bg, *Bgl*II site; *H*, *Hin*dIII site; Ba, *Bam*HI site; E, *Eco*RI site; T, *Tac*I site. kb, kilobases. * Chr-12 has two unmapped *Tac*I sites.

ment and all differ from the 3.2-kilobase fragment of chr-1. The hybridizing *Hin*dIII fragment of chr-13 is 12 kilobases long; 7.1 kilobases lie within the insert, so that here too the 3.2-kilobase fragment of chr-1 cannot be accounted for. With chr-16, two hybridizing regions were delineated (see above). The right-hand putative gene (*r*), which is probably not completely contained in the fragment, is considered identical to that in chr-35. As the hybridizing region of chr-35 has no features in common with chr-1, chr-16 (*r*) is also different from chr-1. The hybridizing *Hin*dIII fragment of chr-16 (*l*) is completely contained in the insert and is far smaller than that of chr-1. We conclude that the putative genes of chr-3, chr-12, chr-13, chr-16, chr-26, chr-30 and chr-35 differ from that of chr-1. The same conclusion is reached from the fact that none of the *Eco*RI fragments of chr-1, hybridizing or not, are present in any of the clones mentioned above except for a 7.6-kilobase fragment of chr-3 which is close in size to the 7.8 kilobases of chr-1. From similar arguments based on the data of Fig. 2 regarding comparisons of the other clones and additional Smith–Birnstiel mapping of chr-3, chr-10, chr-13, chr-26 and chr-35, we conclude that the 12 putative IFN-α genes fall into not less than eight distinct classes.

Hif-chr-35 (and the right-hand segment of Hif-chr-16, to which it is probably identical) is the only DNA with a *Bgl*II site in the putative coding region (compare with table in Fig. 2). As the two different IFN-α cDNAs examined to date, Hif-2h and Hif-206, have one and two *Bgl*II sites, respectively, within their coding sequences, it seems likely that only the chr-35 gene with its single *Bgl*II site is a counterpart to one of the two cloned cDNAs, most likely to Hif-2h. This conclusion was reinforced by observing that when the 3'-terminal Hif-2h cDNA segment, which contains only the 3' non-coding region, was used as a probe, the chr-35 restriction fragments gave a much stronger hybridization response than those of any of the other chromosomal DNAs. As 3' non-coding regions of homologous genes diverge more strongly than their coding sequences[3,10], a 3' probe discriminates between different but related sequences more readily than total probes. The chromosomal counterpart to Hif-206 has not yet been found.

How many of the chromosomal clones contain sequences coding for polypeptides with IFN activity? As the cytopathic effect reduction assay[11] can detect minute amounts of IFN, less than one active molecule per bacterial cell, we tested the lysates of *E. coli* infected with the hybrid λ phages. Eight of 10 phage strains examined (all but chr-10 and chr-12) gave lysates containing IFN activity, ranging from 3 to 50 U ml^{-1}. For chr-10 and chr-12, the hybridizing *Hin*dIII–*Hin*dIII or *Eco–Eco* fragments, subcloned into the *Pst* site of pBR322, expressed IFN activity in *E. coli* (K. Henco and M. Streuli, unpublished results).

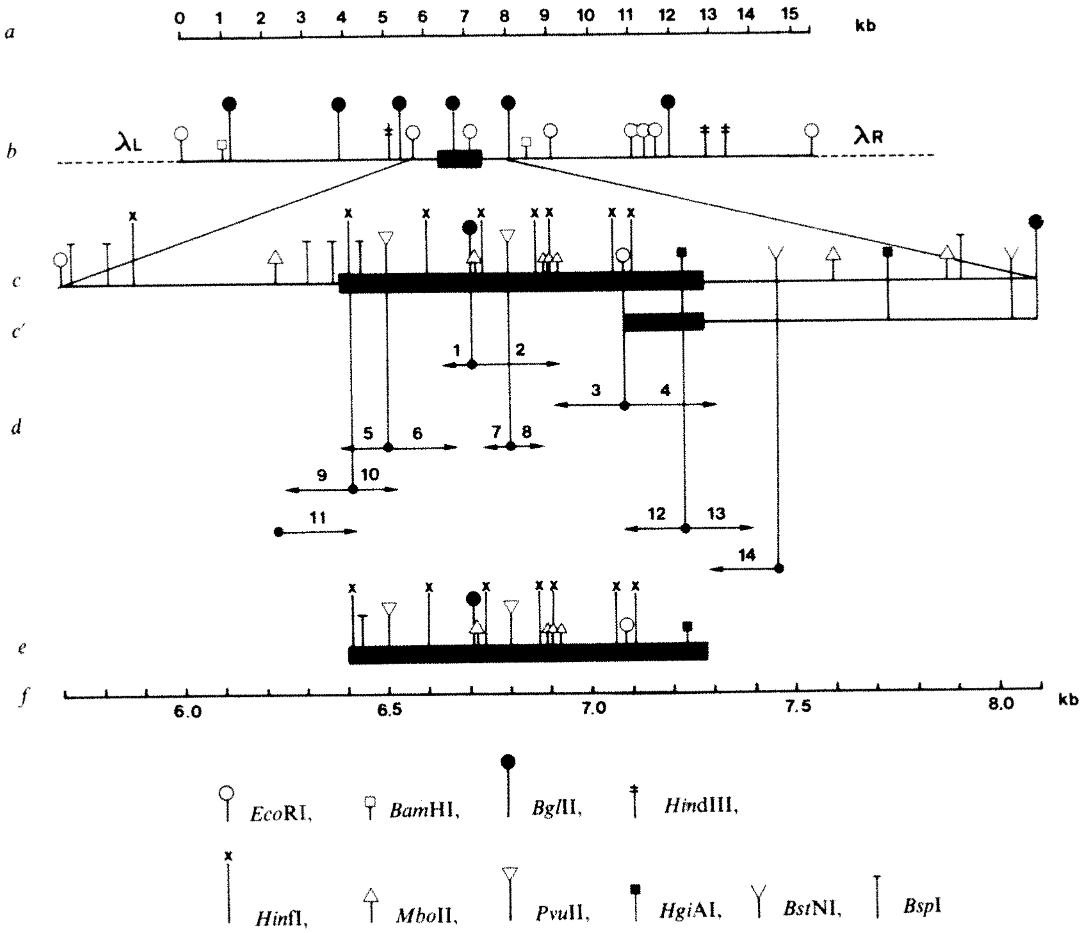

Fig. 3 Restriction map of the cloned human chromosomal DNA fragment chr-35; strategy for the nucleotide sequence determination. The gene-containing region of chr-35 was subcloned: chr-35 was cleaved with *Hin*dIII and *Bam*HI, and the 3.4-kilobase fragment (which contains the region hybridizing to the Hif-2h cDNA probe, compare with Fig. 1) was elongated with dC residues, annealed to pBR322 which had been cleaved with *Pst*I and elongated with dG[13]. Clones of *E. coli* HB101 transformed with the resulting hybrids were screened by *in situ* colony hybridization[53] with the ^{32}P-labelled Hif-2h fragment described in Fig. 1 legend. Plasmids (Z-pBR322(*Pst*)/HchrIF-35HB or HchrIF-35HB) were prepared from the positive clones by method B described by Wilkie *et al.*[54]. The orientation of the insert was established by digesting the plasmid with *Eco*RI and determining the length of the shorter fragment. The orientation coinciding with that of the β-lactamase gene was designated α, the opposite one, β. Restriction sites were determined by Smith–Birnstiel mapping[55]: HchrIF-35HBα was digested with *Eco*RI, labelled at the 5' termini and digested with *Bgl*II (and *Pst*I, to cleave an undesired fragment of about 1 kilobase). The 1.04-kilobase *Eco-Bgl*II (3'-proximal) and the 0.96-kilobase (5'-proximal) *Eco-Bgl*II fragments were isolated by agarose gel electrophoresis as described[56]. Both fragments were partially cleaved with *Hin*fI, *Bsp*I and *Mbo*II, respectively, the products separated on a 1% agarose gel in Tris-acetate buffer (*p*H 7.8) containing 1 μg ml^{-1} ethidium bromide, and radioactive bands were visualized by autoradiography (data not shown). *Bst*NI and *Hgi*AI sites were similarly determined only on the 1.04-kilobase (3'-proximal) *Eco-Bgl*II fragment (*c'*). *a*, Scale in kilobase pairs (kb) for *b*; *b*, restriction map of chr-35 DNA in Charon 4A DNA; *c*, blow-up of restriction site map of the IFN coding sequence and flanking regions determined on HchrIF-35HBα; *e*, map of the cloned cDNA insert of Hif-2h (from Mantei *et al.*[4]); *f*, scale in kilobase pairs applicable to *c–e*. For nucleotide sequence determination, HchrIF-35HBα was cleaved with the restriction enzyme indicated and 5'-terminally labelled as described by Mantei *et al.*[4]. Labelled fragments were cleaved with a second restriction enzyme, the products were separated by electrophoresis through a 5% polyacrylamide gel in Tris-borate-EDTA buffer[57], extracted from the gel and purified as described[56]. The various fragments for sequencing were prepared as follows (the number indicates the nominal fragment chain length in base pairs, the ends are designated by the enzyme which generates them, the labelled end is indicated by an asterisk, and the numbers in parentheses refer to the arrows shown in *d*). (1) and (2), Cleavage of HchrIF-35HBα with *Bgl*II, labelling, cleavage with *Eco*RI and *Pst*I, isolation of (1) *Bgl*-Eco*-940, and (2) *Bgl*-Eco*-360. (3) and (4), Cleavage of HchrIF-35HBα with *Eco*RI, labelling, cleavage with *Bsp*I, isolation of (3) *Eco*-Bsp*-680 and (4) *Eco*-Bsp*-880. (5), (6), (7) and (8), Cleavage of HchrIF-35HBα with *Pvu*II, labelling, cleavage with *Bgl*II and *Eco*RI, isolation of (5) *Pvu*-Eco*-780, (6) *Pvu*-Bgl*-215, (7) *Pvu*-Bgl*-90 and (8) *Pvu*-Eco*-290. (9) and (10), Cleavage of HchrIF-35HBα with *Eco*RI, isolation by 1% agarose gel electrophoresis in Tris-borate EDTA buffer[57] of *Eco-Eco*-1300, cleavage with *Hin*fI, isolation of *Hinf-Hinf*-450 (for [9]) and *Hinf-Hinf*-180 (for [10]), labelling, cleavage with *Mbo*II (for [9]) or *Ava*II (for [10]), isolation of (9) *Hinf*-Mbo*II-190 and (10) *Hinf*-Ava*II-150. (11), Cleavage of HchrIF-35HBα with *Mbo*II, labelling, cleavage of HchrIF-35HBα with *Mbo*II, labelling, cleavage with *Bgl*II, isolation of (11) *Mbo*-Bgl*-465. (12), (13) and (14), Cleavage of HchrIF-35HBα with *Bsp*I and *Bgl*II, isolation by agarose gel electrophoresis as above of *Bsp-Bgl*-1200, cleavage with *Hgi*AI (for [12] and [13]), or *Bst*NI (for [14]), labelling, cleavage with *Mbo*II (for[12] and [13]) or *Eco*RI (for [14]), isolation of (12) *Hgi*-Mbo*II-300, (13) *Hgi*-Mbo*II-360, and (14) *Bst*-Eco*-380.

This shows that all cloned DNA segments contained at least one potentially active IFN gene, and that these genes most likely did not contain introns in their coding regions, as *E. coli* is believed to be incapable of splicing mRNAs[12]. Our data thus suggest that the genome of an individual human contains not less than eight different IFN-coding sequences, supported by the fact that the proportion of IFN-related sequences detected in the clone bank is about one in 16,000. Assuming a value of 3×10^9 base pairs for the haploid human genome, the expected value for a single-copy gene in a bank with an average DNA fragment size of 16 kilobases (the average value found for the 10 clones examined) would be about one in 190,000; thus, the frequency of Hif-2h-related segments is 12 times higher than expected for a single gene. When Lawn *et al.*[6] screened 300,000 plaques from the same gene bank with a β-globin cDNA probe, they identified two clones. The expected value for a single gene should have been 1.6 clones per 300,000 plaques, however the probe could potentially cross-hybridize with two γ and a δ gene as well. We conclude that the number of distinct DNA segments cross-hybridizing with IFN-α1 cDNA may be around 10–15, and that many of these will prove to code for IFN-like proteins.

Identification of a chromosomal gene corresponding to IFN-α1

The cDNA insert of Hif-2h (which codes for IFN-α1) has a single *Bgl*II site within the coding region[4]. The chromosomal IFN-related DNA clone with the same feature was chr-35. This DNA was further characterized by restriction analysis and Southern blotting; Fig. 2 shows that the region hybridizing to the Hif-2h probes lies within a 3.4-kilobase region flanked by a *Bam*HI and a *Hin*dIII site. To facilitate further analysis, this fragment was subcloned into the *Pst*I site of pBR322 using the dC–dG tailing procedure[13]. Several clones of *E. coli* transformed with the resulting hybrids were isolated, cultures were grown to an apparent OD_{650} of 0.8 and the bacteria collected and lysed as described[1]. Seven of 10 clones examined showed IFN activities of 75–500 U per g of cells. One of the IFN-producing clones, Z-pBR322(*Pst*)/Hifchr35-HBα, was characterized by restriction analysis. Figure 3 shows that its restriction map is indistinguishable from that of the cDNA insert of Hif-2h; in particular, there is no indication of introns within the coding sequence, that is, between the *Hin*fI site in the 5′ non-coding region, and the *Eco*RI site in the 3′ non-coding region.

To prove this conclusion, and to determine whether or not the 5′ and 3′ non-coding regions contain introns, it was necessary to compare the nucleotide sequences of Hif-2h cDNA and the relevant segments of the chr-35 DNA.

Nucleotide sequences of the chromosomal gene chr-35 and the cDNA coding for IFN-α1

The nucleotide sequence of Hif-2h cDNA has been reported previously[4]. The coding region, which includes a signal sequence, comprises 567 base pairs and is followed by a 242-base pair 3′ non-coding region. The 5′ non-coding region consists of 56 nucleotides and is probably incomplete, as with all cDNA clones generated by the technique we used[14]. Moreover, it has been found that artifactual sequences can be generated in the process of synthesizing the double-stranded cDNA copy of a mRNA, especially in the 5′ region[15]. We therefore redetermined and extended the 5′-proximal nucleotide sequence essentially as described by Tsujimoto and Suzuki[16]. We prepared a *Pvu*II–*Bsp* minus-strand restriction fragment, extending from nucleotide +44 to nucleotide +5 (see Fig. 3) and labelled at the *Pvu*II end. This fragment was hybridized to poly(A) RNA from IFN-producing leukocytes and reverse transcriptase was used to elongate it with unlabelled deoxyribonucleotides. The denatured product, analysed on a polyacrylamide gel (Fig. 4), showed a major band of about 115 nucleotides. Thus, about 75 nucleotides had been added to the primer, indicating a 5′ non-coding sequence of about 70 nucleotides. The major radioactive band was sequenced by the Maxam–Gilbert procedure[17] and the sequence shown in Fig. 6 obtained. The sequence of the cDNA transcribed directly on the mRNA is identical to that of the cloned cDNA, except for the four 5′-terminal nucleotides; moreover, it is longer by 11 residues. As at least two species of IFN-α are expressed in human leukocytes, the mRNA species which served as template for direct reverse transcription may differ from that which gave rise to the cloned cDNA. However, as shown below, the chromosomal DNA is identical to the cloned Hif-2h cDNA except for the four discrepant nucleotides,

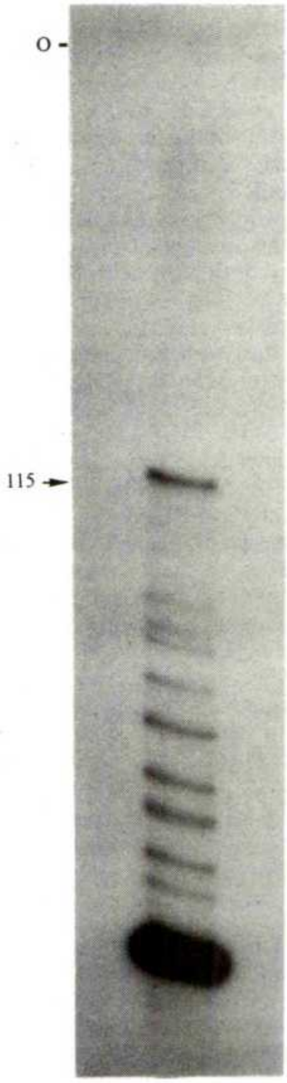

Fig. 4 Determination of the nucleotide sequence of cDNA complementary to the 5′ end of IFN mRNA. Synthesis of cDNA complementary to the 5′ end of IFN mRNA was accomplished as follows: the plasmid Hif-2h, which contains the almost complete cDNA to IFN-α1 mRNA, was cleaved with *Pvu*II and the 5′ termini labelled with ^{32}P-phosphate as described[4], to a specific activity of 1.2 μCi pmol^{-1}. Following cleavage with *Bsp*I, the products were denatured and applied to a 16% polyacrylamide gel for strand separation[17]. The 40-base pair *Pvu*II-*Bsp* minus-strand fragment (which extends from positions 44 to 5, see Fig. 6) was recovered as described[56]. The fragment (0.5 pmol, 0.5 μCi) was mixed with 3 μg 12S poly(A) RNA from virus-induced human leukocytes[1] in 4.5 μl NaCl (6.6 mM), 0.6 mM EDTA, 6.6 mM HEPES (*p*H 7.5). After heating for 90 s to 100 °C, NaCl was added to 0.18 M and the mixture (5 μl) incubated 40 min at 60 °C. After addition of Tris-HCl (*p*H 7.5) to 40 mM, dithiothreitol to 1 mM, $MgCl_2$ to 5 mM, dGTP, dATP, TTP, and dCTP to 0.5 mM each (final volume 30 μl), incubation was carried out with 3.5 U reverse transcriptase for 90 min at 37 °C. The mixture was extracted with phenol, precipitated with ethanol, and the DNA subjected to electrophoresis through a 12% polyacrylamide gel in 50 mM Tris-borate (*p*H 8.3), 1 mM EDTA, 7 M urea, for 5 h at 900 V. Autoradiography was for 21 h. The band with the lowest mobility (corresponding to a fragment about 115 nucleotides long) was eluted and sequenced as described[4,17]. The sequence is given in Fig. 6.

where it agrees with the direct reverse transcript. Thus, the discrepancy is likely due to the type of artefact described by Richards *et al.*[15].

Does the direct reverse transcript extend to the 5′ terminus of the mRNA as Tsujimoto and Suzuki[16] found? The case of IFN-α1 was examined using an S_1 mapping procedure. A 780-base pair *Pvu*II–*Eco*RI restriction fragment of the chromosomal DNA, which extends from position +44 to −740 and comprises the region corresponding to the putative 5′ terminus of the mRNA, was prepared with a 5′-terminal label at the *Pvu*II end, hybridized to poly(A) RNA from IFN-producing leukocytes and digested with S_1 nuclease. As a size marker, a sample of the labelled probe was degraded by the Maxam–Gilbert procedure[17]. Polyacrylamide gel analysis revealed two major protected fragments (Fig. 5) of 115 and 116 base pairs, and a series of minor, shorter fragments. Mouse β-globin mRNA, analysed by this procedure, yields two DNA fragments longer by four and five nucleotides than expected[18], perhaps because the presence of a cap hinders digestion of the DNA probe by S_1 nuclease. We conclude that the position of the 5′-terminal nucleotide of the major portion of the mRNA lies about 67 nucleotides upstream from the first AUG triplet, agreeing with conclusions drawn from the analysis of the direct cDNA transcript. We tentatively assume that the 5′ end of the IFN-α1 mRNA has the sequence AG... and begins at position −67 (Fig. 6); however, it could equally map at the AG two nucleotides further upstream. Most eukaryotic mRNAs start with the sequence AC... (ref. 19), however the rat preproinsulin II mRNA is believed to begin with the sequence AG[20]. A faint set of bands, mapping 98 base pairs upstream (about 5% of the radioactivity of the major bands) was also detected. These are probably due to incompletely digested probe, as similar findings have been noted occasionally with the globin mRNA system; however we cannot yet exclude a longer species of IFN mRNA, perhaps a precursor.

Some restriction sites of the chromosomal IFN subclone Hif-chr35Hbα were mapped, and the nucleotide sequence corresponding to the gene and its flanking regions determined as outlined in Fig. 3 legend. Comparison of the chromosomal and the cDNA sequence (Fig. 6) shows complete identity, from the 5′ end of the cDNA sequence obtained by direct reverse transcription to the last nucleotide preceding the poly(A) tail, as determined from the cloned cDNA. Thus, no intron could be detected in the chromosomal sequence corresponding to mature IFN mRNA.

Is the IFN-α1 gene devoid of introns?

The IFN-α1 primary transcript could initiate upstream from the position corresponding to the 5′ end of the mature mRNA, and an intron could be contained within this segment of the precursor. Maturation of the pre-mRNA would then require splicing, followed by removal of a 5′ segment. It will be interesting to determine whether the weak bands detected by S_1 mapping are due to IFN-α1 precursor transcripts longer than mature IFN-α1, and whether or not mature IFN mRNA is capped: *in vitro* transcription of the chromosomal gene might provide further clarification. Anyway, note that 28 nucleotides upstream from the putative 'cap' site there is a sequence 5′-TATTTAA-3′ flanked on both sides by GC-rich segments, which may correspond to the 'Hogness box' described 23 to 25 nucleotides upstream from the cap site for many chromosomal genes[21]. This suggests that initiation of transcription does occur at the putative cap site, and that there are no introns within the IFN-α1 transcriptional unit. Certainly there are no introns within the IFN-α1 coding sequence, and the fact that most, if not all, chromosomal IFN genes identified so far lead to the synthesis of IFN in *E. coli* suggest that this is generally true for IFN-α sequences. In this regard the IFN-α1 (and possibly all IFN-α) genes seem to resemble the sea urchin histone genes which also have no introns[22], and to differ from all other protein-coding nuclear genes of higher eukaryotes described so far, which have at least one, but frequently many, introns[23–25].

Messenger RNAs of SV40 accumulate in the cytoplasm only if the corresponding primary transcripts contain an intron[26,27]. Moreover, Hamer and Leder[28] have shown that β-globin coding sequences cloned in SV40 DNA only give rise to stable mRNAs if the primary transcript contains an intron, either in the SV40 or in the globin moiety. This cannot be true for all coding transcripts, as neither do histone genes have introns[22], nor does the primary transcript of the polypeptide IX gene of adenovirus type II contain an intron counterpart[29]. Also, much of retroviral RNA is exported from the nucleus without splicing[30,31]. Since 5,6-dichloro-1-β-D-ribofuranosylbenzimidazole (DRB) inhibits the synthesis of most mRNAs, but not that of the adenovirus polypeptide IX mRNA[32], it will be of interest to determine its effect on IFN-α mRNA synthesis.

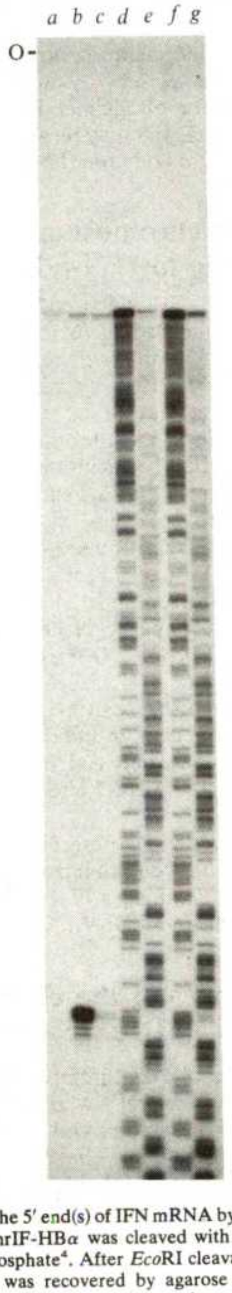

Fig. 5 Mapping of the 5′ end(s) of IFN mRNA by S_1 mapping. The plasmid Z-pBR322(*Pst*)/HchrIF-HBα was cleaved with *Pvu*II and the 5′ termini labelled with ^{32}P-phosphate[4]. After *Eco*RI cleavage, the ^{32}P-labelled 780-base pair fragment was recovered by agarose gel electrophoresis. The fragment (0.03 pmol, 24,000 c.p.m.) was denatured, hybridized in 80% formamide to poly(A) RNA from IFN-producing leukocytes[1], digested with nuclease S_1 (ref. 58), and analysed by polyacrylamide gel eletrophoresis on a 12% gel (18 h, 900 V), all as described in Weaver and Weissmann[18] and Mantei *et al.*[4]. To provide a 'sequence ladder' as length marker, the ^{32}P-labelled fragment described above was subjected to the A+G and C+T degradations described by Maxam and Gilbert[17] and in protocols provided by the same authors. The autoradiogram shown was obtained after a 5-day exposure. Lane *a*, 0.1 μg poly(A) RNA from non-induced leukocytes; lane *b*, 2 μg induced leukocyte RNA; lanes *c*, *f* and g, 0.2 μg induced leukocyte RNA; lanes *d* and *f*, A+G degradation products; lanes *e* and g, C+T degradation products.

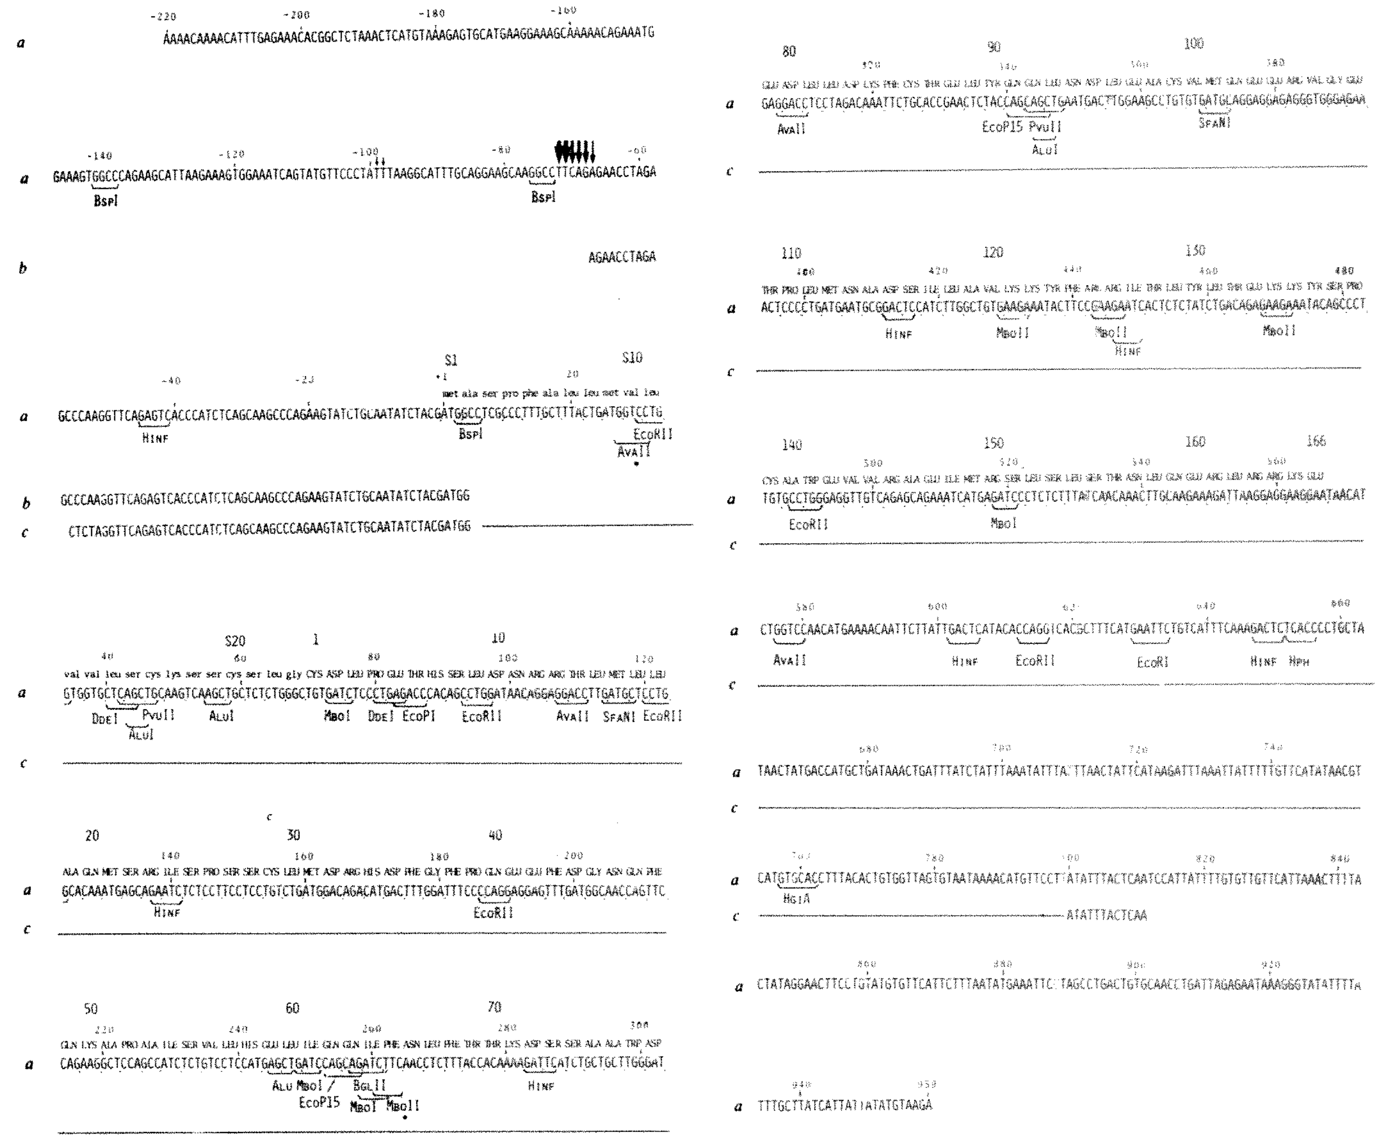

Fig. 6 Nucleotide sequence of the chromosomal IFN-α1 coding segment and its flanking regions. *a*, The 5'-labelled fragments described in Fig. 3 legend were degraded according to Maxam and Gilbert[17] with the modifications described in protocols provided by the same authors in September 1978 and fractionated as described in ref. 4. *b*, The sequence of cDNA complementary to IFN-α1 mRNA determined as described in Fig. 4 legend. *c*, Nucleotide sequence of the cloned IFN-α1 cDNA (Hif-2h, from Mantei *et al.*[4]); the continuous line indicates identity with the sequence in *a*. The vertical arrows indicate the location (±1 nucleotide) of the probe termini generated by the S_1 RNA mapping procedure, as described in Fig. 5 legend.

The multiplicity of interferon genes

We have shown that chromosomal IFN genes isolated from a gene bank derived from an individual embryo fall into at least eight different classes, as judged by restriction site distribution. As there is more than one difference between the classes in almost all cases, the genes probably differ by more than the occasional point mutation, as is commonly found with polymorphic genes[33,34]. As the cloning procedure may introduce deletions into chromosomal DNA[35], a conclusive classification requires confirmation by analysis of independent gene isolates and/or Southern analysis of uncloned chromosomal DNA. We believe that all the genes we have described are of the α (or leukocyte) type because (1) the homologies between α and β (or fibroblast) type IFN are so limited that cross-hybridization is unlikely (ref. 36 and W. Fiers personal communication) and (2) because all IFN-β cDNAs analysed so far contain a *Bgl*II site[37–39], and the only chromosomal IFN gene with a *Bgl*II site in the set analysed (chr-35) is definitely an α-type gene.

The genes we analysed could be derived from at least four different loci assuming that substantial polymorphism exists, but more likely reflect the existence of eight different loci. A linkage map will resolve this question; so far, there is evidence that at least some of the genes are clustered, for example chr-10 and chr-16 each contain two IFN sequences.

Are all IFN genes expressed in eukaryotic cells? As most, if not all, chromosomal IFN genes identified so far give rise to biologically active IFN in *E. coli*, they obviously are potentially expressible and do not resemble the α-globin-like silent gene found by Nishioka *et al.*[40]. Clearly, analysis of the IFN fractions derived from leukocyte IFN preparation by HPLC[41] may reveal the number and nature of IFNs produced by these cells. The heterogeneity of leukocyte IFN preparations[41] often ascribed to varying degrees of glycosylation may reflect the gene multiplicity described here. As an IFN species isolated from lymphoblastoid cells and partially sequenced[5] (IFN-α3) differs from two species of IFNs known to be expressed in virus-treated leukocytes (IFN-α1 and IFN-α2), conceivably different types of cells may preferentially express different IFN α genes. The easiest analyses are probably at the mRNA level, using as probes the 3' non-coding regions of the different IFN-α genes, which seem to differ the most between different genes[3].

We conclude that at least eight but perhaps as many as 10–15 distinct *IFN* genes exist. This gene multiplicity suggests that

IFNs may be functionally heterogeneous. The most striking functionally heterogeneous proteins encoded by a multigene family are the immunoglobulin variable chains, where each gene product probably has a different epitope specificity. The human β-globin family comprises at least five members, some of which differ distinctly in their biochemical properties, and which are synthesized at different stages of development[42,43]. With other families, such as those of the chorion proteins[44,45] or actins[46], it is not clear to which extent the genes code for proteins of different functions. The differences in amino acid sequences of at least some of the IFN genes[3-5] are certainly substantial enough to allow for proteins with quite different properties. As reported elsewhere, one striking functional difference between IFN-α1 and IFN-α2 is their relative virus-protective activity on cells of different species: the ratio of activities on bovine and human cells is 20–50 for IFN-α1 and one or less for IFN-α2 (refs 3, 47). This difference in cross-species reactivity could reflect different specificity for cell receptors, and questions whether different IFN species may be addressed to different target cells within the same host. It will also be of interest to ascertain whether each of the IFN species shows the full range of activities ascribed to leukocyte IFN preparations[39,48].

We thank Dr T. Maniatis for the human gene bank, Dr J. Beard for reverse transcriptase, Dr P. Dierks for $[\gamma\text{-}^{32}\text{P}]$ATP, A. Schamböck for S_1 nuclease, A. Kiss for *Bsp*I and Dr P. Sharp for bringing the experiments with DRB to our attention. The work was supported by the Schweizerische Nationalfonds (3.481.79), the Kanton of Zürich and Biogen S.A.

A family of structural genes for human lymphoblastoid (leukocyte-type) interferon

Geoffrey Allen & Karl H. Fantes

Departments of Immunochemistry and Virology, Wellcome Research Laboratories, Langley Court, Beckenham, Kent BR3 3BS, UK

Amino acid sequences of tryptic and chymotryptic peptides from human lymphoblastoid interferon (IFN-α) have been determined. The results show that IFN-α consists of a family of proteins with at least five different, but homologous, primary structures. There appears to be little, if any, glycosylation of the major components of IFN-α.

TWO major classes of human type I interferons (IFNs), leukocyte (IFN-α) and fibroblast (IFN-β), may be distinguished serologically and have been shown to be the products of separate structural genes[1]. Amino-terminal peptide sequences showed no homology[2,3], although there is homology elsewhere in the sequences[4]. Interferon produced by the Namalwa lymphoblastoid cell line after induction by Sendai virus is primarily of the leukocyte type[5]. Human leukocyte (and Namalwa) IFN is heterogeneous, as shown by SDS-polyacrylamide gel electrophoresis[6-10], isoelectric focusing[11-16], high-performance liquid chromatography[17] and affinity chromatography[9]. This heterogeneity has been ascribed to different extents of glycosylation of the molecule[7,9,15,18,19] or partial degradation of a native molecule[8,20]. We show here that IFN-α produced by Namalwa cells consists of a family of proteins with at least five different, but homologous, amino acid sequences, and is therefore the product of several structural genes. No direct evidence for glycosylation has been found, although it cannot, at present, be excluded.

Separation of interferons

Studies on the structures of human IFNs have been limited by the small amounts of pure material available. However, Namalwa IFN, produced on a large scale at Wellcome Research Laboratories[21] and purified by a combination of methods including trichloroacetic acid precipitation, acid ethanol extrac-

0028–0836/80/400408—04$01.00

tion and antibody affinity chromatography, was available in relatively large quantities. About 4 mg was used in the present work. The IFN was separated into two forms by chromatography on a column (10 × 1,980 mm) of Sephadex G-75 (Superfine) in NH_4HCO_3(50 mM)/0.01% thiodiglycol. Each form (IFN-αA and IFN-αB, of apparent molecular weights 22,000 and 18,500, respectively) gave multiple bands upon SDS-gel electrophoresis (Fig. 1).

Sequencing of interferons

Amino acid compositions of IFN-αA and IFN-αB were determined, and were found to be similar to each other, but significantly different from those reported for human leukocyte[17] and one component of lymphoblastoid[22] IFNs. Less than 0.2 residues of glucosamine or galactosamine per molecule were determined in either IFN-αA or IFN-αB. Details of these studies will be reported elsewhere (G. A., manuscript in preparation).

Tryptic peptide maps of performic acid-oxidized IFN-αA and IFN-αB were prepared on cellulose thin-layer plates by electrophoresis at *p*H 4.4 and chromatography in butan-1-ol/acetic acid/water/pyridine (15:3:12:10 by vol). Peptides were detected with ninhydrin and arginine-containing peptides with phenanthrene quinone[23]. The maps were quite different: only free lysine and arginine and one other major spot in each clearly coincided, although some weak spots on the map of IFN-αB corresponded to some of the strong spots on the map of IFN-αA. The number of tryptic peptides from IFN-αA indicated that this fraction of IFN consisted of a single polypeptide of molecular weight about 18,000, with, perhaps, limited microheterogeneity; in contrast, more peptides were present in the tryptic digest of IFN-αB than would be derived from a single polypeptide chain of this size.

Amino-terminal sequences of IFN-αA and IFN-αB (about 3 nmol each) were determined by the method of Chang *et al.*[24], using 4-*N*,*N*-dimethylaminoazobenzene-4′-isothiocyanate. The results for the 14 N-terminal residues were similar:

IFN-αA (–)-Asp-Leu-Pro-Glx-Thr-His-Ser-Leu-Gly-Ser- (–)- Arg-Thr-

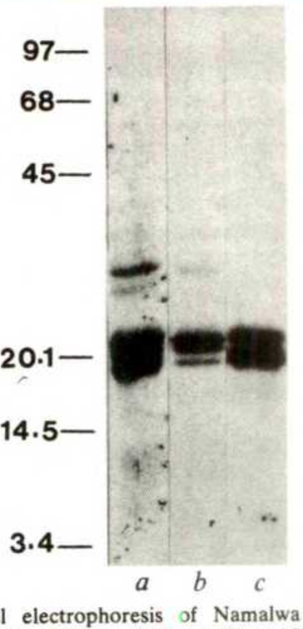
IFN-αB (–)-Asp-Leu-Pro-Gln-Thr-His-Ser-Leu-Gly-$\overset{\text{Asn}}{\underset{\text{Ser}}{+}}$-Arg-Arg-Thr-.

The first six steps of the degradation gave very clear results (except that some glutamic acid as well as glutamine seemed to be present at position 5 in IFN-αA), showing that any impurities with a free N-terminal residue were present at less than 5% of the molar amount of IFN. No N-terminal residue was detected for either IFN-αA or IFN-αB. The N-terminal residue was identified as cysteine from the study of peptides from the reduced and [*S*-^{14}C]carboxymethylated protein. As little butyl acetate-soluble coloured material was released upon treatment of the dimethylaminoazobenzene thiocarbamyl proteins with trifluoroacetic acid, the N-terminal cysteine residue in the native protein is probably involved in a disulphide bond.

Tryptic peptides from IFN-αA and tryptic and chymotryptic peptides from IFN-αB were purified from ~1 mg digests of the performic acid-oxidized or reduced and ^{14}C-carboxymethylated proteins by gel filtration followed by thin-layer peptide mapping. Peptide sequences were determined by either the micro-'dansyl–Edman' method[25] or the method of Chang *et al.*[24].

Comparison of interferon sequences

While this work was in progress, a complete amino acid sequence, deduced from the nucleotide sequence of cloned cDNA derived from leukocyte IFN mRNA, was published[26]. Peptide sequences determined here could be aligned unambiguously by homology with the sequence of Mantei *et al.*[26], and a summary of the directly determined peptide sequences is presented in Fig. 2. Many differences between the sequences of IFN-αA, IFN-αB and that presented in ref. 26 are evident. The N-terminal 20 residues determined by Zoon *et al.*[2] are represented among the sequences determined here, except that no N-terminal serine was detected. Residues 72–113 of IFN-αA were isolated as a single tryptic peptide, and only the first 19 residues of this could be sequenced. Sequence information has been obtained for all but five residues of IFN-αB. Several peptides were isolated in yields too low to permit sequencing, and other peptide sequences will probably be identified with further study.



CALCUTTA 700009

Fig. 1 SDS-gel electrophoresis of Namalwa IFN. Samples (~5 μg) of Namalwa IFN (*a*), IFN-αA (*b*) and IFN-αB (*c*) were submitted to SDS-polyacryacrylamide gel electrophoresis (15% acrylamide) using the system of Laemmli[32], but with slab rather than tube gels. The gel was fixed in 15% trichloroacetic acid, stained with 0.1% Coomassie blue R250 in methanol/acetic acid/water (45:10:45 by vol) overnight and destained in 7% acetic acid. The positions of marker proteins run in parallel are shown: 97, phosphorylase; 68, bovine serum albumin; 45, ovalbumin; 20.1, soybean trypsin inhibitor (Kunitz); 14.5, lysozyme; 3.4, insulin B chain.

As predicted from the tryptic peptide map, IFN-αA consists of an almost homogeneous peptide chain, but microheterogeneity was observed at a few positions. IFN-αB is a mixture of at least three different polypeptides (all different from both of those in IFN-αA), as shown most clearly by the isolation of three different tryptic peptides from residues 14–23 and from residues 24–31:

14 23
Thr-Leu-Met-Leu-Leu-Ala-Gln-Met-Ser-Arg,

14 22
Thr-Leu-Met-Leu-Leu-Ala-Gln-Met-Arg,

14 23
Ala-Leu-Ile-Leu-Leu-Ala-Gln-Met-Gly-Arg, and

24 31
Ile-Ser-Pro-Ser-Ser-Cys-Leu-Met-Asp-Arg,

24 31
Ile-Ser-Pro-Phe-Ser-Cys-Leu-Lys,

24 31
Ile-Ser-Leu-Phe(Ser, Cys)Leu-Lys.

High yields of C-terminal peptides were obtained from both IFN-αA and IFN-αB, showing that proteolysis close to the C terminus does not occur during the biosynthesis and isolation of lymphoblastoid IFN.

The total number of different polypeptide sequences cannot be determined from the present work, but the minimum number is five (at least two in IFN-αA and at least three in IFN-αB). The complete separation of the polypeptide components which would be required for the determination of the precise number of different total sequences has been achieved only on a very small scale[10,17], insufficient for sequencing studies by established

Fig. 2 Summary of amino acid sequences identified in Namalwa interferon. The sequences determined in tryptic (and some other) peptides of IFN-αA and tryptic and chymotryptic peptides of IFN-αB are aligned by homology with the complete sequence of leukocyte IFN 1 (IFN-α1) determined by analysis of cDNA (ref. 26). The sequences are written in the standard three-letter notation. In addition, *Ile* denotes Ile or, less likely, Leu; *Leu* denotes Leu or, less likely, Ile (the method of Chang *et al.*[24] does not clearly distinguish between these residues); and *Arg* denotes Arg or Lys (residue 23 of IFN-αA provides a site for tryptic cleavage, and either arginine or lysine could be placed in this position). The numbering system is that of IFN-α1; IFN-αA has a deletion at residue 44 (—). Peptide sequences which have not been shown experimentally to be connected are separated by parentheses. Gaps in the sequences indicate positions for which no residue has been identified. Where more than one residue has been identified at a single position, the alternative residues are written below the line.

methods. Complete sequences of further individual components may well be obtained more readily from the analysis of nucleotide sequences in cloned cDNA, and, indeed, a second species of leukocyte IFN cDNA has recently been detected (M. Streuli, S. Nagata and C. Weissmann, unpublished results quoted in ref. 4).

The sequence of IFN-αA differs from that described in ref.26 in at least 20 positions, whereas peptides in IFN-αB were, on the whole, more closely related to the published sequence. However, Leu 60 and Ile 64 have not been found in peptides isolated from IFN-αB. The analysis of peptide sequences is not yet complete, so the sequence of Mantei *et al.*[26] may be present in purified Namalwa IFN, but probably only as a minor component.

If the sequence of Mantei *et al.* is included, multiple residues have been identified at 41 positions out of 166 (25%). Although this is not the total figure for mismatch, clearly the several leukocyte-type IFNs are much more closely related than are leukocyte and fibroblast IFNs, between which 71% of the amino acid residues differ[4]. A quantitative study of homology is not yet justified, as the data base is incomplete, but note that a highly conserved region, residues 133–151, where no differences have been detected between the various leukocyte-type IFNs, is also a region which shows strong homology between fibroblast and leukocyte IFNs[4]. This suggests a common functional role for this portion of the polypeptide chain.

The low content of aminosugars and the lack of detection of typical glycopeptides (characterized by a lower elution volume from Sephadex G-50 columns and a lower R_F on TLC than would be expected from their amino acid compositions) suggest that the major components of lymphoblastoid IFN are not glycosylated. Also, no sequence of the type Asn-X-(Ser or Thr), generally required for glycosylation of asparagine residues, has been identified. A glycosylation site could, however, be present in residues 91–113 of IFN-αA, which have not been placed in sequence. The neutral sugar content has not been determined, so some O-linked glycosylation, or glycosylation of minor components, cannot be excluded. Several observations[7,9,15,18,19,27] suggest that leukocyte and lymphoblastoid IFNs are glycosylated, although some workers have doubted that leukocyte IFN is a glycoprotein[12,28]. Further study is required before a definite conclusion can be reached.

The total number of different polypeptide sequences constituting human leukocyte IFN (and hence the number of structural genes) may be sufficient to account for all the heterogeneity seen by isoelectric focusing and gel electrophoresis (at least seven components were detected here, as shown in Fig. 1, but it has not been demonstrated that all of these are active as IFNs). If so, the different apparent molecular weights of the different components of IFN as determined by SDS-gel electrophoresis are not related to significant differences in the true molecular weights, but rather to such factors as binding of different amounts of SDS or different conformations of IFN-SDS complexes. The separation by gel filtration into IFN-αA and IFN-αB is also probably not related to significant differences in molecular weights, but to different conformations, IFN-αA being, presumably, more elongated in structure.

Importance of multiple interferon structural genes

The functional significance of multiple structural genes for IFN remains to be elucidated. Multiple genes have been identified for other proteins, such as actin[29-31]. With actin, the proteins are synthesized in large amounts and there are well established differences in functional properties between the different gene products. Possibly, different IFN gene products have different biological activities, or different specificities towards different target cells, and they may be differentially induced by different viruses.

We thank Dr C. Weissmann for making available sequence information before publication.

Note added in proof: The complete sequence of a second species of human leukocyte interferon (IFN-α2), deduced from the nucleotide sequence of cloned cDNA, has recently been determined[33]. IFN-α2 is very similar to, and may be identical with, one of the components of IFN-αA.

A human leukocyte interferon cDNA was enzymatically synthesized, inserted into the vector pBR322, and cloned in Escherichia coli. *The DNA sequence codes for a 23-amino acid signal peptide followed by an interferon polypeptide of 165 amino acids. An expression plasmid was constructed which permits the synthesis in* E. coli *of 2.5×10^8 units of interferon per litre of culture. This LeIF protected squirrel monkeys from lethal encephalomyocarditis virus infection.*

THE interferons (IFNs) are a family of proteins characterized by a potent ability to confer a virus-resistant state in their target cells[1,2]. In addition, IFNs can inhibit cell proliferation and modulate immune response (reviewed in ref. 2). These properties have led to the clinical use of IFN for the treatment of viral infections and malignancies.

The classical, or type I, IFNs consist of at least two distinct gene products which differ antigenically[3,4] and have different target cell specificities[5]. Leukocyte interferon (LeIF) and fibroblast interferon (FIF) are named for the cells from which they are derived. Messenger RNAs for LeIF and FIF have been isolated and translated *in vitro* and in *Xenopus* oocytes[4,6-8].

Both LeIF[9,10] and FIF[11] have been purified to homogeneity; reported molecular weights range from 17,500 to 21,000. The specific activities of these preparations are remarkably high, 2×10^8 to 1×10^9 U per mg protein. Unfortunately the yields from eukaryotic cells have been correspondingly low. Two litres of human blood are required to produce approximately 1 μg of

0028-0836/80/400411—06$01.00

purified LeIF[9]. Nevertheless, advances in protein sequencing techniques have permitted the determination of partial amino acid sequences[11–13].

Recombinant DNA technology provides an alternative method of producing large quantities of IFN using bacterial cells. Human FIF cDNA has recently been cloned[14,15] and biologically active mature FIF expressed in *Escherichia coli*[15]. Likewise, a species of human LeIF cDNA has been cloned in *E. coli* and expressed in an apparent precursor form with a signal peptide attached[16]. We describe here the construction of a plasmid directing the high level expression in *E. coli* of a human LeIF which exhibits *in vivo* antiviral activity.

Construction and identification of clones containing LeIF cDNA sequences

Cells from the human myeloblastoid line KG-1 (ref. 17) were collected 5 h after induction with Sendai virus and the 12S sucrose gradient fraction of poly(A) RNA was isolated as described elsewhere[18]. This mRNA had an IFN titre of 8,000 U μg^{-1} in the *Xenopus laevis* oocyte assay[4]. Five µg of mRNA was used to prepare double-stranded cDNA by standard procedures[19,20]. The cDNA was electrophoresed on a 6% polyacrylamide gel and 110 ng of material from 600 to 1,300 base pairs in length were recovered by electroelution. A 20-ng portion of this cDNA was tailed with deoxyC residues[21], annealed with 100 ng of plasmid pBR322 (ref. 22) which had been tailed with deoxyG residues at the *Pst*I site, and used to transform *E. coli* K12 strain 294 (ref. 23). Approximately 1,000 tetracycline-resistant, ampicillin-sensitive transformants were obtained per ng of cDNA. A rapid plasmid isolation procedure[24] was used to prepare about 1 µg of plasmid DNA from each of 500 individual transformants. Each DNA sample was denatured and aliquots were applied to each of three nitrocellulose filters following a published procedure[25].

The amino acid sequences of several tryptic fragments of human LeIF have been determined (W. Levy, J. Shively and S. P., unpublished results). This information permitted the design of synthetic deoxyoligonucleotides potentially complementary to different regions of LeIF mRNA. The two tryptic peptides T-1 and T-13 were selected because they had amino acid sequences requiring the synthesis of only 12 and four undecamers, respectively, to account for all possible coding sequences (Fig. 1). Four sets of deoxyoligonucleotide probes were synthesized for each sequence, containing either three (T-1A, B, C, D) or one (T-13A, B, C, D) oligonucleotides each.

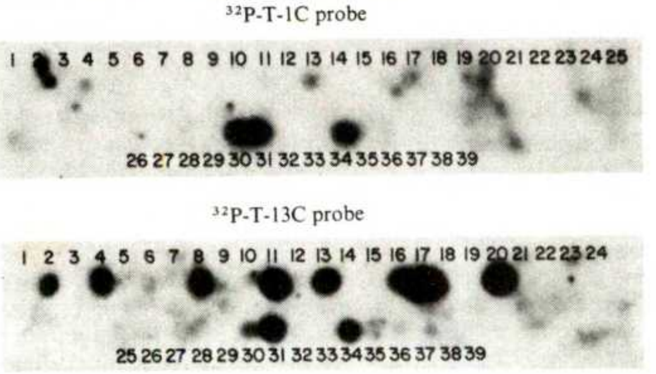
Fig. 1 Synthetic deoxyoligonucleotides designed to prime cDNA synthesis from LeIF mRNA. Amino acid sequences are given for peptide 1 and a portion of peptide 13 derived from a tryptic digest of human LeIF-β1 (W. Levy, J. Shively and S. P., unpublished results). All potential mRNA sequences coding for these peptides are shown. The indicated complementary deoxyoligonucleotides 11-bases long were chemically synthesized by the phosphotriester method[36]. Four individual primers were prepared in the T-13 series. The 12 T-1 primers were prepared in four pools of three primers each using a strategy described elsewhere[15]. ^{32}P-labelled cDNA was prepared from these primers using published reaction conditions[37]. The reactions (60 µl) were performed in 20mM Tris-HC1 (*p*H 8.3), 20 mM KCl, 8 mM $MgCl_2$, 30 mM *β-merceptoethanol*. Reactions included one µg of each primer (that is 12 µg total for T-1 series, 4 µg total for T-13 series), two µg of 12S fraction mRNA from induced cells (or 10 µg of poly(A) mRNA from uninduced cells), 0.5 mM dATP, dGTP, dTTP, 200 µCi [$\alpha^{32}P$]dCTP (2–3,000 Ci $mmol^{-1}$; Amersham), and 60 U reverse transcriptase. Product was separated from unincorporated label by gel filtration on a 10-ml Sephadex G-50 column, treated with 0.3 M NaOH for 30 min at 70°C to destroy RNA, and neutralized with HCl. Hybridizations were performed as described[15,25].



^{32}P-T-1C probe

^{32}P-T-13C probe

Fig. 2 Hybridization of potential LeIF cDNA recombinant plasmids with ^{32}P-labelled synthetic deoxyoligonucleotides. Plasmid DNA from the 39 clones was prepared by a standard cleared lysate procedure[38] and purified by Biorad Agarose A-50 column chromatography. Samples (3 µg) of each preparation were linearized by treatment with *Eco*RI, denatured in alkali and spotted on two separate nitrocellulose filters (1.5 µg per spot)[25]. Individual synthetic deoxyoligonucleotide primers and primer pools were phosphorylated with [$\gamma^{32}P$]ATP as follows: 50 pmol of oligonucleotide and 100 pmol of [$\gamma^{32}P$]ATP (2,500 Ci $mmol^{-1}$; New England Nuclear) were combined in 30 µl of 60 mM Tris-HCl (*p*H 8) 10 mM $MgCl_2$, 15 mM β-merceptothanol. Two units of T4 polynucleotide kinase were added and, after 30 min at 37°C, ^{32}P-labelled primers were purified by chromatography on 10-ml Sephadex G-50 columns. Hybridizations were performed using 10^6 c.p.m. of primer T-13C or 3×10^6 c.p.m. of primer pool T-1C. The hybridizations were performed at 15 °C for 14 h in 6 × SSC, 10 × Denhardt's solution, as described by Wallace *et al.* [28]. Filters were washed for 5 min (three times) at 0 °C in 6 × SSC, dried, and exposed to X-ray film. Results are shown above for primer T-13C and primer pool T-1C.

These synthetic deoxyoligonucleotides were used to prime the synthesis of radiolabelled single-stranded cDNA for use as hybridization probes (see Fig. 1 legend). The template mRNA was either the 12S RNA from KG-1 cells induced with Sendai virus (8,000 U IFN activity μg^{-1}) or total poly(A) mRNA from uninduced leukocytes (<10 U IFN activity μg^{-1}).

The three sets of nitrocellulose filters containing the 500 plasmid samples were hybridized with three different cDNA probes: (1) induced cDNA primed with the T-1 set of primers, (2) T-13-primed induced cDNA, and (3) uninduced cDNA prepared by using both sets of primers. Clones were considered positive if they hybridized more strongly to one or both of the induced cDNA probes (1) and (2) than to the total uninduced probe(3). Thirty clones (pL1–pL30) were selected from the 500 for further analysis.

At this time a partial-length (~750-base pair) LeIF cDNA recombinant plasmid pIFL104, as identified by a mRNA hybridization selection procedure, became available[18]. A unique 260-base pair *Bgl*II restriction fragment isolated from this clone was labelled with ^{32}P (ref. 26) and used as probe to screen another 400 transformants by an *in situ* colony screening procedure[27]. Nine colonies (pL31–pL39) were identified which hybridized to different extents with this probe. Plasmid DNA was prepared from all 39 potential LeIF cDNA clones and rescreened with the same 260-base pair DNA probe using the dot hybridization procedure[25]. Three plasmids (pL4, pL31, pL34) exhibited very strong hybridization signals, four (pL13, pL30, pL32, pL36) hybridized moderately, and three (pL6, pL8, pL14) hybridized weakly with the probe.

The 39 potential LeIF cDNA recombinant plasmids were also screened with ^{32}P-labelled synthetic undecamers (individual T-1 primer pools or individual T-13 primers) directly as hybridization probes. The hybridization conditions were chosen such that perfect base pairing should be required for detectable hybridization signals[28]. Plasmid pIFL104 was found to give significant hybridization with primer pool T-1C and primer T-13C, but no detectable hybridization with the other undecamers. As shown in Fig. 2, several of the 39 potential LeIF plasmids (pL2, 4, 13, 17, 20, 30, 31, 34) also hybridized with both of these probes. Restriction analysis revealed that only one of these plasmids, pL31, also contained a 260-base pair internal *Bgl*II fragment.

Pst I digestion of pL31 showed the size of the cDNA insert to be approximately 1,000 base pairs.

DNA sequence of recombinant plasmid pL31

The entire *Pst*I insert of pL31 was sequenced by both the Maxam–Gilbert chemical method[29] and an enzymatic method[30] using the bacteriophage M13 cloning vector mp7 (P. S., unpublished results). The DNA sequence is shown in Fig. 3. Protein sequence information from LeIF (ref. 13; W. Levy, J. Shively and S. P., unpublished results) permitted the determination of the correct translational reading frame and allowed us to predict the entire LeIF type A (our term for the LeIF encoded by pL31) amino acid sequence, including a precursor segment or signal peptide. The first ATG translational initiation codon is found 60 nucleotides from the 5′ end of the sequence and is followed, 188 codons later, by a TGA termination triplet; there are 335 untranslated nucleotides at the 3′ end, followed by a poly(A) sequence. The putative signal peptide (presumably involved in the secretion of mature LeIF from leukocytes) is 23 amino acids long. The 165-amino acid polypeptide constituting the mature LeIF has a calculated molecular weight of 19,390. The DNA sequence also shows that the tryptic peptides T1 and T13 of LeIF β_1 (Fig. 1) correspond to amino acids 145–149 and 57–61, respectively, of LeIF A. The actual DNA coding sequences found in these two regions are those represented by primer pool T-1C and primer T-13C, as the hybridization data in Fig. 2 had suggested.

The amino acid sequence deduced from the DNA sequence of LeIF type A has only partial identity with the directly determined NH_2-terminal amino acid sequences of LeIFα1 (20 out of 22 positions)[13] and human lymphoblastoid IFN (16 out of 20 positions)[12]. It also differs significantly from the complete amino acid sequence recently deduced from the nucleotide sequence of LeIF I (ref. 31). LeIF I codes for a mature IFN of 166 amino acids, as compared to 165 amino acids for LeIF A. The extra amino acid (aspartic acid) of LeIF I is between amino acids 43 and 44 of LeIF A. Furthermore, only 137 of the remaining 165 amino acids (83%) are identical. The single longest stretch of homology between the two LeIFs is 19 amino acids (residues 132–150), and in one region (residues 100–106) only two out of seven amino acids are identical. The amino acid homology in the signal peptide sequence is 74% (17/23 identical residues). The glycine–cysteine cleavage site between the signal and IFN sequence is the same in both IFNs. In addition, the 3′ untranslated regions of LeIF A and LeIF I mRNAs (335 compared with 242 nucleotides) differ considerably. The explanation for these discrepancies lies in the fact that there is a family of non-identical LeIF genes (including pL4, pL13, pL30, pL32), evidence for which will be reported soon.

Expression of leukocyte pre-interferon A

The precursor form of LeIF A (Le-preIF A) was expressed in *E. coli* by ligating the 1,000-base pair *Pst*I insert into the *Pst*I site of the plasmid pNCV. pNCV is a derivative of pBR322 containing part of the *E. coli* tryptophan operon (extending from the promoter–operator region through the *trp* E gene, with a deletion[32] of a portion of the *trp* leader and *trp* E coding regions) which has been modified to contain a unique *Pst*I site at the C-terminal end of the *trp* E protein coding sequence (H. H., unpublished results). The LeIF A DNA sequence can be inserted into pNCV in either of two orientations. As shown in Table 1, only plasmids having inserts which are orientated correctly with respect to the direction of transcription from the *trp* promoter give detectable IFN activity. Extracts of *E. coli* containing the plasmid pLe-preIF A2 gave approximately 480,000 U of activity per litre of culture, considerably higher than the maximal 20,000 U l^{-1} reported by Nagata *et al.* for Le-preIF D (ref. 16). The Le-preIF A produced by *E. coli* can be visualized by staining and co-migrates with human growth hormone (191 amino acids; molecular weight 22,000) on SDS-polyacrylamide gels (J. Perry, unpublished results). This suggests that the expression of Le-preIF A in pNCV is due to translation initiating at the signal peptide ATG start codon.

Fig. 3 Nucleotide and amino sequences of pL31 (LeIF A). The DNA sequences of both strands of the *Pst*I insert were determined by the Maxam–Gilbert technique and by the dideoxy chain termination procedure[30] after subcloning *Sau*3a fragments of pL31 into the M13 vector mp7 (P.S., unpublished results). Numbers above each line refer to amino acid position (S refers to signal peptide) and numbers below each line to nucleotide position.

Table 1 Interferon activity in extracts of *E. coli*

E. coli 294 transformed by:	Cell density (cells ml^{-1})	IFN activity (U per ml culture)	LeIF molecules per cell
pLe-preIF A2	3.5×10^8	480	120
pLe-preIF A3	3.5×10^8	0	0
pLeIF A25	3.5×10^8	36,000	9,000
pLeIF A25	1.8×10^9	250,000	12,000
pLeIF A118	3.5×10^8	20	5

The 1,000-base pair *Pst*I insert (0.5 μg) from pL31 was ligated to 0.2 μg of *Pst*I-cleaved pNCV and the product used to transform *E. coli* 294. Recombinant plasmids containing inserted LeIF cDNA were identified by colony hybridization[27] using the ^{32}P-labelled 260-base pair *Bgl*II fragment from pL31 as a hybridization probe. Digestion of these plasmids with *Pvu*II identified clones with the LeIF A DNA sequence orientated in the correct orientation (pLe-preIF A2) and in the opposite orientation (pLe-preIF A3). The construction of pLeIF A25 and pLeIF A118 for direct expression of LeIF A is described in Fig. 4 legend. pLeIF A118 has the *trp* promoter orientated such that transcription proceeds away from the LeIF A gene. Extracts were prepared for IFN assay as follows. One-ml cultures were grown in L-broth containing 5 μg ml^{-1} tetracycline to an A_{550} of ~1.0, then diluted into 25 ml of M9 medium containing 0.2% glucose, 0.5% casamino acids and 5 μg ml^{-1} tetracycline. 10-ml samples were collected by centrifugation when A_{550} reached 1.0 and cell pellets were suspended in 1 ml of 15% sucrose, 50 mM Tris-HCl (*p*H 8.0), 50 mM EDTA. One mg of lysozyme was added and, after 5 min at 0 °C, cells were disrupted by sonication. The samples were centrifuged for 10 min at 15,000 r.p.m. in a Sorvall SM-24 rotor. IFN activity in the supernatants was determined by comparison with LeIF standards by the cytopathic effect (CPE) inhibition assay[2]. To determine the number of IFN molecules per cell, a LeIF specific activity of 4×18^8 U mg^{-1} was used[9]. To measure *p*H2 stability, the 250,000 U ml^{-1} extract of *E. coli* 294/pLeIF A25 was diluted 500-fold with MEM giving a concentration of 500 U ml^{-1}. A LIF standard (Wadley Institute) previously titrated against the NIH LIF standard, was also diluted to a final concentration of 500 U ml^{-1}. Aliquots (1 ml were adjusted to *p*H 2 with 1 M HCl, incubated at 4 °C for 52 h, neutralized by addition of NaOH and IFN activity determined by the standard CPE inhibition assay[2]. To measure neutralization by antibody, 25-μl aliquots of the 500 U ml^{-1} samples (untreated) were incubated with 25 μl of rabbit anti-human LeIF (10,000 neutralizing units ml^{-1}) for 60 min at 37 °C, centrifuged at 12,000*g* for 5 min and the supernatant assayed.

Direct expression of mature leukocyte interferon

The procedure followed to express LeIF A directly as a mature IFN polypeptide was a variation of that employed previously for human growth hormone[20]. As shown in Fig. 4, a *Sau*3a restriction endonuclease site is conveniently located between codons 1 and 2 of the LeIF A sequence. Two synthetic deoxyoligonucleotides were designed which incorporate an ATG translational initiation codon, restore the codon for amino acid 1 (cysteine), and create an *Eco*RI sticky end. These oligomers were ligated to a 34-base pair, *Sau*3a–*Ava*II fragment of pL31. The resulting 45-base pair product was ligated to two additional DNA fragments to construct an 865-base pair synthetic–natural hybrid gene which codes for LeIF A and which is bounded by *Eco*RI and *Pst*I restriction sites. This gene was inserted into pBR322 between the *Eco*RI and *Pst*I sites to give the plasmid pLeIF A1.

Next, a 300-base pair *Eco*RI fragment was constructed which contains the *E. coli trp* promoter, operator, and the *trp* leader ribosome binding site but stops short of the ATG sequence for initiation of translation of the leader peptide (D. Kleid and D. Yansura, unpublished results). This DNA fragment was cloned into the *Eco*RI site of pLeIF A1. Transformants carrying plasmids with the *trp* promoter orientated in either possible orientation were assayed for IFN activity (Table 1). Clone pLeIF A25, in which the *trp* promoter was inserted in the desired orientation, gives high levels of activity (2.5×10^8 U l^{-1}). Low levels of activity are obtained even if the *trp* promoter reads away from the LeIF A gene, as in the case of pLeIF A118 (2.0×10^4 U l^{-1}). The IFN produced by *E. coli* 294/pLeIF A25 behaves like authentic human LeIF; it is stable to treatment at *p*H2 and is

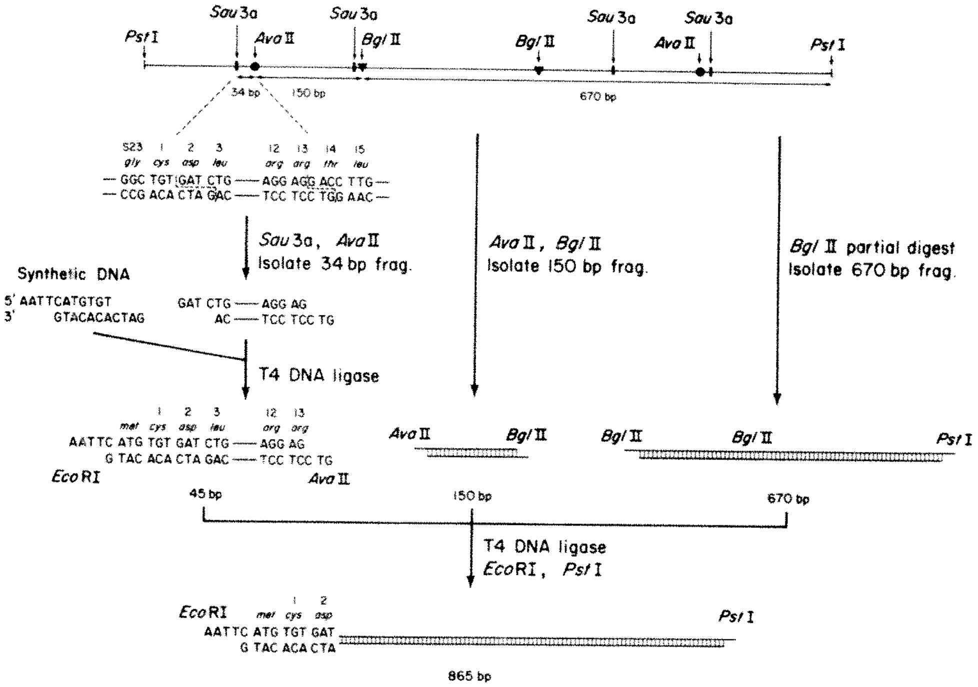

Fig. 4 Construction of a gene coding for the direct synthesis of mature human LeIF A in *E. coli*. 250 μg of plasmid pL31 were digested with *Pst*I and the 1,000-base pair insert isolated by gel electrophoresis on a 6% polyacrylamide gel. Approximately 40 μg of insert were electroeluted from the gel and divided into three aliquots for further digestion. *a*, A 16-μg sample of this fragment was partially digested with 40 U of *Bgl*II for 45 min at 37 °C and the reaction mixture purified on a 6% polyacrylamide gel. Approximately 2 μg of the desired 670-base pair fragment were recovered. *b*, Another sample (8 μg) of the 1,000-base pair *Pst*I insert was restricted with *Ava*II and *Bgl*II. One μg of the indicated 150-base pair fragment was recovered after gel electrophoresis. *c*, 16 μg of the 1,000-base pair piece were treated with *Sau*3a and *Ava*II. After electrophoresis on a 10% polyacrylamide gel, approximately 0.25 μg (~10 pmol) of the 34-base pair fragment were recovered. The two indicated deoxyoligonucleotides, 5′-dAATTCATGTGT (fragment 1) and 5′-dGATCACACATG (fragment 2) were synthesized by the phosphotriester procedure[36]. Fragment 2 was phosphorylated as follows: 200 μl (~40 pmol) of [γ-^{32}P]ATP (5,000 Ci mmol^{-1}; Amersham) was dried down and resuspended in 30 μl of 60 mM Tris-HCl (*p*H 8), 10 mM $MgCl_2$, 15 mM β-mercaptoethanol, containing 100 pmol of DNA fragment and 2 U of T4 polynucleotide kinase. After 15 min at 37 °C, 1 μl of 10 mM ATP was added and the reaction allowed to proceed another 15 min. The mixture was then heated at 70 °C for 15 min, combined with 100 pmol of 5′-OH fragment 1 and 10 pmol of the 34-base pair *Sau*3a–*Ava*II fragment. Ligation was performed for 5 h at 4 °C in 50 μl of 20 mM Tris-HCl (*p*H 7.5), 10 mM $MgCl_2$, 10 mM dithiothreitol, 0.5 mM ATP and 10 U T4 DNA ligase. The mixture was electrophoresed on a 6% PA gel and the 45-base pair product recovered by electroelution. 860,000 Cerenkov c.p.m. were recovered (~30 ng, 1 pmol), combined with 0.5 μg (5 pmol) of the 150-base pair *Ava*II–*Bgl*II fragment and 1 μg (2 pmol) of the 670-base pair *Bgl*II–*Pst*I fragment. The ligation was performed at 20°C for 16 h using 20 U of T4 DNA ligase. The ligase was inactivated by heating to 65 °C for 10 min. The mixture was then digested with *Eco*RI and *Pst*I to eliminate polymers of the gene. The mixture was purified by 6% polyacrylamide gel electrophoresis. 36,000 c.p.m. (~0.04 pmol, 20 ng) of 865-base pair product were isolated. One half (10 ng) of this was ligated into pBR322 (0.3 μg) between the *Eco*RI and *Pst*I sites. Transformation of *E. coli* 294 gave rise to 70 tetracycline-resistant, ampicillin-sensitive transformants. Plasmid DNA isolated from 18 of these transformants was digested with *Eco*RI and *Pst*I. 16 of the 18 plasmids had an *Eco*RI–*Pst*I fragment 865 base pairs in length. One μg of one of these, pLeIF A1, was digested with *Eco*RI and ligated to a 300-base pair *Eco*RI fragment (0.1 μg) containing the *E. coli trp* promoter and *trp* leader ribosome binding site. Transformants containing the *trp* promoter were identified using a ^{32}P-*trp* probe in conjuction with the Grunstein–Hogness colony screening procedure[27]. An asymmetrically located *Xba*I site in the *trp* fragment allowed us to determine recombinants in which the *trp* promoter was orientated in the direction of the LeIF A gene. bp, Base pair.

Table 2 Antiviral effect of various LeIF preparations against EMC virus infection of squirrel monkeys

	3/3	0		0		0	
		0		0		0	

All monkeys were male (average weight 713 g) and had no EMC virus antibodies prior to infection. The monkeys were infected intramuscularly with 100 × LD_{50} EMC virus (determined in mice). The control treated monkeys died at 134, 158 and 164 h post-infection. IFN treatments of 10^6 U were intravenously at −4, +2, 23, 29, 48, 72, 168 and 240 h, relative to infection. The bacterial LeIF was a column chromatography fraction (R. Wetzel, unpublished results) from a lysate of *E. coli* 294/pLeIF A25 at a specific activity of 7.4×10^6 U mg^{-1} protein. The control bacterial proteins were an equivalent column fraction from a lysate of *E. coli* 294/pBR322 at twice the total protein concentration. The LeIF standard was Sendai virus-induced IFN from normal human buffy-coat cells, purified chromatographically to a specific activity of 32×10^6 U per mg protein. Survival of the monkeys in the IFN-treated group is significant at the 5% level by a log rank χ^2 analysis[39]. PFU, plaque forming unit.

neutralized by rabbit anti-human LIF antibodies. The IFN has been partially purified and has an apparent molecular weight of 20,000 (R. Wetzel and M. Ross, unpublished results).

In vivo antiviral activity of LeIF A

The *in vivo* efficacy of IFN needs the presence of macrophages and NK cells, and the *in vivo* mode of action seems to involve stimulation of these cells[33–35]. Thus, it remained possible that the IFN produced by *E. coli* 294/pLeIF A25, though having antiviral activity in the cell culture assay, would not be active in infected animals. Moreover, the *in vivo* antiviral activity of the bacterially produced, non-glycosylated LeIF A might be different from the IFN derived from human 'buffy coat' leukocytes. Therefore the biological activity of bacterially synthesized LeIF A (~2% pure) was compared with buffy coat LeIF (~8% pure) in lethal encephalomyocarditis (EMC) virus infection of squirrel monkeys (Table 2). The control monkeys showed progressive lethargy, loss of balance, flaccid paralysis of the hind limbs and watering of the eyes commencing ~8 h before death. The IFN-treated monkeys showed none of these signs; they remained active at all times and developed no viremia (Table 2). The one monkey in the control group which did not develop viremia by 4 days died latest (164 h post-infection) but showed high titres of virus in the heart and brain on post mortem. The IFN-treated monkeys did not develop antibodies to EMC virus as determined 14 and 21 days after infection. These results demonstrate that the antiviral effects of LeIF preparations in the infected animals can be attributed solely to IFN because the contaminating proteins are quite different in the bacterial and buffy coat preparations. In addition, these results indicate that glycosylation is not required for the *in vivo* antiviral activity of LeIF A. The pharmacokinetics and toxic effects of the natural and bacterially produced LeIFs are currently being compared.

Discussion

With 12S poly(A) mRNA from induced human leukocytes, a full length LeIF A cDNA has been synthesized and cloned in the *E. coli* vector pBR322. This particular clone (pL31) was identified by colony screening using a DNA fragment from a shorter LeIF cDNA clone[18] as hybridization probe. pL31 was also found to hybridize to synthetic deoxyoligonucleotide probes whose sequences were based upon LeIF amino acid sequence data. Several additional types of LeIF recombinant plasmids were identified by hybridization to radiolabelled LeIF cDNA probes. These probes were prepared by using the synthetic deoxyoligonucleotides as primers for the synthesis of cDNA using 12S poly(A) mRNA from induced cells as template. This approach should be generally applicable for the identification of recombinant plasmids obtained through cDNA cloning of rare mRNA species, assuming that some protein sequence information is available.

The 961-base pair DNA sequence of pL31 codes for 188 amino acids, 23 of which are probably cleaved during the process of secretion of mature LeIF from leukocytes. The 188-amino acid leukocyte pre-IF A was expressed in *E. coli* under *trp* promoter control and bacterial extracts were found to be biologically active in tissue culture assay. It is not yet known if the IFN activity is associated with the pre-interferon itself, or if a small proportion of Le-preIF A is processed by *E. coli* to a biologically active form. A plasmid was also constructed which codes for high level expression of the 165 amino acid LeIF A preceded only by a methionine. The present yield of 2.5×10^8 U per litre of culture corresponds to about 600 μg of IFN per litre of culture, assuming an LeIF specific activity of 4×10^8 U mg^{-1} (ref. 9).

This bacterially synthesized LeIF A exhibits the *p*H 2 stability and immunological characteristics of authentic human LeIF, and it protects squirrel monkeys against lethal infection with EMC virus when treatments are initiated prior to viral challenge. Studies are under way to determine if bacterially produced LeIF A has therapeutic, as well as prophylactic, value. Additionally, the *in vivo* activity of LeIF A is being compared with the activities of bacterially produced human fibroblast IFN[15], and several other types of bacterially expressed LeIF.

We thank Dr Doug Fodge and Stephen Rowe for help in establishing the CPE inhibition assay and the *Xenopus* oocyte assays at Genentech and for their valuable contributions during this work; Claire Langdon and Eileen Cunningham for performing the oocyte assays; Parkash Jhurani, Martin Struble and Mark Vasser for deoxyoligonucleotide synthesis and purification; Drs Pat Gray and David Leung for performing some of the hybridization experiments; Jim Fenno and George Prender for assistance in the squirrel monkey experiment. We also thank Dr Norwood Hill and Wadley Institutes of Molecular Medicine for leukocytes and LeIF; Dr J. Beard for reverse transcriptase; Drs Kan Agarwal and Bruce Wallace for helpful suggestions; and Drs Warren Levy and Jack Shively for LeIF protein sequence information prior to publication. A sample of the human LeIF standard and the rabbit anti-human LeIF antibody were obtained from the National Institutes for Allergy and Infectious Diseases, Bethesda, Maryland. This work was performed in accordance with current NIH guidelines.

Morphology of the triple QSO PG1115+08

E. K. Hege, J. R. P. Angel, R. J. Weymann & E. N. Hubbard

Steward Observatory, University of Arizona, Tucson, Arizona 85721

Weymann *et al.*[1] have reported that two faint unresolved objects located within 3 arc s of the QSO PG1115+08 have also the same spectra. The emission lines of C III λ1,909 and C IV λ1,549 at a redshift of 1.72 have central wavelengths and profiles that are indistinguishable between the objects. It is inferred that the three objects are likely to be images of the same QSO produced by intervening matter acting as a gravitational lens. Only one other example of such an effect is known, that is the double QSO 0957+56A,B. In this case, the two QSO images are of roughly equal magnitude ($V\sim17$) and separated by 6 arc s. A plate obtained in excellent seeing by Stockton[2] shows an intervening galaxy at $z=0.4$ lying about 1 arc s from one of the QSO images. The present observations were undertaken to search for evidence of an intervening galaxy in PG1115+08, appearing either directly in a deep image, or as a difference in colour between components, and also to look for any structure in the three images. A colour difference could arise, as was the case for the double QSO, if a galaxy is nearly coincident with one of the QSO images.

The Multi-Mirror Telescope (MMT) was used for this study because of its consistently excellent seeing, with images of 1 arc s or better for much of its use in the past year. As part of a study of the short-term motion and stabilization of the six images relative to each other, and of interferometry between different mirrors, we have been using Steward's intensified television camera on he MMT. Having very high gain, provided by a plumbicon elevision camera coupled to a four-stage image intensifier, it is deally suited for this study of the QSO.

While the present controls allow six images of the MMT to be -aligned well enough to resolve the QSO components in the mbined image, as was done when the first spectra of the fainter mponents were obtained, the image quality in good seeing is graded. For the present work we used only one of the six -m mirrors. The camera was located directly at the Casse- in focus, where the plate scale is 3.6 arc s mm^{-1}. The camera put (in standard video format with 30 full frames of 480 lines s) was recorded on video tape, with a frame number code ded to the video signal. Recordings of ~10 min duration were de through filters corresponding approximately to the B, V I photometric bands as detailed in Table 1. The telescope s not guided during these recordings. Short integrated images re obtained off-line by first digitizing the frame and co-adding field of 10×10 arc s from 30 successive frames (intervals). Between 50 and 100 of these short integrations were then further co-added after being laterally translated so the peak of the brightest QSO image was always in the same pixel. The fixed pattern of a digitized blank video field was subtracted from each 1-s video integration before co-adding. In this is like precise guiding at 1-s intervals. The resulting for the three colour bands and also for a broad band with no filter are shown in Fig. 1. For photographic processing, the fourth root of image intensity is mapped on the linear grey scale.

The camera was mounted with the elevation axis vertical. Effects of field rotation of the altazimuth telescope are negligible over the short observing intervals. Figure 2 shows an 8-s integration in the broad band, with no centering, over a wider field including a neighbouring object, with celestial coordinates marked. Table 1 summarizes the magnitude differences and separations that are derived from analysis of the three QSO components, labelled A, B and C after Weymann *et al.*[1]. The uncertainties in the mean intensity ratios expressed in stellar magnitude differences, reflected by statistical scatter in the ratios measured, are commensurate with the uncertainty in the flat-field response (≤5% r.m.s.) of the four stages of fibre-optic coupled Varo image intensifiers.

Because of the low declination and early transit of the object at the time of observation, these images were taken at large zenith distances. Elongation due to atmospheric dispersion can be seen in the expected vertical direction in all three images in the broadband exposure (4,100–8,500 Å), shown in Fig. 1*c* at $\sec z=1.5$. The best resolution with negligible degradation due to dispersion is found in the red exposure, Fig. 1*d*, despite the greater zenith distance, $\sec z=2.5$ at the time of exposure. The image profiles for components B and C show a FWHM of 0.6 arc s, and are round. The image of the bright component A is, however, distinctly not round, being apparently elongated by ~0.5 arc s at a position angle of about 20°. We believe that we can rule out the elongation being an artefact of the optics or data reduction, as the centering was done on the A image, and the B

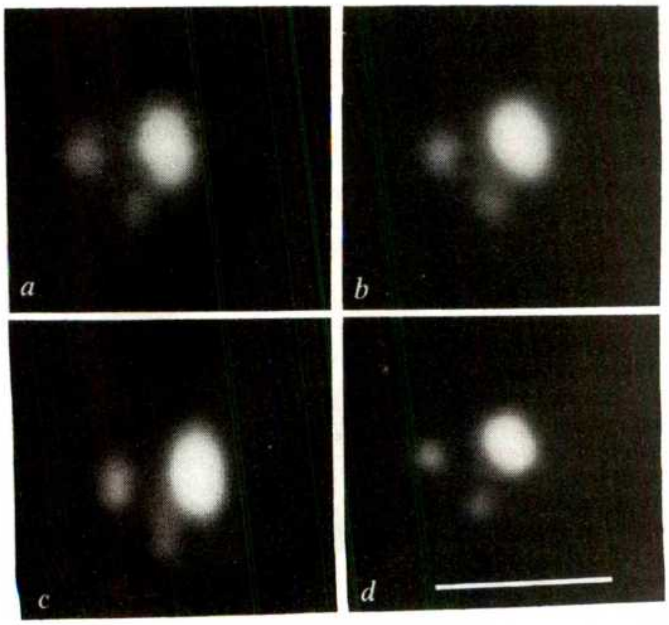

Fig. 1 Single-mirror images of PG1115+08. *a*, Blue; *b*, *V*; *c*, unfiltered; *d*, red. See Table 1 for definition of bandpasses. The images are slightly anamorphic with 13% stretching in the vertical direction. The bar gives the average scale for 5 arc s

0028-0836/80/400416—02$01.00

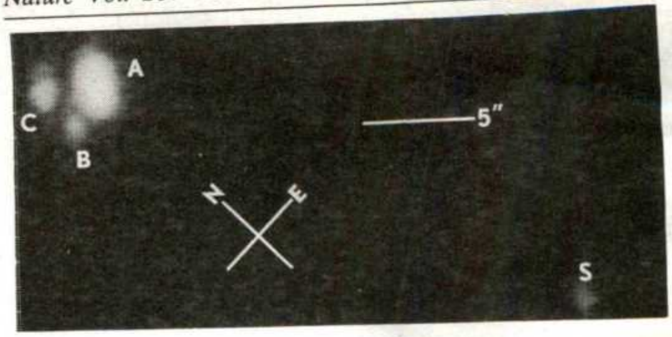

Fig. 2 A wider field image of PG1115+08 in which the celestial coordinates are marked and the components are identified. The object S is at 161°, 23 arc s from component A. The scale and distortion are the same as for Fig. 1.

and C images are indeed round. We have further data at higher magnification which may be able to yield confirmation by the techniques of speckle interferometry.

From the images and analysis above we can make the following observations.

(1) The two companion images each appear like unresolved point sources, seeing limited at the resolution of 0.6 arc s FWHM. The primary image A is not a single stellar object. It would be consistent with two point sources about 0.5 s apart.
(2) The data are consistent with all objects having the same colour, although there is a trend suggesting that C, the further and brighter companion, may be 0.25 mag redder in *B-I* colour.
(3) No other nearby objects brighter than $V \sim 21$ are detected within a radius of 5 arc s from A. If there is an intervening galaxy it must either be fainter than this limit or lying well within 1 arc s of one of the components.

From the observed relative magnitudes and the fluxes measured by R. F. Green and M. Schmidt (personal communication), we can compute fluxes for each of the components. If the slight excess red flux in component C is real and were due to a galaxy similar to the one Young *et al.*[3] measured in 0957+561, we can estimate the galaxy's magnitude by fitting the flux of C by a linear combination of a similar galaxy spectrum and the measured spectrum of A. The best fit is obtained with 15% of A and 17% of such a red galaxy. When the fluxes are recomputed using C = 0.15 A, an estimate of the galaxy flux results which suggests a somewhat fainter and slightly redder galaxy of $m_v \sim$ 20.7. However, we must emphasize that colour differences are not statistically significant, and such a faint galaxy is consistent with but not required by the data.

The research reported here used the Multiple Mirror Telescope Observatory, a joint facility of the University of Arizona and the Smithsonian Institution. We thank J. T. Williams and L. Vaughn for assistance in adapting our instrument to the MMT focal plane and to W. Light for skillful operation of the MMT. We acknowledge use of the image processing facility at Kitt Peak National Observatory in producing the half tone prints. This work was supported in part by the Air Force Geophysical Laboratory.

Whistler mode wave packets in the Earth's foreshock region

M. Hoppe & C.T. Russell

Institute of Geophysics and Planetary Physics, University of California, Los Angeles, California 90024

The definit identification of the basic modes of the variety of electromagnetic waves common in the interplanetary medium upstream of the Earth's bow shock has been difficult because of the Doppl shifting which results from their attempts to propagate in the personic solar wind. We have used magnetometer data from dual ISEE-1 and -2 spacecraft, taken when the spacecraft re separated by a few hundred kilometres, to measure the parent velocities of a subset of these waves. This has allowed e first determination of wave phase velocities, rest-frame fruencies, wavelengths, intrinsic polarizations and thus ve modes. We have now applied this technique to the class f upstream phenomena designated the discrete wave pac. These are isolated fairly monochromatic wave packet wi quencies ~0.4 Hz in the spacecraft frame which rotate i th t-handed sense about the magnetic field direction o ed in the spacecraft frame. Our studies of the time dela en the observation of such wave packets at the tw raft demonstrate conclusively that these waves are, in fact, right-handed polarized wav requencies several times greater than the proton ncy, attempting to propagate upstream against the s but being carried towards the Earth by the solar wind fl

resolution of the ambiguity inherent in the study of wa gating in a moving medium requires two point measu . We have approached this problem by using data s the matching UCLA/ISEE magnetometers to attack t lem, using them to time the delay (Δt) between arance of a wavefront at first one, then the second, spa The wave velocity in the spacecraft frame ($v_{s/c}$) can then by dividing the distance travelled by the wave as ates between the spacecraft by the time taken to tra ance. The distance itself is the projection of the spa aration vector (**S**) in the direction of propagation (pparent velocity is thus

$$v_{s/c} = \frac{\mathbf{S}\cdot\hat{\mathbf{k}}}{\Delta t}$$

tion vector is a well determined quantity (±1 k m ISEE mission ephemeris tapes. The direction gation can be determined through eigenval he magnetic field variance matrix[1]. The dete then allows $v_{s/c}$ to be calculated. The velocity in the intrinsic wave phase velocity (onent due to solar wind convection ection of the solar wind velocity (ropagation

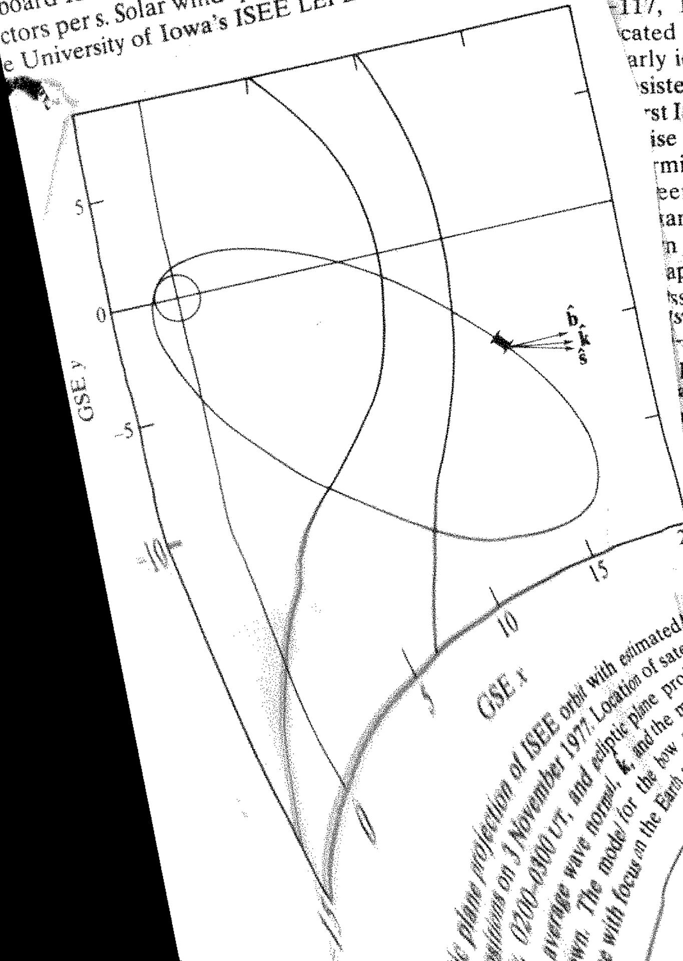
$$v_{s/c} = v_{ph} + \mathbf{V}_{sw}\cdot\hat{\mathbf{k}}$$

© 1980 M

Thus, once the solar wind velocity is known, the intrinsic wave phase velocity can be found by substituting the value of $v_{s/c}$ determined from equation (1) into equation (2) and solving for v_{ph}.

We applied this technique to a set of discrete wave packets observed by the ISEE-1 and -2 spacecraft on day 307 of 1977. The general characteristics of this variety of upstream wave were established by Russell *et al.*[2] in a comprehensive study based on single-spacecraft measurements, which we briefly summarize. The wave packets, which are most often found embedded in trains of irregular lower frequency (0.05 Hz) waves, typically grew rapidly in time and decayed more slowly, generally lasting two or three cycles. Wave packets were observed with frequencies throughout the interval chosen for study, 0.14–1.4 Hz with an average frequency of 0.4 Hz, and were left-hand polarized in 90% of the cases. From measurements of wave ellipticity, Russell *et al.* hypothesized that these waves were intrinsically right-hand polarized whistler mode waves of frequencies several times the proton gyrofrequency. Cold plasma theory predicts that such waves should have phase velocities of ~100 km s^{-1}, which is significantly less than the typical solar wind velocity. Thus, if these waves were, as hypothesized, attempting to propagate upstream against the solar wind flow, they would be swept backwards over the spacecraft, resulting in the observed reversal of polarization. We present here direct experimental verification of this hypothesis.

The time period studied was 0200–0300 UT of day 307 of 1977 (Fig. 1). At this time, the spacecraft were in the interplanetary medium, inbound on the dawn side of the Earth at 1030 LT, several Earth radii (R_e) upstream of the final bow shock crossing which occurred at 0600 UT. The interplanetary magnetic field was essentially radial during this time period and the angle between the field and the nominal shock normal was 25°. Bursts of quasiparallel shock structure were encountered hroughout the inbound portion of this orbit, and the studied nterval is characterized by strong irregular magnetic field disrbances with time scales of 30 s, and by the presence of diffuse prathermal ions (D. D. Sentman, personal communicat). agnetic field data used in this study were high-resolu easurements made by the dual UCLA magnetomet nboard ISEE-1 and -2. Data acquisition rate at this time w ctors per s. Solar wind speeds were estimated using data fr e University of Iowa's ISEE LEPEDEA plama analysers.



1 Ecliptic plane projection of ISEE orbit with estimated spacecraft positions on 3 November 1977. Location of satellites during od of study, 0200–0300 UT, and ecliptic plane projection of ld, b̂, the average wave normal, k̂, and the model bow shock also shown. The model for the bow shock is an ellipse with focus on the Earth and ellipticity 0.8

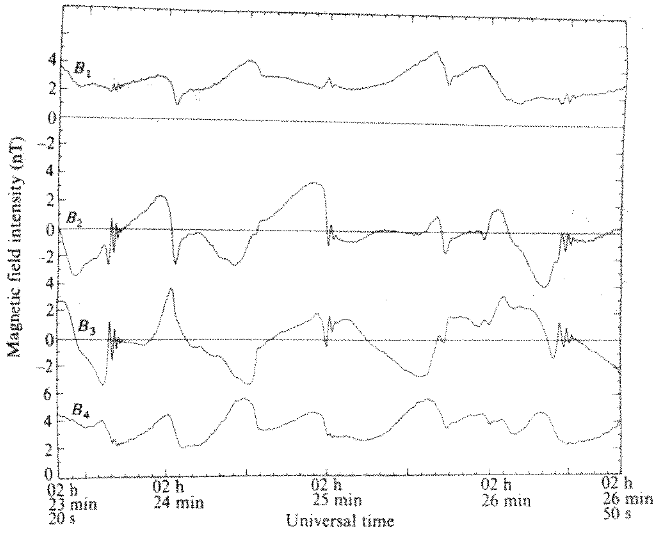


Fig. 2 The three vector components, in GSE coordinates, and the total magnitude of the magnetic field measured by the ISEE-2 magnetometer as the spacecraft was inbound on day 307 of 1977. The spacecraft was at a radial distance of 16.6 R_e, upstream of the bow shock at 1030 LT.

Three typical wave packets are shown in Fig. 2. Note that the amplitude of these waves is a large fraction of the background field. As is the usual case, the packets (seen here beginning 02 h 23 min 39 s, 02 h 24 min 59 s and 02 h 26 min 25 s) are embedded in a train of lower-frequency waves and seen to be intimately related to the low-frequency wave structure, occurring when the field magnitude suddenly returns to low values after a more gradual increase. All the wave packets seen in the studied interval begin at the foot of sharp drops in the field magnitude (B_T), although not all such drops are accompanied by wave packets (for example, sharp decrease in B_T at 02 h 24 min 05 s). The field structure is thus apparently a necessary but not sufficient condition for the development of the packets on this day.

The profiles of the packet which begins at 02 h 23 min 39 s, as seen at the two separate spacecraft, are presented in higher resolution in Fig. 3. The spacecraft separation at this time was −117, 180 and −107 km (GSE coordinates), with ISEE-2 cated upstream and to the west of ISEE-1. The signals are arly identical (the correlation is 0.92) except for a small but sistent time delay between the appearance of the wavefront st ISEE-2 and then, 0.5 s later, downstream at ISEE-1. The ise time delay characteristic of the wave packets was rmined from studies of the behaviour of the correlation een signals from the two spacecraft as a function of lag time, ample of which, for the wave packet shown in Fig. 3*a*, is n in Fig. 3*b*. Correlation coefficients averaged over inter appropriate to the signal duration were calculated for ssive 0.25-s lags, consistent with the magnetometer's sition rate of 4 vectors per s. The correlation averaged over duration of the wave packet peaks at 0.5 s, with secon peaks appearing at 1.5-s intervals, consistent with the ated wave frequency. The time delay expected for a static ure simply convecting with the solar wind flow would have .3 s. The time delay can be determined to within ~ ± 0.1 s uch plots, which at this spacecraft separation allows the ion only of those wave phase velocities ≥70 km s^{-1}. Of wave packets observed in the hour 0200–0300 on day were characterized by velocities too small for us to from the solar wind flow and the measurements on the g 11 cases are presented here.

nination of the second element of the analysis, the velled by the wavefront as it propagates between the equires determination of the direction of propaga ave. This direction can be determined within an

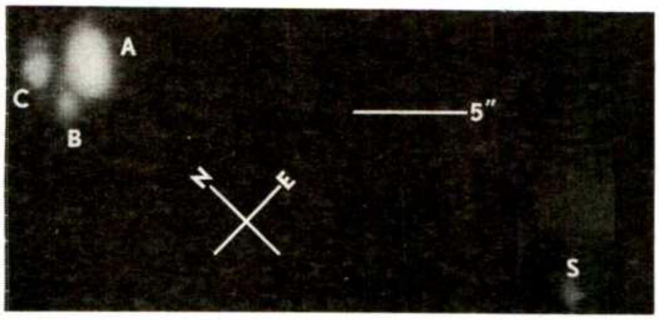

Fig. 2 A wider field image of PG1115+08 in which the celestial coordinates are marked and the components are identified. The object S is at 161°, 23 arc s from component A. The scale and distortion are the same as for Fig. 1.

and C images are indeed round. We have further data at higher magnification which may be able to yield confirmation by the techniques of speckle interferometry.

From the images and analysis above we can make the following observations.

(1) The two companion images each appear like unresolved point sources, seeing limited at the resolution of 0.6 arc s FWHM. The primary image A is not a single stellar object. It would be consistent with two point sources about 0.5 s apart.

(2) The data are consistent with all objects having the same colour, although there is a trend suggesting that C, the further and brighter companion, may be 0.25 mag redder in *B-I* colour.

(3) No other nearby objects brighter than $V \sim 21$ are detected within a radius of 5 arc s from A. If there is an intervening galaxy it must either be fainter than this limit or lying well within 1 arc s of one of the components.

From the observed relative magnitudes and the fluxes measured by R. F. Green and M. Schmidt (personal communication), we can compute fluxes for each of the components. If the slight excess red flux in component C is real and were due to a galaxy similar to the one Young *et al.*[3] measured in 0957+561, we can estimate the galaxy's magnitude by fitting the flux of C by a linear combination of a similar galaxy spectrum and the measured spectrum of A. The best fit is obtained with 15% of A and 17% of such a red galaxy. When the fluxes are recomputed using C = 0.15 A, an estimate of the galaxy flux results which suggests a somewhat fainter and slightly redder galaxy of $m_v \sim 20.7$. However, we must emphasize that colour differences are not statistically significant, and such a faint galaxy is consistent with but not required by the data.

The research reported here used the Multiple Mirror Telescope Observatory, a joint facility of the University of Arizona and the Smithsonian Institution. We thank J. T. Williams and L. Vaughn for assistance in adapting our instrument to the MMT focal plane and to W. Light for skillful operation of the MMT. We acknowledge use of the image processing facility at Kitt Peak National Observatory in producing the half tone prints. This work was supported in part by the Air Force Geophysical Laboratory.

Table 1 Magnitude differences and separations of the QSO components A, B and C

Pair	Magnitude difference*				Separation (arc s)	Angle¶
	B†	*V*‡	No filter§	*I*‖		
A–B	2.35	2.34	2.40	2.38	1.9 ± 0.1	263° ± 5°

Whistler mode wave packets in the Earth's foreshock region

M. Hoppe & C. T. Russell

Institute of Geophysics and Planetary Physics, University of California, Los Angeles, California 90024

The definite identification of the basic modes of the variety of electromagnetic waves common in the interplanetary medium upstream of the Earth's bow shock has been difficult because of the Doppler shifting which results from their attempts to propagate in the supersonic solar wind. We have used magnetometer data from the dual ISEE-1 and -2 spacecraft, taken when the spacecraft were separated by a few hundred kilometres, to measure the apparent velocities of a subset of these waves. This has allowed the first determination of wave phase velocities, rest-frame frequencies, wavelengths, intrinsic polarizations and thus wave modes. We have now applied this technique to the class of upstream phenomena designated the discrete wave packets. These are isolated fairly monochromatic wave packets with frequencies ~0.4 Hz in the spacecraft frame which rotate in the left-handed sense about the magnetic field direction as observed in the spacecraft frame. Our studies of the time delay between the observation of such wave packets at the two spacecraft demonstrate conclusively that in the plasma rest frame these waves are, in fact, right-handed polarized waves with frequencies several times greater than the proton gyrofrequency, attempting to propagate upstream against the solar wind, but being carried towards the Earth by the solar wind flow.

The resolution of the ambiguity inherent in the study of waves propagating in a moving medium requires two point measurements. We have approached this problem by using data sets from the matching UCLA/ISEE magnetometers to attack this problem, using them to time the delay (Δt) between the appearance of a wavefront at first one, then the second, spacecraft. The wave velocity in the spacecraft frame ($v_{s/c}$) can then be found by dividing the distance travelled by the wave as it propagates between the spacecraft by the time taken to travel this distance. The distance itself is the projection of the spacecraft separation vector (**S**) in the direction of propagation ($\hat{\mathbf{k}}$), and the apparent velocity is thus

$$v_{s/c} = \frac{\mathbf{S} \cdot \hat{\mathbf{k}}}{\Delta t} \tag{1}$$

The separation vector is a well determined quantity (±1 km) available from ISEE mission ephemeris tapes. The direction of wave propagation can be determined through eigenvalue analysis of the magnetic field variance matrix[1]. The determination of Δt then allows $v_{s/c}$ to be calculated. The velocity is a combination of the intrinsic wave phase velocity (v_{ph}) and an additional component due to solar wind convection, which is equal to the projection of the solar wind velocity ($\mathbf{V}_{sw}$) in the direction of wave propagation

$$v_{s/c} = v_{ph} + \mathbf{V}_{sw} \cdot \hat{\mathbf{k}} \tag{2}$$

Thus, once the solar wind velocity is known, the intrinsic wave phase velocity can be found by substituting the value of $v_{s/c}$ determined from equation (1) into equation (2) and solving for v_{ph}.

We applied this technique to a set of discrete wave packets observed by the ISEE-1 and -2 spacecraft on day 307 of 1977. The general characteristics of this variety of upstream wave were established by Russell *et al.*[2] in a comprehensive study based on single-spacecraft measurements, which we briefly summarize. The wave packets, which are most often found embedded in trains of irregular lower frequency (0.05 Hz) waves, typically grew rapidly in time and decayed more slowly, generally lasting two or three cycles. Wave packets were observed with frequencies throughout the interval chosen for study, 0.14–1.4 Hz with an average frequency of 0.4 Hz, and were left-hand polarized in 90% of the cases. From measurements of wave ellipticity, Russell *et al.* hypothesized that these waves were intrinsically right-hand polarized whistler mode waves of frequencies several times the proton gyrofrequency. Cold plasma theory predicts that such waves should have phase velocities of ~100 km s^{-1}, which is significantly less than the typical solar wind velocity. Thus, if these waves were, as hypothesized, attempting to propagate upstream against the solar wind flow, they would be swept backwards over the spacecraft, resulting in the observed reversal of polarization. We present here direct experimental verification of this hypothesis.

The time period studied was 0200–0300 UT of day 307 of 1977 (Fig. 1). At this time, the spacecraft were in the interplanetary medium, inbound on the dawn side of the Earth at 1030 LT, several Earth radii (R_e) upstream of the final bow shock crossing which occurred at 0600 UT. The interplanetary magnetic field was essentially radial during this time period and the angle between the field and the nominal shock normal was 25°. Bursts of quasiparallel shock structure were encountered throughout the inbound portion of this orbit, and the studied interval is characterized by strong irregular magnetic field disturbances with time scales of 30 s, and by the presence of diffuse suprathermal ions (D. D. Sentman, personal communication). Magnetic field data used in this study were high-resolution measurements made by the dual UCLA magnetometers[3] onboard ISEE-1 and -2. Data acquisition rate at this time was 4 vectors per s. Solar wind speeds were estimated using data from the University of Iowa's ISEE LEPEDEA plama analysers.

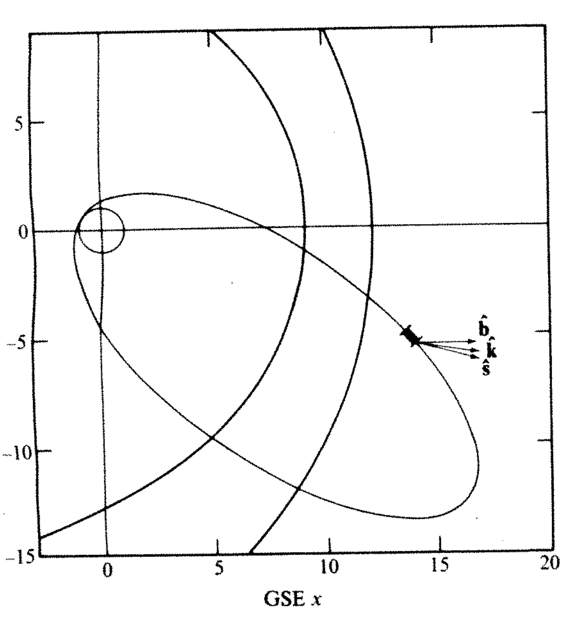

Fig. 1 Ecliptic plane projection of ISEE orbit with estimated shock and magnetopause positions on 3 November 1977. Location of satellites during the period of study, 0200–0300 UT, and ecliptic plane projection of the magnetic field, b̂, the average wave normal, k̂, and the model bow shock normal, ŝ, are also shown. The model for the bow shock used in this calculation is an ellipse with focus on the Earth and ellipticity 0.8.

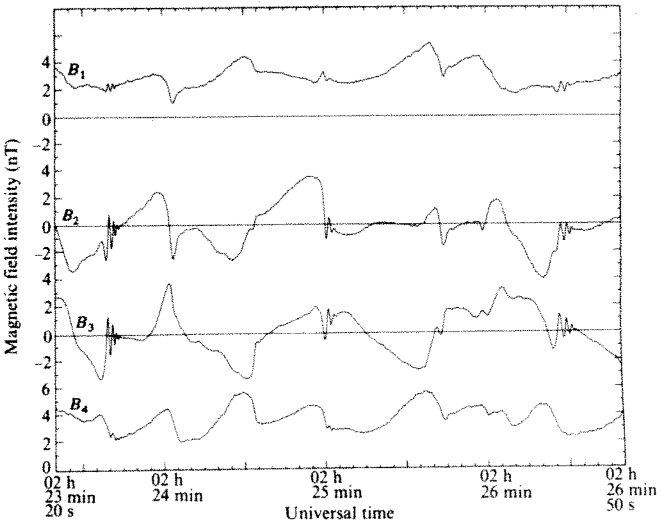

Fig. 2 The three vector components, in GSE coordinates, and the total magnitude of the magnetic field measured by the ISEE-2 magnetometer as the spacecraft was inbound on day 307 of 1977. The spacecraft was at a radial distance of 16.6 R_e, upstream of the bow shock at 1030 LT.

Three typical wave packets are shown in Fig. 2. Note that the amplitude of these waves is a large fraction of the background field. As is the usual case, the packets (seen here beginning 02 h 23 min 39 s, 02 h 24 min 59 s and 02 h 26 min 25 s) are embedded in a train of lower-frequency waves and seen to be intimately related to the low-frequency wave structure, occurring when the field magnitude suddenly returns to low values after a more gradual increase. All the wave packets seen in the studied interval begin at the foot of sharp drops in the field magnitude (B_T), although not all such drops are accompanied by wave packets (for example, sharp decrease in B_T at 02 h 24 min 05 s). The field structure is thus apparently a necessary but not sufficient condition for the development of the packets on this day.

The profiles of the packet which begins at 02 h 23 min 39 s, as seen at the two separate spacecraft, are presented in higher resolution in Fig. 3. The spacecraft separation at this time was −117, 180 and −107 km (GSE coordinates), with ISEE-2 located upstream and to the west of ISEE-1. The signals are nearly identical (the correlation is 0.92) except for a small but consistent time delay between the appearance of the wavefront at first ISEE-2 and then, 0.5 s later, downstream at ISEE-1. The precise time delay characteristic of the wave packets was determined from studies of the behaviour of the correlation between signals from the two spacecraft as a function of lag time, an example of which, for the wave packet shown in Fig. 3*a*, is shown in Fig. 3*b*. Correlation coefficients averaged over intervals appropriate to the signal duration were calculated for successive 0.25-s lags, consistent with the magnetometer's acquisition rate of 4 vectors per s. The correlation averaged over the 6-s duration of the wave packet peaks at 0.5 s, with secondary peaks appearing at 1.5-s intervals, consistent with the estimated wave frequency. The time delay expected for a static structure simply convecting with the solar wind flow would have been 0.3 s. The time delay can be determined to within ~±0.1 s using such plots, which at this spacecraft separation allows the resolution only of those wave phase velocities ≳70 km s^{-1}. Of the 24 wave packets observed in the hour 0200–0300 on day 307, 13 were characterized by velocities too small for us to resolve from the solar wind flow and the measurements on the remaining 11 cases are presented here.

Determination of the second element of the analysis, the distance travelled by the wavefront as it propagates between the spacecraft, requires determination of the direction of propagation of the wave. This direction can be determined within an

180° ambiguity by minimum variance analysis. Values computed by this technique independently from data from each of the spacecraft were in good agreement, and our analysis is based on averaged values. The time evolution of the field of the packet of Fig. 3*a* is shown in Fig. 4, where the variation is presented in the principal axes system. The field variation in the plane of the wavefront is plotted on the left. Note that the field rotates in the left-hand sense about the ambient field direction, which is into the paper in this case. As seen here, the wave packets generally exhibit a nearly perfectly circular polarization. This same sense of rotation, left handed in the spacecraft frame, has been observed in all cases. The planarity of the wave is documented by the linearity of the right-hand plot, which shows the field variation in the plane formed by the direction of maximum variance and the wave normal. The nearly perfect plane circular polarization of this packet is typical and well justifies our identification of the direction of wave propagation with the minimum variance direction, which requires such

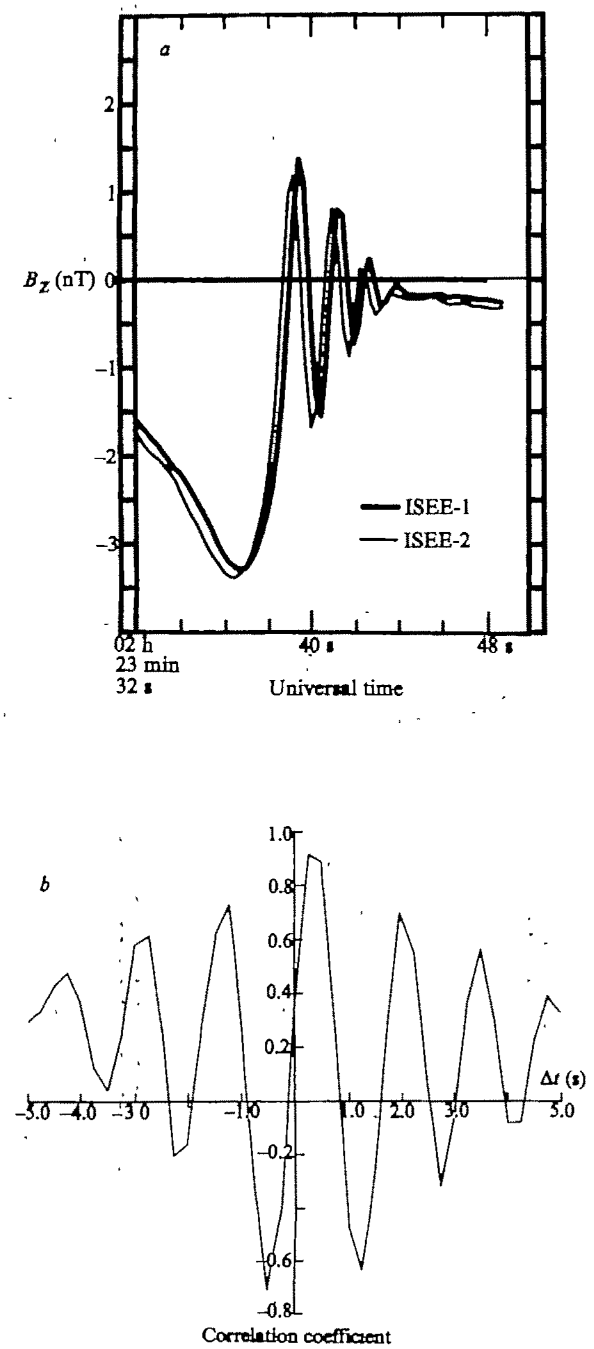

Fig. 3 *a*, Overlay of wave-packet signatures in the *z* component of the field of the two spacecraft for wave packet beginning at 02 h 23 min 39 s. *b*, The weighted correlation coefficient of signals from the two spacecraft as a function of imposed successive 0.25-s lag times (Δt). The correlation coefficient is the average lagged product of the times series on the two spacecraft for each of the three vector components weighted by the variance in that component. The correlation coefficients for each of the three components were quite similar. The correlation has been averaged over the 6-s duration of the 02 h 23 min 39 s wave packet. Positive Δt corresponds to signals which appeared first at ISEE-2.

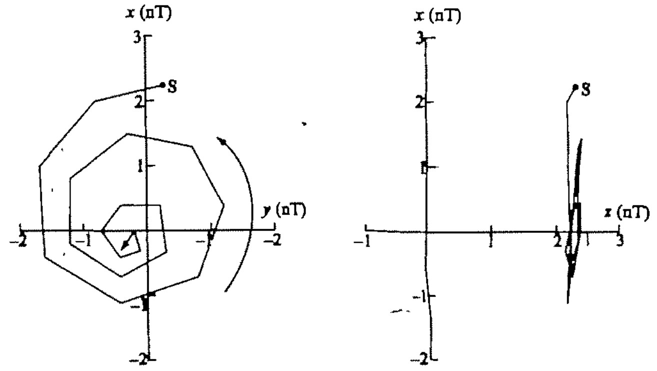

Fig. 4 The time evolution of the field vector of the 02 h 23 min 39 s packet, beginning at point S. The *x*, *y* and *z* axes correspond, respectively, to the directions of the maximum, intermediate and minimum variance eigenvectors

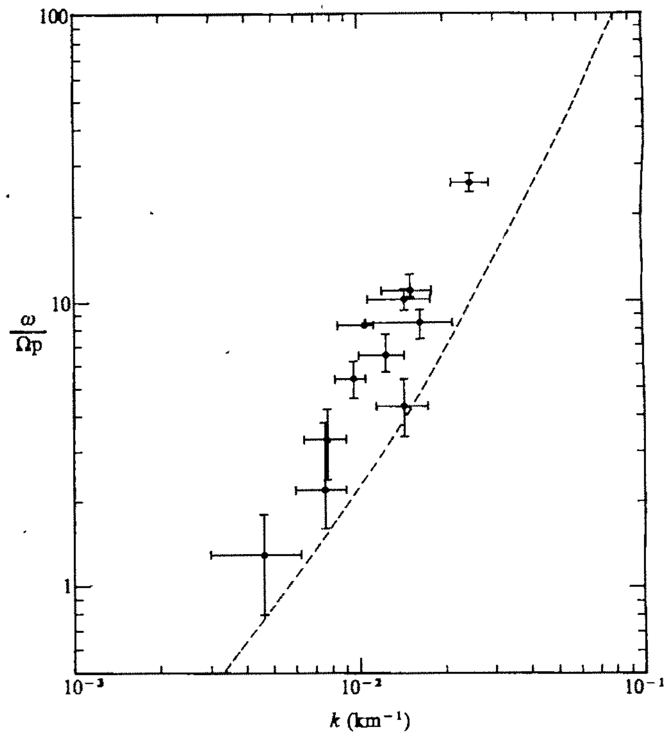

Fig. 5 Experimentally determined rest-frame frequencies, normalized to the local proton gyrofrequency, are plotted against wave number. Error bars represent uncertainties due to an estimated 0 1-s imprecision in Δt, which is the most significant source of error during this time interval. Also plotted (dashed line) is the relation expected from the cold plasma dispersion relation for a solar wind density of 3 cm^{-1}, magnetic field magnitude of 3 nT and propagation angle of 25°, average values typical of this time period

polarization for its validity. The direction of minimum variance is well determined in all cases. Typical ratios of the intermediate to minimum eigenvalue are ~50, indicating that minimum variance directions are generally determined to within at least 1°. This direction tends to lie close to that of the ambient magnetic field with the typical angle between $\hat{\mathbf{k}}$ and **B** being ~25°.

From measurements of the wave frequency in the spacecraft frame (f_0) together with the wave velocity as determined above, one can also calculate the wavelength (λ): $\lambda = v_{s/c}/f_0$. The wavelength divided by the phase velocity then yields the plasma frame frequency (f_r): $f_r = \lambda/v_{ph}$. The results of such determinations for the wave packets studied here are presented in Fig. 5, where the angular frequency, ω, has been normalized to the local proton gyrofrequency, Ω_p, and plotted as a function of wave number k.

For comparison, we have presented the cold plasma dispersion relation for estimated ambient solar wind parameters and the 25° propagation angle typical of these packets, plotted as the dashed line in Fig. 5. The general trend of the data is quite consistent with the theoretical prediction although experimentally determined values tend to lie on the high side of the curve.

Theoretical approaches to these waves have been suggested previously by Wu[4], Hasegawa[5] and Gul'yel'mi and Bondarenko[6] who, respectively, invoke wave-echo phenomena, a two-stream instability between the solar wind and magnetosheath plasma and MHD soliton formation. The extreme turbulence occurring both in the magnetosheath and in the foreshock region during quasiparallel shock conditions as seen here argues against the feasibility of a plasma echo mechanism causing the waves. The present results are also inconsistent with both modes derived from the two-stream instability, which are a right-handed mode with $v_0 \gg \mathbf{V}_{sw}$ and a left-handed mode propagating downstream. The agreement between the predictions of MHD soliton theory and wave packet characteristics found by Gul'yel'mi and Bondarenko is not confirmed by the present work.

In conclusion, the measurements present a consistent general picture of whistler mode plasma waves attempting to propagate upstream against the solar wind flow with phase velocities of the order of several times the Alfvén speed and wavelengths of the order of several hundreds of kilometres. Because the waves are being blown backwards over the spacecraft, their frequencies have been shifted from values several times the proton gyrofrequency in the rest frame to higher values in the spacecraft frame, and their intrinsic right-hand polarizations have become apparent left-hand polarizations at the spacecraft. The wave packets in this interval occur coincidentally with a sharp drop in the field strength which follows a more gradual rise in magnitude. As these structures are being blown downstream, the discrete wave packets are, in fact, on the upstream side of these lower-frequency structures, much like the whistler waves often seen at the foot of the bow shock[7,8]. Thus, the low-frequency structures shown in Fig. 2 seem to be little shocks attempting to stand in the solar wind flow but being too weak and being blown backwards towards the Earth.

This work was supported by the National Aeronautics and Space Administration through grants NAS 5-25772 and NAS 5-20094 through the University of Iowa subcontract no. R 44855. We thank L. A. Frank and D. D. Sentman for the use of the ISEE LEPEDEA data from which the solar wind parameters were derived and the presence of backstreaming suprathermal ions during the period was verified.

Kinetics of void-lattice formation in metals

K. Krishan

Reactor Research Centre, Kalpakkam 603 102, Tamil Nadu, India

Since the discovery[1] that voids form in neutron-irradiated stainless steel and that these could form into a three-dimensional lattice[2], void-lattices have been observed in some b.c.c. metals[2,3] such as Mo, W, Nb, and Ta, and in f.c.c. metals[4,5] such as Al and Ni. The irradiation conditions in which a void-lattice is formed are not understood[6], but several explanations[7–11] of the stability of the void-lattice have been given on the basis of void–void elastic interaction[9–11]. Our present approach regards the void-lattice formation as a phase transition associated with the bifurcation of the homogeneous steady state in the mean field theory[12,13]. The void-lattice is an interesting example of a class of phase transitions manifested by open, nonequilibrium, dissipative structures and have an inherent capability of self-organization. Although void-lattice formation has already been examined on this basis[14,15], we show here that the transition is induced in certain microstructural conditions where vacancy loop dynamics has an important role. The theory generally agrees with experimental features and predicts that another spatially dependent state exists which can influence irradiation-induced phenomena that have important technological implications for the development of fast reactor materials.

In the homogeneous rate theory[12,13] the steady-state vacancy and interstitial concentrations C_V and C_I respectively, jointly represented by a column matrix $\mathbf{C}_P$, are stable against any spatial deviations $\delta\mathbf{C}_P$ produced due to the fluctuations within the grain of size d. The stability[16] is due to the presence of sinks like voids, vacancy loops, interstitial loops and network dislocations whose sink densities are represented by ρ_s, ρ_v, ρ_i and ρ_d respectively. If D_v and D_I are vacancy and interstitial diffusion constants, Z_I the bias, $\beta_V = D_V(\rho_s + \rho_d + \rho_i + \rho_v)$, $\beta_I = D_I\rho_s + Z_I D_I(\rho_d + \rho_i + \rho_v)$ and α the recombination parameter, then the deviations $\delta\mathbf{C}_P$ in a linear approximation close to the steady state are governed by the equation

$$\delta\mathbf{C}_P = (\mathbf{A}_{11} + \mathbf{D}\nabla^2)\delta\mathbf{C}_P \tag{1}$$

where

$$\mathbf{A}_{11} = \begin{pmatrix} -\beta_V - \alpha C_I & -\alpha C_V \\ -\alpha C_I & -\beta_I - \alpha C_V \end{pmatrix} \tag{2}$$

The matrix **D** is diagonal with elements D_V and D_I and the Laplace operator allows for point defect diffusion and the possibility of forming spatially ordered dissipative structures[17]. Using bifurcation analysis we choose a convenient orthogonal basis in terms of which the time and space evolution of any arbitrary deviation $\delta\mathbf{C}_P$ can be studied. We also examine how the basis functions themselves evolve and, therefore, attempt solutions of the type

$$\delta\mathbf{C}_P = \mathbf{f}_P e^{\omega_M t} \sin\left(\frac{m_1\pi x}{d}\right) \sin\left(\frac{m_2\pi y}{d}\right) \sin\left(\frac{m_3\pi z}{d}\right) \tag{3}$$

where m_1, m_2, m_3 are integers $\neq 0$, $\mathbf{f}_P$ is a column matrix for the amplitudes and $\nabla^2\delta C_V = M^2\delta C_V$ with $M^2 = (\pi^2/d^2)(m_1^2 + m_2^2 + m_3^2)$. The boundary condition $\delta\mathbf{C}_P = 0$ at the grain surface has been imposed consistent with the grain boundary being an effective sink. Further, after the bifurcation due to the spatial dependences, flows or currents $j_V = -D_V\nabla\delta C_V$ and $j_I = -D_I\nabla\delta C_I$ in the point defects will develop. These flows must be consistent with the symmetry of the host lattice. This amounts to imposing additional constraints on the indices m_1, m_2 and m_3. If we now substitute equation (3) into (1) we obtain values of the frequencies ω_M which satisfy equation (1) and find that $\omega_M < 0$

0028–0836/80/400420—02$01.00

for all values of sink densities ρ. This means that in this model the original homogeneous state is stable and any arbitrary deviations will decay to zero. In other words no soft mode $\omega_M = 0$ can arise because for no positive value of M^2 is the condition

$$\det|\mathbf{A}_{11} - DM^2| = 0 \qquad (4)$$

satisfied.

In the above analysis the response of the extended defect structure to changes in $\mathbf{C}_P$ has been ignored. This response is important and provides the additional interaction or coupling which leads to the bifurcation of the homogeneous state. This coupling arises mainly through the terms $\beta_V C_V$ and $\beta_I C_I$ which give the rate of loss of point defects to sinks. These terms are nonlinear when one includes the response of the microstructure as β_V and β_I are related through the sink densities to the sizes and concentrations of the extended defects. Let the column matrix $\delta\mathbf{C}_e$ represent the deviations δr_s in the void radius r_s and δN_v in the vacancy loop concentration N_v. These deviations will be functions of the spatial positions of the voids and vacancy loops. The contribution of interstitial loops can be included along with network dislocations under a suitable approximation. The equation of motion within the framework of the linear analysis is given by

$$\frac{d}{dt}\begin{pmatrix}\delta\mathbf{C}_P\\ \delta\mathbf{C}_e\end{pmatrix} = \left\{\begin{pmatrix}\mathbf{A}_{11} & \mathbf{A}_{12}\\ \mathbf{A}_{21} & \mathbf{A}_{22}\end{pmatrix} + \begin{pmatrix}\mathbf{D}\nabla^2 & 0\\ 0 & 0\end{pmatrix}\right\}\begin{pmatrix}\delta\mathbf{C}_P\\ \delta\mathbf{C}_e\end{pmatrix} \qquad (5)$$

where from the BEK theory[13], $\mathbf{A}_{22}$ is diagonal with elements $\dot{r}_v/\bar{r}_v$ and $-\dot{r}_s/r_s$; $\bar{r}_v$ is the initial radius of the vacancy loops. The coupling matrices $\mathbf{A}_{12}$ and $\mathbf{A}_{21}$ are functions of ρ_v and ρ_s. Following our previous arguments we again attempt solutions of the type given by equation (3) for $\delta\mathbf{C}_P$ and similar space dependent solutions for $\delta\mathbf{C}_e$ where the amplitude term $\mathbf{f}_P$ will now be replaced by a column matrix $\mathbf{f}_e$ for the extended defects. It is convenient, however, to partition the 4×4 matrix in equation (5) into two separate equations, one for $\delta\mathbf{C}_P$ and the other for $\delta\mathbf{C}_e$ using the standard partitioning techniques. Examining as before the possibility of a soft mode $\omega_M = 0$ we obtain now in place of equation (4) the condition

$$\det|\mathbf{A}_{11} - \mathbf{A}_{12}\mathbf{A}_{22}^{-1}\mathbf{A}_{21} - \mathbf{D}M^2| = 0 \qquad (6)$$

This equation for certain values of ρ_v and ρ_s, which are the critical values for the transition, has solutions for positive values $M^2 = 3\pi^2/d^2$. This is the first bifurcation and represents the onset of the void-lattice formation.

Several experimentally observed features of the void-lattice formation emerge from this analysis. Figure 1 shows a phase diagram in the ρ_v, ρ_s space with the critical values of the densities obtained from equation (6) showing where the first bifurcation occurs. Whether the system reaches critical density values depends on how the system evolves in time and this has to be obtained by a solution of the BEK equations[13]. After the first bifurcation secondary bifurcations take place together with the ordering of the void-lattice. This introduces coarsening in the void distribution with correlations in void positions gradually emerging as is seen experimentally. The analysis of secondary bifurcations is difficult because of the stability factors coupled with the complex time and spatial dependence of the states involved. Such an analysis may have to be done by computer simulation techniques as in the case of simpler models which show similar self-organization behaviour[17]. Energy considerations as discussed by Malen and Bullough[9] probably influence the final stages of void-lattice formation leading to the high stability of such a lattice. However, preliminary results show that as a function of ρ_v the parameter M^2 saturates at a value of about $10^{15}\ \mathrm{m}^{-2}$ which, for a given grain diameter $d \sim 10^{-5}$ m, gives $m_1 \simeq m_2 \simeq m_3 \simeq 100$, implying a void-lattice spacing of about 1,000 Å in reasonable agreement with experiments. The symmetry of the void-lattice must be the same as the host lattice because of the constraints imposed due to physical considerations on m_1, m_2 and m_3 arising due to the currents which develop after the bifurcation. However, a more fundamental approach, although difficult to analyse, would be to examine the factors which cause only those fluctuations which are consistent with the host lattice symmetry to grow. The phase transition involved is symmetry breaking from a homogeneous to a space periodic one. This explains why voids initially form randomly and only subsequently become ordered. The structure of the matrix $\mathbf{A}_{22}$ shows that $\dot{r}_v < 0$ is a requirement for bifurcation. The instability is therefore related to the vacancy loop formation. This is generally confirmed by experiments as electron-irradiation which produces voids effectively, but not vacancy loops, fails to give rise to regular void arrays. Such arrays are formed in both neutron and charged particle irradiation where vacancy loops are formed due to collapse of cascades. Note that no specific property of the vacancy loops is involved but rather the manner in which they couple with point defects. Such microstructural induced ordering effects can be expected in fairly general conditions in situations involving irradiation, stress or temperature gradients. It is in this context that the partial void ordering in nitrided steel[18] by electron irradiation has to be viewed, where the possible trapping of vacancies by nitrogen gas atoms could produce the same effect as vacancy loops.

These results are interesting both because they explain many features of void-lattice formation, and because the possibility of a phase transition to a new spatially dependent state has important implications for several irradiation-induced phenomena which are of interest in the development of materials for fast reactors.

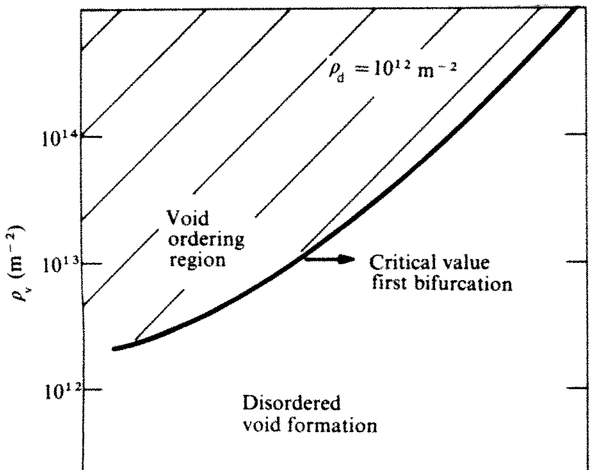

Fig. 1 Phase diagram showing where the first bifurcation appears. A vacancy migration energy of 1.3 eV has been used. For bifurcation and onset of void-lattice formation the system must evolve into the void ordering region.

I thank Drs G. Venkataraman, S. Dattagupta and G. Ananthakrishna for their comments and suggestions.

Influence of modal composition on deformation in garnet lherzolite nodules

M. R. Smith

Department of Geology and Mineralogy, University of Oxford,
Parks Road, Oxford OX1 3PR, UK

A textural distinction has been drawn, in peridotites derived from kimberlite pipes, between relatively undeformed granular types and strongly deformed sheared types[1], that corresponds roughly with the absence and presence of large strained olivine grains (porphyroclasts) surrounded by smaller, recrystallized grains (neoblasts). More detailed classifications have also been proposed[2–6]. The textural variety is probably caused by both widespread mantle creep and more localized phenomena connected with kimberlite eruption[7–12]. From consideration of dynamically recrystallized grain size[11] and dislocation densities[12], it seems that nodules that contain neoblasts have been deformed in high stress and strain rate conditions, over short periods of time, before eruption. The formation of the sheared textures and the eruption of the kimberlite are approximately simultaneous. I report here detailed textural observations on 10 garnet lherzolite nodules collected from kimberlite pipes in South Africa and Lesotho. They all have sheared textures, as defined above, showing a range from small amounts of grain boundary recrystallization to almost complete consumption of olivine porphyroclasts. Sections were cut parallel to the foliation and modal analyses were accurately determined by point counting one slide from each sample. The number of olivine porphyroclasts on each slide was then independently counted. The fewer the grains, the greater is the accuracy of estimating their number. Average porphyroclast areas were then calculated (Table 1). The data suggest that modal composition controls the extent of shearing.

Figure 1 shows the relationship between average porphyroclast area and percentage of olivine from the 10 thin sections. It seems that the lower the olivine content, the higher is the degree of deformation as recognized by the smaller areas of olivine porphyroclasts. The range of textures encompassed by the sheared group can be attributed to the range in olivine percentages.

This relationship can be justified by considering that the correlation will still hold if the sum of the other minerals present in the rock (pyroxene and garnet) is plotted along the x-axis. Kohlstedt and Van der Sande[13] have estimated that the climb velocity of dislocations in enstatites is $<0.1\%$ of that in olivine. This behaviour results in a high creep resistance of orthopyroxene compared with olivine[14] in the high temperature, hot working flow regime characteristic of these xenoliths. Despite recovery, strain rates are high enough to increase the strain energy at grain boundaries to a point where olivine begins to recrystallize while orthopyroxene continues to deform by slip and rotation. This is confirmed in natural examples which show that enstatites, diopsides and garnets have a lesser tendency to polygonize and recrystallize[2–5]. Thus these minerals act as relatively rigid material while olivine recrystallization dominates. Where metasomatic philogopite is seen to replace garnet on decompression it can also be included.

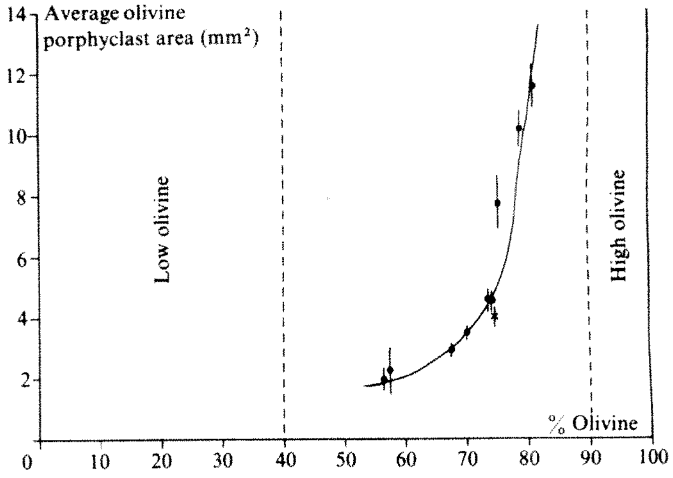

Fig. 1 Dependence of olivine porphyroclast grain size on amount of olivine after onset of recrystallization.

At the onset of deformation, stresses are maximized at porphyroclast grain boundaries as evidenced by recrystallization along them. If strain rates are high enough, concentrations of strain energies along these boundaries eventually cause recrystallization until the olivine porphyroclasts are entirely consumed. Olivine/olivine grain boundaries will be destroyed as neoblasts are produced along them while orthopyroxene/olivine, clinopyroxene/olivine and garnet/olivine boundaries will be relatively preserved. Thus strain energies high enough for olivine recrystallization will be retained at the latter boundaries between the rigid material and the olivine grains. Rigid/olivine boundary lengths will depend on modal percentages, hence percentage rigid material will determine available concentrations of strain energy, the release of which is accomplished by recrystallization.

The cross in Fig. 1 (nodule: BD2501) indicates a lower than expected area value. This sample has a higher percentage of garnet plus clinopyroxene, relative to orthopyroxene, than all the other samples, and optical evidence shows that these minerals are more resistant to recrystallization and disruption than orthopyroxene. Higher strain energies may have persisted at garnet/olivine and clinopyroxene/olivine boundaries while the pyroxenes began to recrystallize and so reduced the areas yet further. Similarly the square in Fig. 1 (nodule: XDB5) has no garnet and little clinopyroxene and has a high area value. The high olivine field ($>90\%$) marks an area where recrystallization cannot continue after the onset of deformation. Indeed the

nodules showing the largest modal proportion of olivine (nodule: KJAG22) has only 0.8% neoblasts and shows olivine tablets of the type considered[11] to be formed by relief of strain energies during kimberlite eruption.

The existence of sheared dunites (>90% olivine) at Thaba Putsoa and the Frank Smith pipe[8] and at Kampfersdam[15] seems to conflict with the relationship in Fig. 1. The dunites found at Thaba Putsoa, however, are reported as having "porphyroclasts of olivine up to 1 cm in diameter" (very large). At the onset of deformation, and in suitable conditions, olivine/olivine grain boundaries will be destroyed and a certain percentage of recrystallized olivine will, hence, be present to exhibit porphyroclastic textures. The porphyroclast sizes will thus remain at a constant maximum to the right of the second dotted line in Fig. 1.

In contrast, deformation of dunites "to varying degrees"[15] at Kampfersdam and other pipes cannot be explained by the above mechanism. The Kampfersdam dunites have been interpreted to be high temperature nodules due to the coarseness of their olivine groundmass. The recrystallization mechanism involving percentage of rigid material may only dominate within a certain range of conditions which are not, at present, possible to define, although current detailed geochemical studies (S. Beswetherick personal communication) may produce information. On the other hand, there may, in this case, have been a genuine externally imposed gradient in strain which is not evident in the specimens plotted on Fig. 1. The low olivine field (<40%) may indicate complete destruction of olivine porphyroclasts but the increased interaction of rigid/rigid grain boundaries as olivine percentage is reduced may tend to prevent further recrystallization.

An example of the modal compositional effects is shown by the single nodule (KDT11) which shows bands of high and low olivine contents. Figure 2 shows a grain map of this nodule in which the textural range of different samples is seen at the contact zone between bands. Larger olivine porphyroclasts tend to be restricted to the olivine rich bands while only neoblasts are seen in the areas where orthopyroxene predominates.

The above observations have important implications for the origin of the range of sheared textures we see at the surface. An externally imposed strain gradient is apparently not the only factor required to produce the spectrum of sheared textural types seen. The spectrum may be produced, at least partially, by compositional differences in the xenolith source regions. From phase considerations, production of basaltic liquids from garnet lherzolite results from partial melting in the approximate ratio, 1 olivine : 5 orthopyroxene : 10 clinopyroxene : 10 garnet[16]. The high orthopyroxene + clinopyroxene + garnet modal peridotites will correspond roughly with material less depleted in basalt, hence degree of partial melting may determine extent of shearing. Although granular nodules—those that do not contain recrystallized olivine—were not included in this study, note that in the least sheared samples studied the textures become similar to some granular types. The textural contrast between sheared and some granular forms may then be a transition related to extent of depletion. Before onset of deformation olivine grain sizes may have been considerably larger.

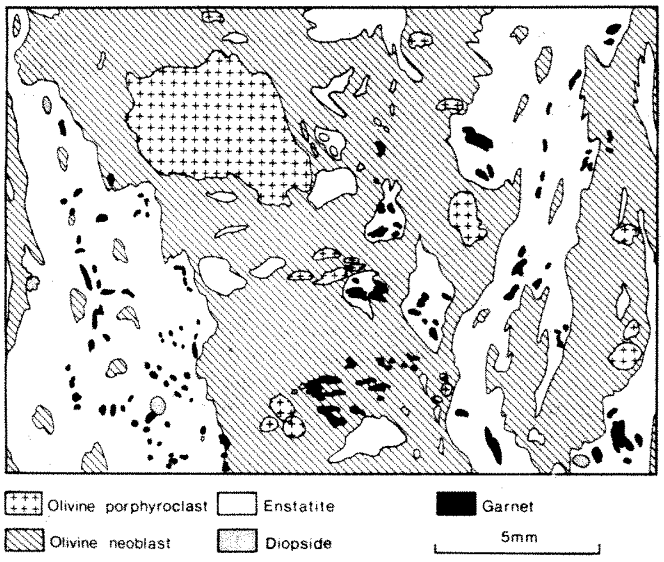

Fig. 2 Grain map of KDTII showing compositional banding with preference of olivine porphyroclasts for olivine bands.

The present data indicate that the factor that controls extent of shearing, as recognized by consumption of olivine porphyroclasts by recrystallization, may be modal composition. From a structural point of view there is a genetic connection between degree of shearing and mechanical properties of the rock. It seems that the observed strain gradient would then be a function of internal compositional factors and not an external stress, temperature or strain rate gradient.

I thank J. B. Dawson, A. J. Erlank, J. J. Gurney and P. H. Nixon for collecting the nodules and K. G. Cox and D. G. Fraser for critically reading the manuscript. This work was supported by the NERC.

A problem posed by vapour-dominated geothermal systems

Gerald Schubert* & Joe M. Straus

Space Sciences Laboratory, The Aerospace Corporation, Los Angeles, California 90009

Malcolm A. Grant

Applied Mathematics Division, Department of Scientific and Industrial Research, Wellington, New Zealand

Vapour-dominated geothermal systems present an apparently extraordinary physical phenomenon—a layer of water lying stably on a body of steam. The first geothermal exploitation at Lardarello, Italy, was in such an area. We present here an analysis of the gravitational stability of water over steam in a porous medium. This shows that the near surface condensate layer of a vapour-dominated geothermal system can be stably maintained above the main steam reservoir by restoring forces associated with the displacement of the phase-change interface. For typical conditions in vapour-dominated geothermal systems, stability can be maintained provided that the permeability of the rocks at the depth of the steam–water boundary does not exceed about 40 nm^2 (0.04 millidarcy). The stability requirement determines the thickness of the condensate layer or the proximity of the top of the steam reservoir to the surface.

---

*Permanent address: Department of Earth and Space Sciences, University of California, Los Angeles, California 90024.

The basic structure of vapour-dominated systems is revealed by pressure measurements in wells drilled to different depths, as shown in Fig. 1 for the Kamojang geothermal field in Indonesia. The water table lies 100–150 m below ground surface. From there to 500 m depth, pressure increases as in normal groundwater, that is, approximately hydrostatically at a rate determined by the density of liquid water. Below 500 m depth, however, pressure increases only very slowly with depth; the rate of increase with depth is approximately that in a static column of steam. Pressure profiles similar to that in Fig. 1 have been published for the Lardarello geothermal field[1].

A section through the Kamojang field[2] (Fig. 2) illustrates the physical structure of a vapour-dominated geothermal system[3–5]. A layer of brine, or very saline water, overlying a magmatic heat source, is presumed to exist at greater depth than shown in Fig. 2. The heat supply boils steam off from the brine, and this steam ascends through the fractured rock. It continues to rise until, at about 500 m depth, it meets the 'condensate layer', the liquid-dominated layer overlying the steam system. In the centre of the field some steam passes through this liquid, much like bubbles rising through water, and gives rise to a surface discharge of steam in fumaroles, steaming ground, acid springs and mud pools. Outside the central area of the field, steam does not escape from the steam reservoir.

Although drilling shows that steam is the pressure-controlling phase in the main reservoir of a vapour-dominated system, various observations demonstrate that the steam in this region must be in contact with some liquid water which is at or near residual saturation. The total production of steam at Lardarello is much greater than could be stored in a steam phase, although it could be accommodated as liquid[6]. At two of the vapour-dominated systems now explored, the geysers in California and Kamojang, although no longer at Lardarello, the fall in pressure caused by exploitation is accompanied by a fall in temperature, consistent with a temperature related to the steam–water saturation curve. Temperatures measured in the main steam reservoir of the Kamojang field (Fig. 1) agree with the saturation temperatures corresponding to the measured pressures. Measurements at the geysers also suggest that temperature increases with depth along the boiling point curve in the steam reservoir[7].

In the liquid-dominated condensate layer, temperatures generally lie on a linear conduction profile[2,7]. This is a consequence of both the surface temperature and the relatively low permeability of the near surface rocks as compared with those in the main steam reservoir. Where the near surface rocks are relatively more permeable, steam rises closer to the surface, and actually reaches it in some locations[2]. In these areas, the temperature profile would lie on the saturation curve at all depths.

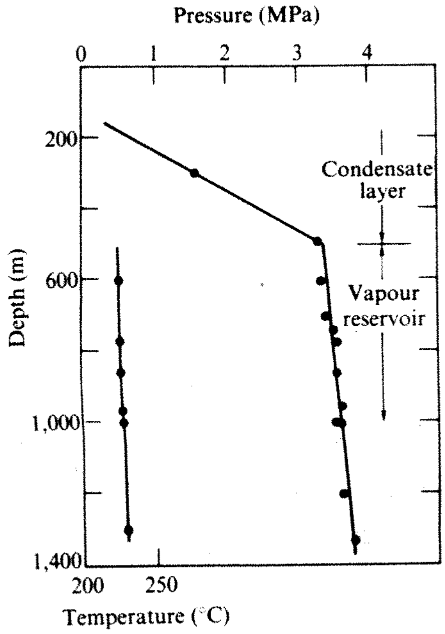

Fig. 1 Measurements of pressure and temperature in the Kamojang geothermal field in Indonesia (excluding the vicinity of well 7).

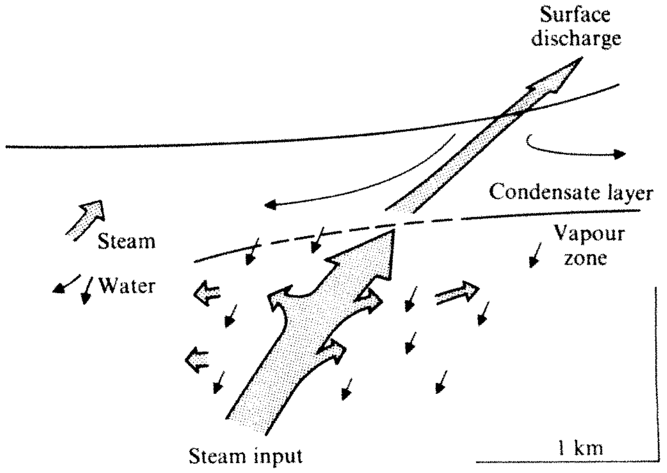

Fig. 2 Inferred structure of the Kamojang field[2].

The major problem posed by the structure of Fig. 2 is why does the water not fall down? A sealed cap cannot separate the condensate layer from the steam reservoir because the natural discharge of the systems indicates that there is continuous permeability, at least in some places, between the mobile steam beneath and the mobile water above. If the water–steam interface behaved as a boundary between immiscible fluids, the configuration of water over steam would be gravitationally unstable for any permeability of the rocks in the vicinity of the interface, no matter how small. This can be understood by imagining a disturbance to the system which resulted in some downward flow of water towards the interface. If the water and steam were immiscible fluids, the boundary between them would be displaced downwards by such a disturbance. As a consequence, a vertical column of fluid in the region of the disturbance would contain more water and thus would be heavier than a column of fluid in the undisturbed quiescent state. The additional weight of the perturbed column provides a downward force tending to reinforce the original disturbance and displace the interface even further. Thus, the configuration is unstable.

A phase-change interface, however, distorts quite differently in response to such a disturbance because the interface must remain on the Clapeyron or equilibrium curve separating the phases. The location of a phase-change boundary is mainly dependent on temperature and pressure, and, unlike the case of the interface between immiscible fluids, flow can occur across a phase-change interface. Downward flow of water towards the steam–water boundary brings fluid to the interface that is colder than the fluid at the undisturbed location of the boundary as a consequence of the natural geothermal gradient. This causes the boundary to be displaced upward to lower pressure because it must remain on the Clapeyron curve. The phase-change interface distorts in a direction opposite to the sense of flow towards it, in striking contrast to the behaviour of the interface between immiscible fluids. As a result of the upward displacement of the phase-change boundary, a vertical column of fluid in the region of the disturbance would contain less water and thus would be lighter than a column of fluid in the undisturbed state. The reduced weight of the perturbed column provides an upward buoyancy force tending to oppose the original disturbance and stabilize the system. Another effect which tends to reinforce the stabilizing tendency of advection of colder water toward the phase change is that when water moves downward towards the phase change and the boundary moves upwards in response, there is a mass flow across the phase change which converts water into steam. This phase transformation requires the absorption of the latent heat of vaporization and results in cooling of the surrounding fluid. As noted immediately above, cooling leads to upward displacement of the phase boundary and stabilization of the system. The cooling produced by the effects of advection and latent heat absorption promotes one destabilizing tendency associated with the thermal contraction of the water—colder water weighs more, and this additional weight of the column tends to drive the system in the same direction as the original downward perturbation.

To assess these effects quantitatively we have analysed the gravitational stability of horizontally infinite superposed fluid layers separated by a phase-change interface in a porous medium. The basic state consists of a motionless layer of water above a static layer of steam. Pressure increases with depth in the undisturbed state according to the hydrostatic law; the liquid and vapour densities govern the slopes of the pressure–depth profiles in the water and steam layers, respectively. Temperature is assumed to increase linearly with depth in the basic state. The stability of this configuration is governed by Darcy's law, which relates velocity and pressure perturbations, the incompressible continuity equation (density changes within each phase are negligible), which relates horizontal and vertical velocity perturbations, and the phase equilibrium equation, which relates pressure perturbations to the distortion of the water–steam interface. The differential equations for the disturbances are linearized and solved subject to the following conditions: (1) isothermal upper and lower boundaries, (2) no flow through the lower boundary, (3) constant pressure on the upper boundary, (4) continuity of pressure, temperature and mass flow at the water–steam interface, and (5) balance of conductive heat flux and latent heat release at the phase-change boundary.

The analysis shows that stabilization of water overlying steam requires

$$K < \frac{2k}{L\left(\frac{\mathrm{d}p}{\mathrm{d}T}\right)_{\mathrm{c}}} \frac{\left(\frac{\bar{\mu}_{\mathrm{l}}}{\bar{\rho}_{\mathrm{l}}}+\frac{\bar{\mu}_{\mathrm{v}}}{\bar{\rho}_{\mathrm{v}}}\right)}{\left(1-\frac{\bar{\rho}_{\mathrm{v}}}{\bar{\rho}_{\mathrm{l}}}\right)} \left\{ \frac{\Gamma\left(\frac{\mathrm{d}p}{\mathrm{d}T}\right)_{\mathrm{c}}}{g\bar{\rho}_{\mathrm{l}}} - \frac{\left(\frac{\bar{\rho}_{\mathrm{v}}}{\bar{\rho}_{\mathrm{l}}}+\frac{\bar{\mu}_{\mathrm{v}}}{\bar{\rho}_{\mathrm{v}}}\frac{\bar{\rho}_{\mathrm{l}}}{\bar{\mu}_{\mathrm{l}}}\right)}{\left(1+\frac{\bar{\mu}_{\mathrm{v}}}{\bar{\rho}_{\mathrm{v}}}\frac{\bar{\rho}_{\mathrm{l}}}{\bar{\mu}_{\mathrm{l}}}\right)} \right\}, \qquad (1)$$

where ρ is density, μ is dynamic viscosity, $(\mathrm{d}p/\mathrm{d}T)_{\mathrm{c}}$ is the slope of the Clapeyron curve, L is the latent heat, Γ is the geothermal gradient, g is the acceleration of gravity, k is the combined thermal conductivity of the fluid and matrix (dominated by the conductivity of the rocks), K is the permeability, and subscripts l and v refer to liquid and vapour, respectively. All the quantities in equation (1) are to be evaluated at the quiescent position of the water–steam interface. Condition (1) is necessary for stability. Although it is not sufficient, an exact analysis[8] shows that the value of permeability given by the right side of equation (1) is a good estimate of the maximum permeability for which stabilization is possible.

The evaluation of equation (1) leaves little uncertainty in the largest value of permeability allowing stabilization of the condensate layer. This is because all the quantities in equation (1), except for k and Γ, depend only on temperature, and there is little temperature variation within and among the steam reservoirs of natural vapour-dominated systems. In addition, the condensate layers are generally several hundred metres thick, precluding any large uncertainty in the value of Γ. Finally, the thermal conductivities of reservoir rocks are known to within factors of 2 or 3. Using a value of 242 °C for the temperature at the condensate layer–steam zone interface (see Fig. 1), $\Gamma = 0.555\ ^{\circ}\mathrm{C\,m^{-1}}$ and $k = 4\ \mathrm{J\,m^{-1}\,s^{-1}\,K^{-1}}$, we find that K must be less than 80 nm^2 (0.08 millidarcy) for the condensate layer to be gravitationally stable [a more exact analysis[8] shows that $K \lesssim 40\ \mathrm{nm}^2$ (0.04 millidarcy) for stability].

A permeability of 40 nm^2 is more than an order of magnitude smaller than permeabilities generally thought to occur in the main reservoirs of geothermal systems. It is not surprising, however, that relatively low permeability is required near the condensate layer–steam zone interface to keep the water from falling down into the underlying region of steam. The significance of our result is the fact that any stabilization is possible for a non-zero value of permeability. The natural discharge of vapour-dominated geothermal fields attests to the through-flow of steam within the system. This could not occur if some impermeable layer were required to seal or cap the main steam reservoir to stabilize the condensate layer. It is the special behaviour of the phase-change interface between water and steam that permits stabilization of the systems with a non-zero permeability; if the interface behaved in a manner similar to the boundary between immiscible fluids the rocks would have to be impermeable to keep the condensate layer from falling down.

The low permeability required for the stability of the condensate layer probably determines the thickness of the layer. During the formation of a wet geothermal system, rising steam from the relatively permeable main reservoir penetrates rocks whose permeability decrease with proximity to the surface. The top of the main reservoir will extend upwards until condensate can be stabilized by rocks of sufficiently small permeability.

We thank Geothermal Energy N.Z. Ltd, managers of the Kamojang Project, acting on behalf of the Indonesian and New Zealand governments, for supplying the data used in Figs 1 and 2. This work was supported, in part, by NSF grant ENG 76-82119.

The Gulf of Lion: subsidence of a young continental margin

M. S. Steckler & A. B. Watts

Lamont-Doherty Geological Observatory, and Department of
Geological Sciences of Columbia University, Palisades,
New York 10964

The origin of the subsidence of Atlantic-type continental margins is of much interest to geology and geophysics. The main problem at these margins is in explaining the substantial thicknesses of mainly shallow-water sediments which accumulate soon after rifting and plate separation. We have now used biostratigraphic data from commercial wells to study the subsidence history of a young Atlantic-type continental margin. Backstripping the sediment load reveals that the margin has been subsiding at nearly mid-ocean ridge rates. Geological data indicate that lithospheric stretching alone cannot account for this amount of subsidence and other processes must be involved.

Studies of biostratigraphic data from deep commercial boreholes suggest that the tectonic subsidence of margins is thermal in origin[1–5]. Sleep[1] suggested the subsidence is due to cooling of the lithosphere following uplift and erosion. This model cannot, however, fully explain the amount of tectonic subsidence observed at these margins[3] or the lack of evidence of domal uplift during rifting[6]. McKenzie[7] proposed a model in which the subsidence is due to cooling of the lithosphere following stretching and thinning at the time of rifting. This model seems to explain the tilted and rotated blocks bounded by listric faults which develop during rifting[8,9].

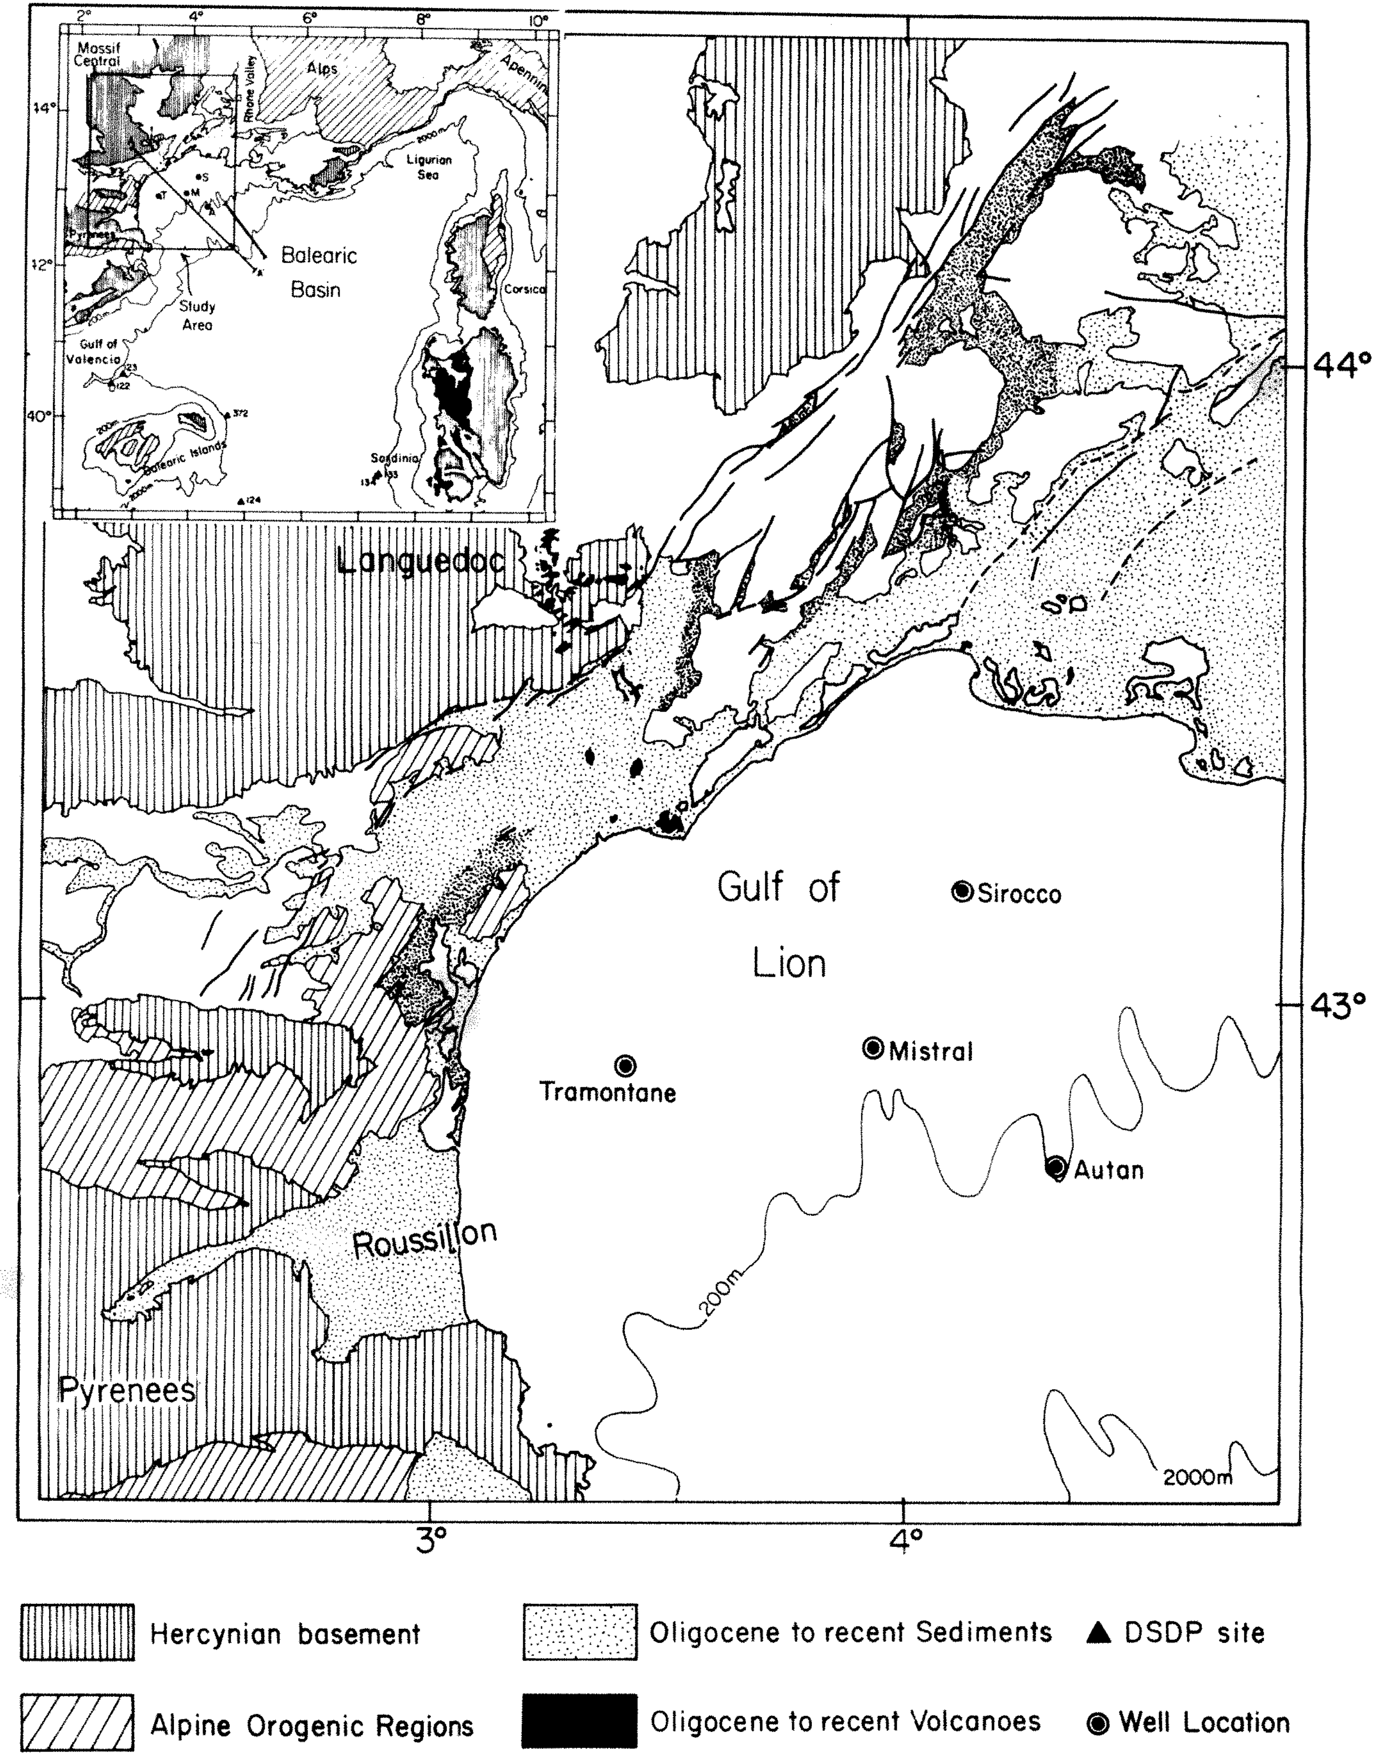

Fig. 1 Geology of the Gulf of Lion. The heavy lines are faults which have been active during the Oligocene, dashed where inferred. The heavier dots show the location of Oligocene red beds. Inset, generalized geology of the regions surrounding the Balearic Basin and location of Gulf of Lion. The heavy line is the location of the 'Christiane' multichannel seismic profile[30,32], A–A' is the location of the profile shown in Fig. 2.

By quantitatively accounting for the effects of sediment and water loading the tectonic subsidence of a margin can be isolated[2–4]. To correct for sediment and water loading, the sedimentary section should be reconstructed at intervals during the development of the margin, taking into account the effects of compaction, changes in water depths and eustatic sea-level changes. The sedimentary section should then be isostatically unloaded, or backstripped[2,3].

Most previous studies have been based on stratigraphic data from the thickly sedimented, relatively old margins, such as eastern North America. The wells in these studies generally did not sample the pre-rift and syn-rift sediments or crystalline basement rocks and therefore do not provide either a complete record of the subsidence history or a reliable age for the opening of the central North Atlantic. A detailed knowledge of the early subsidence history is important in discriminating between different models for the origin of the margin.

A good example of a well sedimented young Atlantic-type continental margin is the Gulf of Lion in the Balearic Basin (Fig. 1). Geophysical data indicate that the Balearic Basin contains up to 6 km of sediments, including over 1 km of Messinian evaporites, overlying a thin oceanic-type crust[10–12]. Geological and palaeomagnetic evidence[11,13–16] suggests the basin formed by Oligocene/Miocene rifting of Corsica–Sardinia from France (Fig. 1). Messinian evaporites had been interpreted[17] as indicating that the western Mediterranean was not a deep basin until post-Miocene time. However, DSDP site 372 east of Menorca[18] established that the western Mediterranean was already a deep basin by the Lower Burdigalian (~20 Myr BP). Although the tectonic setting of the basin is poorly known, it may have formed as a back-arc basin behind a migrating island arc–trench system to the east[16]. Extensive Oligocene through Lower Miocene andestic volcanism related to this arc is found in western Sardinia[19].

Figure 1 summarizes the geological setting of the Gulf of Lion. The Eocene in southern France was a period of overthrusting associated with the Pyrenean orogeny[20,21]. The Oligocene, in contrast, was a period of extension and normal faulting[20,21], much of which seems to have reactivated older fault trends. Continental sediments accumulated in NE–SW trending grabens in Languedoc and Roussillon. Similar extension and graben structures also occurred in Sardinia and along the margins of the Balearic Islands[22,23]. Drainage patterns in southern France during the Eocene and Oligocene were towards the north and west, away from the present Mediterranean[24,25]. Then, in the Lower Miocene (Aquitanian) a major transgression occurred marking the opening of the Balearic Basin[26,27].

The structure and stratigraphy of the Gulf of Lion margin is known from commercial drilling and seismic reflection data. Three of the wells drilled recovered over 3 km of Miocene to Recent sediments overlying Palaeozoic basement[28,29]. In addition, the Autan well (Fig. 1) recovered 244 m of ?Oligocene red beds[29]. The seismic data in the Gulf of Lion[30–33] show a gently dipping Pliocene to Recent sedimentary section unconformably overlying a more steeply dipping Miocene section. Information on the basement structure of the Gulf of Lion is sparse but available data[28,33] indicate the Miocene to Recent sedimentary section overlies horst and graben structures which are infilled by continental sediments of probable Oligocene age (Fig. 2). Thus, the available geological and geophysical data show that the structural evolution of the Gulf of Lion region margin was similar to that of a normal Atlantic-type continental margin[12].

We have used biostratigraphic data from three wells[29] in the Gulf of Lion (Figs 1, 2). The sediments in each well were backstripped[2,3] to obtain the tectonic subsidence of the margin. The wells were corrected for compaction using available sonic, density and porosity logs (L. Montadert, personal communication) and backstripped with the Airy model of isostasy[2,34] and a mantle density of 3.33 g cm^{-3}. The palaeobathymetry for the wells was based on the micropalaeontological studies of Cravatte *et al.*[29]. We did not correct for eustatic sea-level changes as they are not well known in the Neogene due to uncertainties in the timing of Antarctic glaciation.

The sedimentary record in the wells is interrupted by a major erosional unconformity due to the Messinian salinity crisis[30,35] (Fig. 3). The unconformity is observed as a discontinuity in the lithological logs. We backstripped each well using as wide a range of estimates for the magnitude of the erosional event as

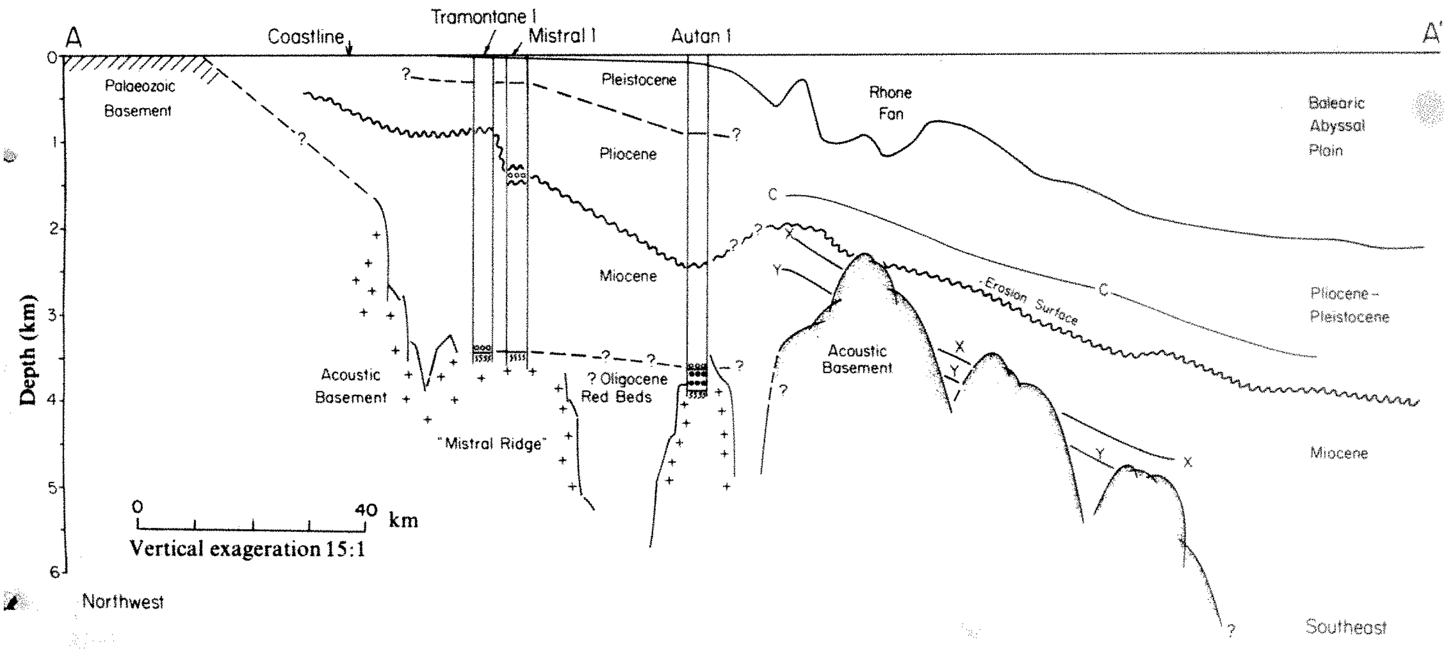

Fig. 2 Profile across the Gulf of Lion margin. Prominent seismic reflectors and acoustic basement are projected from the 'Christiane' profile[30]. In the wells: ○, basal conglomerates; ●, continental red beds. The wells bottomed in Palaeozoic schists[28,29]. The basement structure suggests prominent horsts and grabens infilled by red beds (refs 28, 33 and L. Montadert, personal communication) seaward of a hinge zone.

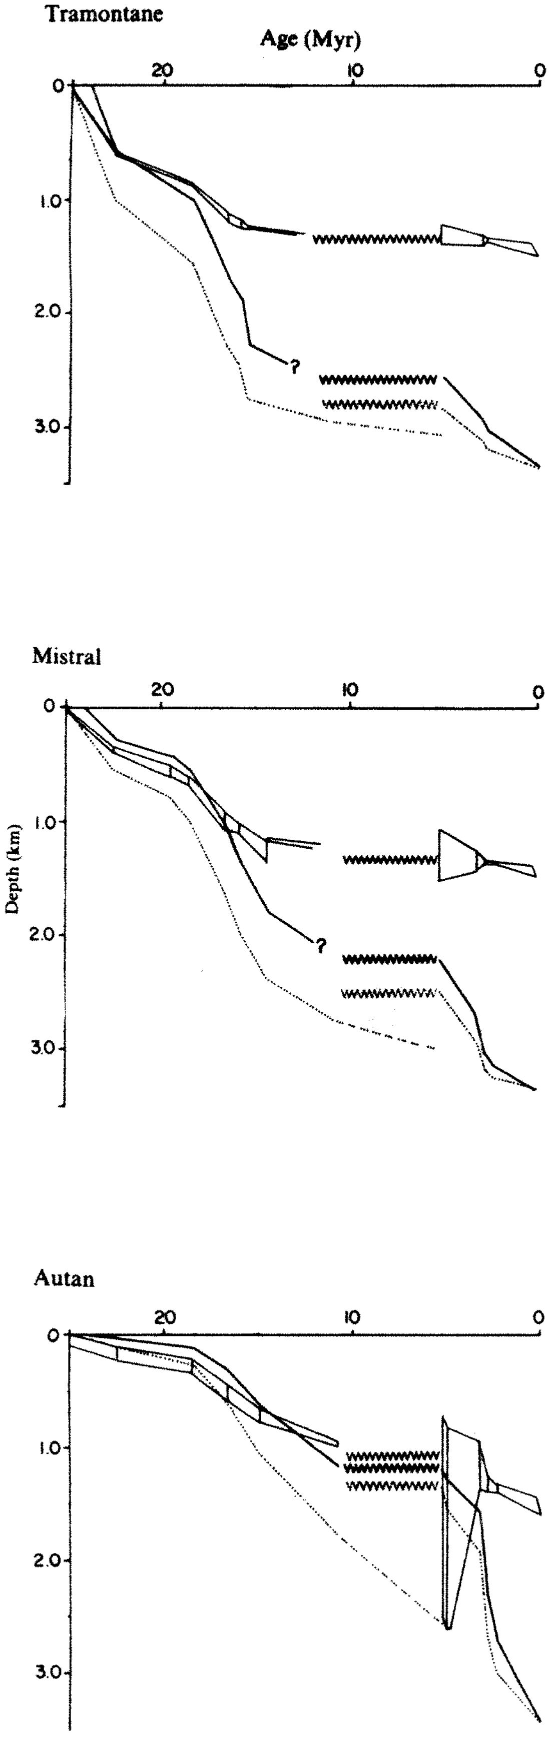

Fig. 3 Subsidence in the three wells studied. The heavy solid lines are the observed sediment thicknesses. The dotted lines represent the reconstructed sediment accumulation after correction for compaction, dashed where later removed by erosion. The double solid line is the subsidence after backstripping. The width of the lines represent the range of estimates for the water depth based on micropalaeontological studies[29].

was compatible with the well logs and found that in each case the trend of the tectonic subsidence (Figs 3, 4) was continuous through the salinity crisis. This agrees with the interpretation of the Messinian event as an evaporitic drawdown[32,35].

Using the observation that the tectonic subsidence was continuous, it is possible to estimate the amount of erosion of the margin during the salinity crisis. We found that 1,200–1,500 m of sediments were eroded at Autan and that much less were eroded at the more landward Mistral (380–600 m) and Tramontane (<320 m) wells. The water depths immediately following the salinity crisis were estimated to be 700–900 m at Autan and correspondingly smaller at the more landward wells, in agreement with those determined from micropalaeontological studies[29]. At the Autan well, however, by using the trend of the tectonic subsidence we can estimate a much smaller range of water depths than that which can be estimated from micropalaeontology (bathyl).

The tectonic subsidence at each well (Fig. 3) constitutes less than half of the total sediment accumulation and continues smoothly through the Messinian event. The tectonic subsidence is similar in form for each of the wells. The main difference occurs in the early subsidence which is larger in a landward direction. Small variations in the rate of the tectonic subsidence appear to correlate from well to well and may be due either to changes in sea-level[36] or to uncertainties in absolute age dating of the sediments.

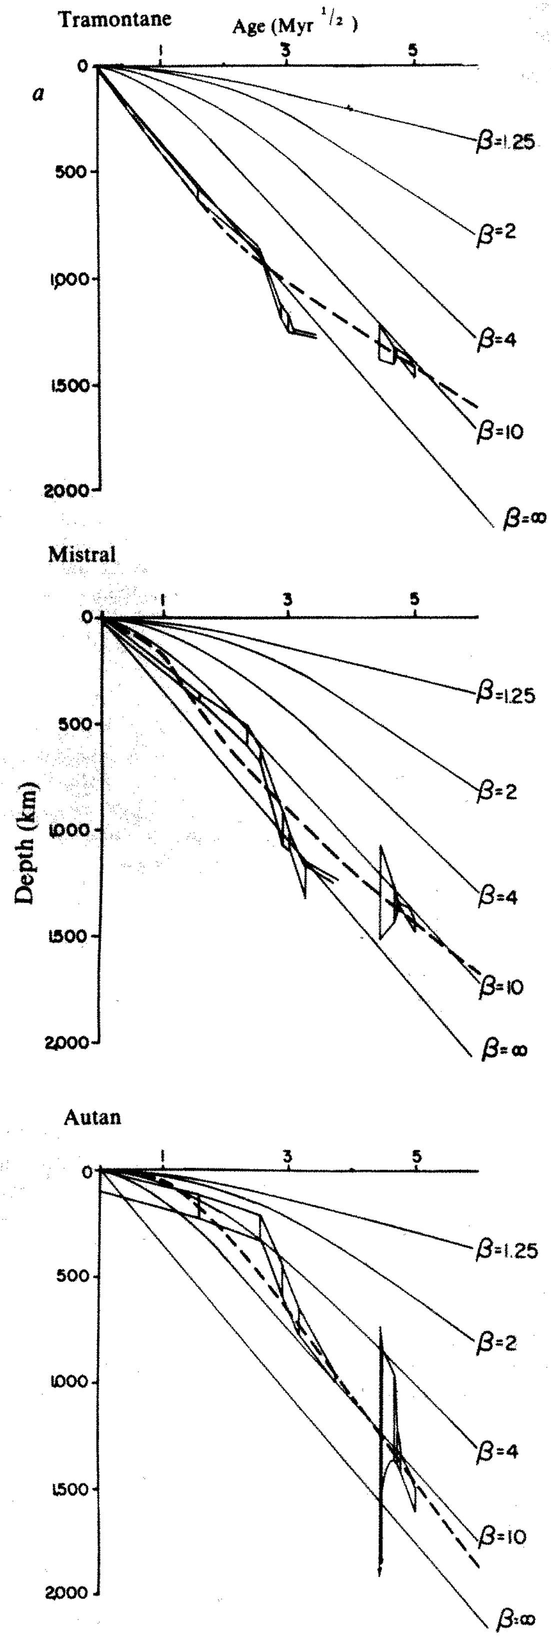
The most likely cause of the tectonic subsidence is thermal contraction following stretching and thinning of the margin at the time of rifting. A useful way to examine the thermal subsidence of a margin is to plot the tectonic subsidence against $\sqrt{\text{age}}$ (ref. 7). Figure 4 shows the tectonic subsidence for the wells along with that predicted by a lithospheric stretching model[7]. The origin in Fig. 4 is 25 Myr BP which is the best estimate for the age of opening of the basin[13,14,16,27]. The parameter $\beta = \infty$ is equivalent to the subsidence of a mid-ocean ridge.

The total tectonic subsidence at each well is large and seems to exceed $\beta = 10$. The fit of the subsidence data to the model, however, is poor. The tectonic subsidence early in margin history is progressively greater in a more landward direction and at Tramontane exceeds that of a mid-ocean ridge.

Numerical modelling of the continental margin off Norway[37] has shown that lateral transport of heat towards the continent may be important in the early history of the margin. We have, therefore, modified McKenzie's[7] model to include a finite crustal thickness for oceanic lithosphere and the effects of lateral as well as vertical conduction of heat. The subsidence was computed for a two-dimensional model in which β varied across the margin (Fig. 4*b*). The fit to the subsidence data has been greatly improved (Fig. 4*a*) and the estimates of β (2.6 to 6) at the wells reduced. These considerations suggest that thermal cooling, both vertical and lateral, of a hot, thinned lithosphere can explain the tectonic subsidence of the margin.

The magnitude of the tectonic subsidence implies that the continental basement in the Gulf of Lion was greatly extended during rifting. Extension of this magnitude, however, does not seem to be compatible with the geology of the Gulf of Lion. Normal faulting and graben structures containing Oligocene red beds occur both on land[20,21] and off-shore (ref. 33 and L. Montadert, personal communication). However, the volume of these pre-rift and syn-rift sediments is relatively small compared with the volume of the post-rift sediments (Figs 1, 2). All the wells drilled in the Gulf of Lion (Fig. 1) contain little or no Oligocene sediments (Fig. 2) and are located on horsts. If the lithosphere had been stretched by the estimated values of β then the sediment accumulation during rifting should have been in excess of 4 km. Thus, the small observed subsidence associated with rifting precludes large amounts of stretching of continental crust, while the magnitude of the thermal subsidence requires extensive heating of the lithosphere during rifting.

These results suggest that although there was extension during the Oligocene, the passive heating resulting from stretching[7] cannot fully account for the observed tectonic subsidence of the



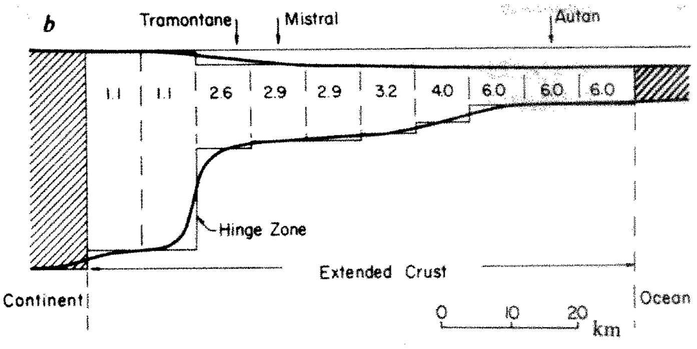


Fig. 4 *a*, Tectonic subsidence plotted against square root of the age. Width of lines represents range of estimates for water depth[29]. Age of opening was assumed to be at 25 Myr BP. Light lines, theoretical subsidence calculations from lithospheric stretching model[7]. $\beta = \infty$ corresponds to mid-ocean ridge subsidence. Dashed lines, subsidence calculations for two-dimensional model illustrated in *b*, Crustal section of the two-dimensional model used to estimate subsidence at the wells. Dashed lines represent boundaries of the blocks used for calculations. The values for each block are the estimates of β. The heavy lines illustrate the crustal thinning that occurred at the margin at the time of stretching (25 Myr BP). Note the large values of initial water depths. No vertical exaggeration.

margin. Thus, other mechanisms of heating the margin at the time of rifting are required. One possibility is that a thick crust and relatively high thermal gradients already existed in the lithosphere before rifting, due to Pyrenean Eocene overthrusting and/or andesitic volcanism in the nearby island arc–trench system. Alternatively, continental rifting may be caused by deep seated processses in the mantle which result in an active heating of the lithosphere at the margin. Further work on other Atlantic-type continental margins is needed to distinguish between these possibilities.

We thank L. Montadert for the sonic, density and porosity logs for the wells. This work was supported by a Phillips Petroleum Company Fellowship to M.S.S. and NSF grant OCE 77-10647. Lamont–Doherty Contribution no. 3036.

Model experiments on the 100,000-yr glacial cycle

J. Oerlemans*

Royal Netherlands Meteorological Institute, De Bilt, The Netherlands

It is believed that during the Quaternary era changes in global ice volume were mainly due to changes in the size of the ice sheets on the Eurasian and American continents. Time spectra of oxygen isotope records from deep-sea cores and of the Earth's orbital parameters are remarkably similar in the 10,000–120,000-yr range[1,2], suggesting that changes in global ice volume are forced by insolation variations. Model studies by Weertman[3,4] and Pollard[5] have confirmed this point to some extent: the 20,000- and 40,000-yr cycles can be reproduced, but the 100,000-yr cycle does not show up. Recently, Imbrie and Imbrie[6] have fitted simple nonlinear mathematical models to δ^{18}O curves. They found that reasonable fits are obtained if the time scale for ice-sheet growth is about 27,000 yr and for decay about 7,000 yr. The present study considers the problem of the 100,000-yr cycle in a similar way. Experiments with a Northern Hemisphere ice-sheet model show that the 100,000-yr cycle and its sawtooth shape may be explained by ice sheet/bedrock dynamics alone. This cycle seems to be an internally generated feature and is not forced by variations in the eccentricity of the Earth's orbit.

First, consider the 'classical' record of core V12-122 (Fig. 1). This core has a comparatively high resolution and spans about the last 500,000 yr. Two features that are immediately evident are that the dominant signal is a periodic one, with a period of about 100,000 yr, and that this cycle is strongly asymmetric, having a sawtooth shape. The strong response of the cryosphere on the 100,000-yr time scale, as compared with those on the 20,000- and 40,000-yr time scales, suggests some kind of resonance. Variations in eccentricity of the Earth's orbit may have combined with the internal dynamics of the climate system to create a strong signal in global ice volume.

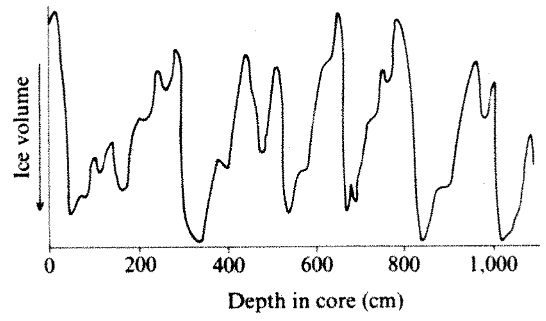

Fig. 1 A plot of the δ^{18}O record of the Carribean core V12-122 (data from ref. 12). According to the 'tune-up' time scale of Hays *et al.*[2], the glacial maximum found at a depth of 840 cm in this core occurred at 430,000 yr BP. The most pronounced features are the 100,000-yr cycle and the asymmetric shape of these cycles.

Figure 1 suggests that the time needed to create full-size ice sheets is 50,000–100,000 yr, considerably more than has been suggested by theoretical studies[4,7]. I will discuss some model results indicating that such a growth time scale is in accordance with bedrock/ice sheet dynamics.

The most dramatic feature of Fig. 1 is the speed with which deglaciations seem to take place ~10,000 yr. Also important is the fact that just before deglaciation starts, the growth rate of the ice volume does not fall, which indicates that during the glacial maxima the Northern Hemisphere ice sheets were far from equilibrium. Also, the difference in δ^{18}O between a glacial minimum and the subsequent maximum is fairly constant, suggesting an inherent instability of the climate system, and probably of the cryosphere.

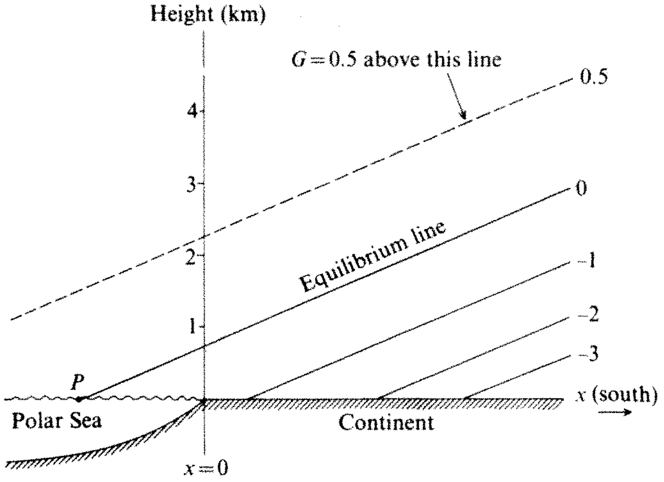

Fig. 2 Mass–balance conditions for a Northern Hemisphere ice sheet, as parameterized in the model. The intersection of the equilibrium line with sea level is called the 'climate point', and is indicated by *P*. Insolation variations are represented by shifting *P* north- and southwards. Values of the constants used are: $a = 0.73 \times 10^{-3}\ \mathrm{yr}^{-1}$, $b = 0.27 \times 10^{-6}\ \mathrm{m}^{-1}\mathrm{yr}^{-1}$, $\chi = 0.65 \times 10^{-3}$. Values for *G* are given beside each line.

A mechanism that might explain this instability is bedrock sinking. Weertman[4] first suggested this as a possible cause for rapid deglaciation in connection with the Northern Hemisphere ice sheets. I will now discuss model experiments which deal with this point.

The Northern Hemisphere ice-sheet model to be used is described by the equations[8]

$$\frac{\partial H}{\partial t} = \frac{\partial}{\partial x}\left[D\frac{\partial(H+h)}{\partial x}\right] + DH/Y^2 + G \tag{1}$$

$$\frac{\partial h}{\partial t} = -\alpha(H+3h) \tag{2}$$

$$G = a(H+h-E) + b(H+h-E)^2 \tag{3}$$

Equation (1) formulates the conservation of ice mass; it is essentially a nonlinear diffusion equation. The diffusivity for ice mass *D* increases monotonically with ice thickness *H* and the slope of the ice surface $\partial(H+h)/\partial x$ (where *h* is the bedrock height with respect to some geopotential level). The *x*-axis points in a southward direction, so the evolution of the ice sheet is explicitly computed along a meridian. The term DH/Y^2 governs lateral ice-mass discharge, where *Y* is a characteristic east–west length scale of the ice sheet. *G* is the mass balance of the sheet, and is a function of height with respect to the equilibrium line [see equation (3)]. The height of the equilibrium line (defined by $G = 0$) is denoted by *E*; it increases linearly with *x* at a rate χ (Fig. 2).

Equation (2) deals crudely with isostatic adjustment of the Earth's crust. In the equilibrium case, $h = -H/3$ corresponds to a rock density of three times that of ice. The time scale of adjustment is given by $1/3\alpha$.

Figure 2 shows in detail the appearance of the mass balance. Insolation variations may be interpreted as shifting the equilibrium line northwards and southwards. During periods with large eccentricity of the Earth's orbit, the amplitude of the 'climate point' *P*, due to precession of the equinoxes, is about 10° in terms of equivalent latitude[9]. Only during such periods does *P* reach the continent; normally, it is located in the Polar Sea.

---

If P lies on the continent for some time, an ice sheet will start to grow. Due to the feedback between surface elevation and mass balance the ice sheet may continue to grow even if insolation increases and P returns to the Polar Sea. Bedrock sinking, however, attempts to cancel this feedback.

I have carried out several numerical integrations of equations (1)–(3). The model was solved on a grid with 70 km spacing, the lateral scale Y being 1,000 km. (For more technical detail, see ref. 8.) In the first experiment, a periodic forcing was imposed by varying the position of the climate point according to

$$P = -140 + 490 \times \sin(2\pi t/T) \text{ km} \qquad (4)$$

Remember that $P < 0$ implies that P is located in the Polar Sea. T was set to 20,000 yr, so equation (4) roughly represents conditions during maximum eccentricity. The precise form of the forcing function seems to be relatively unimportant—once the ice sheet reaches a height of ~500 m, ice-sheet dynamics take over. Thus, the only requirement is that P remains for a sufficient time on the continent. In view of this, our model can be kept simple by using equation (4) as a universal forcing function in this experiment.

Figure 3 shows four model runs with various time scales for isostatic adjustment (T^*). Figure 3*a* ($T^* = \infty$) shows the case without any movement of the bedrock. The ice sheet grows slowly, then more rapidly, and comes into a stable oscillation with quite small amplitude. A huge increase in the height of the equilibrium line would be required to remove the ice sheet.

Figure 3*b* and *c* show what happens if adjustment takes place on time scales of 30,000 and 10,000 yr, respectively. The ice sheet grows at a smaller rate now, and after about 100,000 yr disappears 'spontaneously'. Apparently, the sinking of the bedrock brings a large part of the ice surface beneath the equilibrium line, thus setting the breakdown in motion. Here, significantly, a sawtooth shape appears.

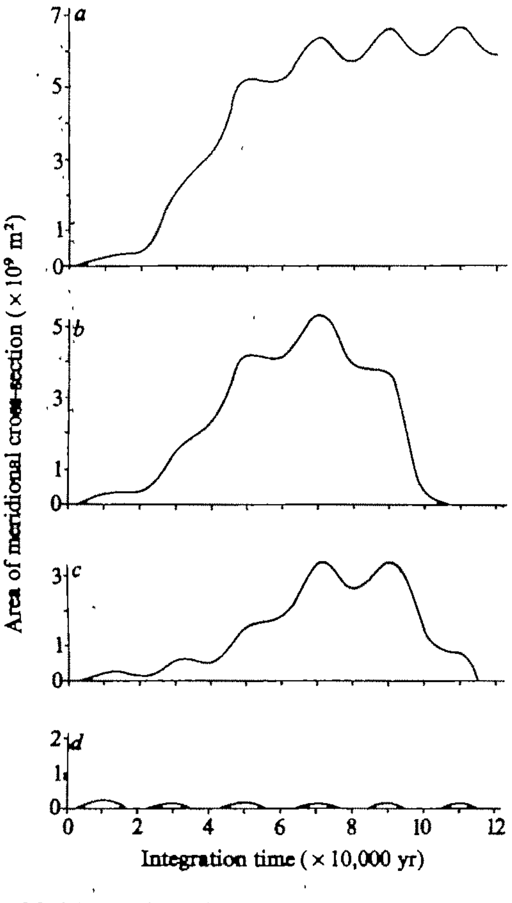

Fig. 3 Model runs with various time scales of isostatic adjustment (T^*). The area of the meridional cross-section through the ice sheet is given along the vertical axis. To obtain the ice-sheet volume, this should be multiplied by a characteristic east–west extent of the sheet. Values for T^* are: *a*, ∞; *b*, 30,000 yr; *c*, 10,000 yr; *d*, 5,000 yr.

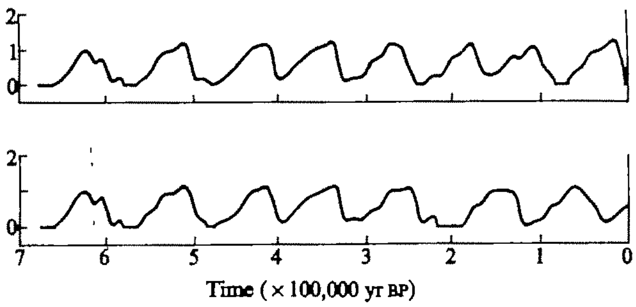

Fig. 4 Two model runs in which the Milankovitch insolation variations are imposed. The vertical axis gives a measure of the ice volume, a value of 1 on the scale corresponds to a meridional ice-sheet size of about 2,000 km and a maximum ice thickness of about 3,000 m. For more details on the parameterization of the mass balance see ref. 9. The only difference between the two runs is the value of T^*, 10,000 and 11,000 yr, respectively, in the upper and lower runs.

Figure 3*d* shows the situation when $T^* = 5{,}000$ yr, so that the isostatic balance is restored very quickly. In this case, the ice sheet cannot grow—the bedrock sinking completely cancels the effect of the height–mass balance feedback.

I next examined the situation in which the model is forced by real insolation variations. These variations were computed from expansions of the orbital parameters given by Berger[10] and translated into mass–balance variations by using an ice/snow melt model[9]. In each of two runs performed, the integration was started at 675,000 yr BP, with initial condition $H(x) = h(x) = 0$.

Figure 4 shows the results. The only difference between the two runs is the value used for the time scale of isostatic adjustment. The agreement in the character of the simulated curves and the δ^{18}O record is striking—a 100,000-yr periodicity and an asymmetric shape of the glacial cycles. However, a different situation is obtained with regard to the phase of the cycles. Although dating of the δ^{18}O record is in fact not accurate enough to verify the model simulation of all glacial cycles, a comparison of the curves shown in Fig. 4 indicates that the phase of the glacial cycles seems to be extremely sensitive to the model parameters. I believe that this property of the model reflects a realistic feature: the global climatic variations of the Pleistocene seem to have been of a stochastic periodic nature. In view of this, it seems unlikely that the present model can produce an 'in-phase simulation' of the observed ice-volume record, but it does provide a physical explanation for the occurrence of the glacial cycles.

One of the implications of the present results is that the 100,000-yr cycle is mainly internally generated by the interaction of the bedrock adjustment and the height–mass balance feedback. This means that the occurrence of a 100,000-yr peak in the power spectrum of the δ^{18}O record[2] is unrelated to variations in eccentricity. Recent work by Kominz and Pisias[11] strongly supports this view: they found that coherence spectra of an oxygen isotope record and the orbital parameters showed no significant peak around a period of 100,000 yr.

Because the present theory deals with two large ice sheets on the Northern Hemisphere continents, it seems unlikely that they can be simulated with exactly the same model parameters. It is possible, however, that the Laurentide ice sheet dominates, and trails the Eurasian one with it through the atmospheric/oceanic teleconnection. Another objection to the theory is the passive role of the Southern Hemisphere. I must stress that the fact that global ice volume seems to lag the Southern Hemisphere sea-ice extent or sea-surface temperature[2] need not imply that events in the Southern Hemisphere initiate glacial cycles. This may be simply a matter of different response times.

Thus, my main conclusion is that the 100,000-yr cycle can be explained by ice sheet/Earth's crust dynamics, as was suggested by Weertman[4]. Due to bedrock sinking, ice sheets grow very slowly. If the bedrock sinking becomes more substantial, a larger part of the ice surface comes below the equilibrium line, setting the breakdown in motion. Another glacial cycle starts if two conditions are fulfilled—summer insolation should be well below 'normal' and the bedrock should have been raised again.

Carbon-13 in tree-ring cellulose as an indicator of past climates

T. Mazany, J. C. Lerman & A. Long

Laboratory of Isotope Geochemistry, Department of Geosciences, University of Arizona, Tucson, Arizona 85721

Following Urey's suggestion[1] that the ^{13}C abundance (usually expressed as a relative ratio: $^{13}C/^{12}C$ or $\delta^{13}C$) fixed in plant carbon may be temperature dependent, several authors have investigated the relationship between $\delta^{13}C$ and climate. These workers searched for a coefficient relating $\delta^{13}C$ variations to temperature variations[2–7]. The results, obtained on field collected samples, failed to yield agreement about the extent of a climatic effect or even its existence. Growth chamber experiments, performed on different plant species in controlled conditions to eliminate environmental factors other than temperature, showed no clear relationship between $\delta^{13}C$ and temperature[8,9]. These various contradictory results suggest that factors other than temperature contribute to determining $\delta^{13}C$ in plants. We now present evidence that the variations of the relative abundance of stable isotopes of carbon in tree rings indicate past climate changes. Thus carbon isotope composition appears to be a proxy indicator that may help to extend the meteorological data base into pre-instrument times.

To gain a better understanding of the relationship between $\delta^{13}C$ values in tree rings and climate, we analysed two dendrochronologically-dated tree sections collected at Chetro Ketl, an archaeological site in Chaco Canyon, New Mexico. These samples, one, of ponderosa pine (*Pinus ponderosa*) dating from AD 810 to 1045 (sample CK-713), the other, a white fir (*Abies concolor*) dating from AD 931 to 1047 (sample CK-857), were provided by the Laboratory of Tree-Ring Research at the University of Arizona. Tree-ring material was chosen for the experiments because it can be absolutely dated, and, in this case, tree-ring width variations provided information on climate variations with which to correlate our isotope data. These variations are derived from the regional tree-ring chronologies for Chaco Canyon, of which there is one for ponderosa pine and one for white fir[10,11]. The dendrochronological record is obtained by standardizing the ring widths of each one of several trees in one region, forming ring-width indices, with a mean value of 1.0 (see refs 10–12). These indices are averaged over the several individual trees to obtain the regional tree-ring chronology, which is given as a time series of mean standardized ring-width indices[12–14]. This filters the growth effects experienced by individual trees, while preserving climatically induced variations. In the Chaco Canyon and similar arid areas, ring-widths generally relate to climate in the following way: wide rings are produced during wet-cool years, and narrow rings during warm-dry years[14–16]. The strength of these qualitative relationships has been discussed in statistical terms in recent work by Fritts *et al.*[17].

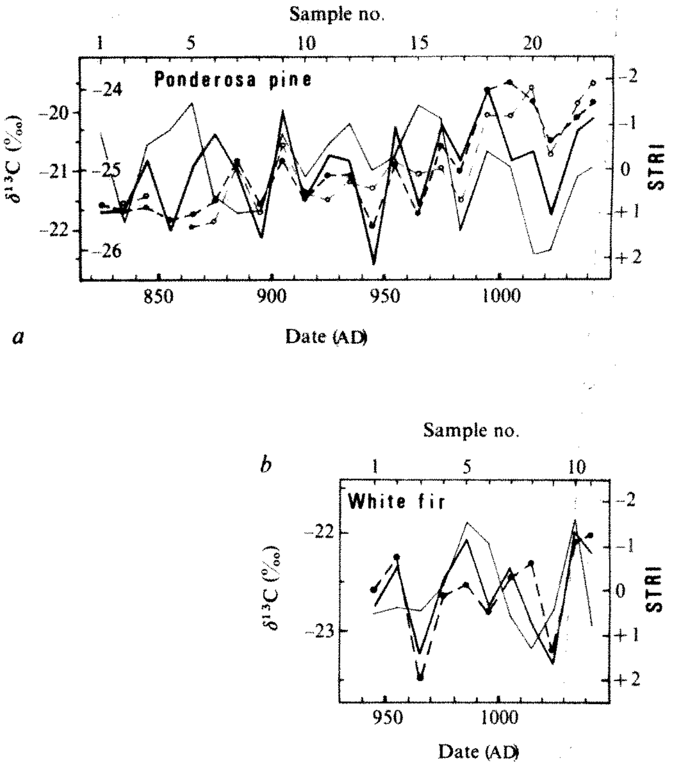

Fig. 1 Time series $\delta^{13}C$ values and tree-ring indices in the three sections from the Chetro Ketl site. All $\delta^{13}C$ values are expressed by reference to the PDB standard. The $\delta^{13}C$ scales and the STRI (standard tree ring index) scales have been normalized by subtracting to each value in a series the mean of each series then dividing it by the corresponding standard deviation. *a*, Thick line: decadal means of the Chaco Canyon regional ponderosa mean STRI. Thin line: decadal means of the individual STRI for the sampled section. Open circles: $\delta^{13}C$ (lignin) decadal values (inner scale). Solid circles: $\delta^{13}C$ (cellulose) decadal values (outer scale). *b*, Thick line: decadal means of the Chaco Canyon regional white fir mean STRI. Thin line: decadal means of the individual STRI for the samples section. Solid circles: $\delta^{13}C$ (cellulose) decadal values.

Before we could ascertain the significance of a time series of carbon isotope values and test the potential of this method for the reconstruction of palaeoclimates, we had first to determine which chemical component of wood—cellulose or lignin—is most sensitive to climate; and second, to assess the uniformity of the isotope record by studying the δ values in different tree species from the same site and by measuring the variations in isotope values of a single set of rings around the tree circumference. We began our experiment by sampling a single radius of the ponderosa pine section. This provided 22 samples of 10 yr each and one of 6 yr, beginning at AD 820. These and later samples were ground into sawdust and extracted with benzene and ethanol in a Soxhlet extractor to remove oils, waxes, resins and other relatively mobile materials which may not be coeval with the corresponding tree ring. The extracted wood was separated into cellulose and lignin using standard chemical procedures similar to those described by Browning[18]. Carbon dioxide obtained from combustion of lignin or cellulose at 800 °C was analysed with an isotope ratio mass spectrometer (Micromass 602C) with an overall precision better than 0.1‰. The results are shown in Table 1 and in Figs 1*a* and 2*a*. (In the discussion that follows we give the correlation coefficients *r* as well as their values adjusted to remove the trends reflected by the first-order autocorrelations. These adjusted values are given

0028-0836/80/400432—04$01.00

within square brackets. The adjustment was done by transforming the values in each measured series using the formula given in ref. 17, p. 21. The figures in parentheses are the 95% confidence limits.)

Results from this analysis show that the $\delta^{13}C$ values of cellulose and lignin strongly correlate with each other, $r = 0.914$ (0.80 to 0.96) [0.858 (0.65 to 0.95)] (Fig. 2*a*). The cellulose, however, has a higher correlation coefficient, $r = -0.653$ (−0.33 to −0.84) [−0.837 (−0.64 to −0.93)] with the ponderosa pine regional tree-ring index than does the lignin $r = -0.497$ (−0.08 to −0.76) [−0.666 (−0.29 to −0.86)] (Figs 1*a*, 2*a*, *b*). Thus, in our second experiment, on white fir samples, we analysed only the cellulose. The white fir section gave 11 samples dated between AD 940 and 1045, coeval with the outer 11 ponderosa pine samples. The $\delta^{13}C$ values for white fir are in general about 1.5‰ lower than the $\delta^{13}C$ values in ponderosa pine and also correlate well with the white fir regional tree-ring indices $r = -0.800$ (−0.38 to −0.95) [−0.761 (−0.25 to −0.94)] (Figs 1*b* and 2*c*).

Studies by other investigators have shown circumferential variations of $\delta^{13}C$ within a tree ring[19,20]. To check for the variations of $\delta^{13}C$ values for different azimuths around our ponderosa pine tree section and their effect on our results we analysed three different sets of rings from four radial cuts other than the original radius samples. Only cellulose was isolated. The results on different radii show circumferential variations of an amplitude of about 1‰, but the relative variations observed between the different sets of rings are almost identical (Fig. 3). However, a sequence of average isotope values composed of $\delta^{13}C$ values from several radii reflects the tree-ring width variations more closely than $\delta^{13}C$ values from a single radius (for example, the one at azimuth = 0°) does.

Our results suggest a valid correlation between carbon isotope values and climate. The $\delta^{13}C$ values for both cellulose and lignin reflect the climatic variations recorded by the regional tree-ring width indices. Of the two wood components, cellulose seems to be the most sensitive to climate. Two facts argue against this relationship being an artefact of ring width as Wigley *et al.*[21] recently suggested. First, our isotope values, which have been measured on each of the sections (of different species), correlate with the regional climatic regime recorded by the regional tree-ring index and, second but most important, the isotope values do not correlate with the tree-ring indices derived from the measurements on the single tree from which the isotope samples were taken. The correlation coefficients between $\delta^{13}C$ and tree-ring indices for each one of our specimens are not significant at the 95% level: $r = 0.256$ (−0.17 to 0.60) [−0.167 (−0.55 to 0.27)] for the ponderosa pine, and −0.072 (−0.64 to 0.55) [0.065 (−0.59 to 0.67)] for the white fir. This indicates that the carbon isotopes reflect mainly regional conditions and are not largely dependent on factors which affect only individual trees, such as tree growth or other metabolic factors. A source of systematic error might be the fact that samples containing groups of rings instead of individual rings are weighted averages of wood (cellulose), thus the δ-values are not the average values for 10 individual years. In our samples the actual ring widths of the ponderosa pine and white fir sections varied by ±30%, therefore, we do not expect that the method introduced large systematic errors. A precise estimate of the weighting error would require the knowledge of a well defined coefficient (δ-value)/(ring-width). Since such a coefficient could only be determined on the basis of many $\delta^{13}C$ analyses of individual single-year tree-rings, we could in our case, only roughly estimate it and we conclude that its magnitude did not affect our interpretation of the analyses. Obviously, single ring samples are to be preferred for palaeoclimatic research.

Several mechanisms could contribute to the observed relationship between $\delta^{13}C$ and climate. A simple but still speculative one, has been described elsewhere[22]. It is based on the fact that $\delta^{13}C$ in plant cellulose depends on the $\delta^{13}C$ value of the atmospheric CO_2 which surrounds the leaves during photosynthesis. The atmospheric $\delta^{13}C$ values vary diurnally as well as seasonally, and are more negative in times and places of greater plant respiration[22–25] because CO_2 contributed by plant respiration is depleted in $\delta^{13}C$ (for example, causing plants grown in the recirculated respired CO_2 atmosphere of very dense forests to have a δ-value as low as −39‰) (see refs 22–25). Consequently, during times when climate favours greater vegetation activity, the local atmosphere $\delta^{13}C$ values would become more negative, a change reflected in the carbon fixed in the plant cellulose[24,25].

No other factors, such as biochemical temperature effects, are necessary to explain the results of our analyses. The time series of Fig. 1*a* also shows an increasing trend in δ with time. This can probably also be ascribed to the local atmosphere existing near the soil, which is fixed by the young tree during its growth[3,5]. The relationship described above between vegetation activity and local atmosphere[22] explains the results of our research on both trees from the Chaco Canyon area (Fig. 1): increased local plant activity produces, (1) wider tree-rings, (2) more negative δ^{13}C values of the local atmosphere CO_2, and, consequently more negative δ^{13}C of plant cellulose. Experimental field work on living junipers was done by Arnold[26]. He compared the δ^{13}C in the leaves with records of close meteorological stations, and found that juniper leaves in a wide area of Arizona have more negative δ-values for years when the temperature during their growth was low and the precipitation high. These conditions are precisely those which determine wide growth rings for trees in these arid areas[12-14].

We should also discuss an apparent contradiction between the results of the present analysis and the model[22]. The model seems to require that trees from the same region should have identical δ^{13}C values, but we evaluated the correlation coefficient between the δ^{13}C values in the cellulose of the ponderosa pine and white fir samples with each other and found it to be only 0.454 (−0.20 to 0.83) [0.518 (−0.17 to 0.87)]. At first this seems to conflict with a model hypothesizing atmospheric CO_2 fluctuations as the mechanism for δ^{13}C fluctuations observed in tree rings. The explanation for this rather low correlation between δ^{13}C values of our two trees from the same region is that these trees inhabit different ecological niches which would have different local atmospheres. Ponderosa pine is found in warm and dry environments while white fir is partial to cooler and wetter environments[27]. More plant growth occurs in the wetter white fir environment, thus CO_2 more locally respired by white fir trees and other plants contributes to a more negative δ^{13}C value for the local atmosphere CO_2. This would not be in equilibrium with the bulk atmosphere, particularly in the early morning, as our field measurements showed for the White Mountains, California[22]. The white fir δ^{13}C values reflect this more negative value. This also may account for the absence of large positive peaks in the δ^{13}C white fir data, peaks which are present in the ponderosa pine data (Fig. 1*a*, *b*). This could explain the lack of a good correlation between δ^{13}C of both trees, while the lack of good correlation between both regional tree-ring chronologies would be due to each species having a different response[14,15] to climate.

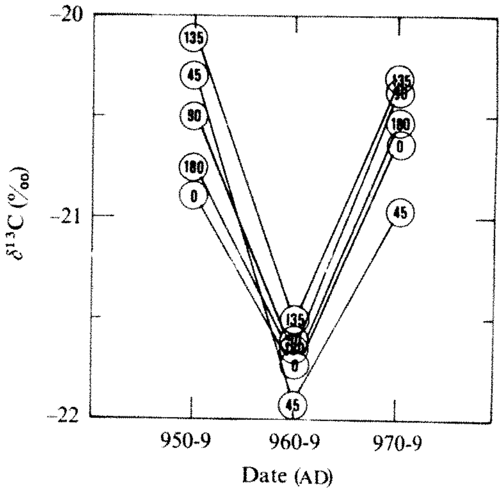

Fig. 3 Radial series: δ^{13}C (cellulose) in the ponderosa pine section at 5 different radii for 3 different decades. The figures indicate the azimuth in degrees. The azimuth 0° samples correspond to the time series of Fig. 1*a*.

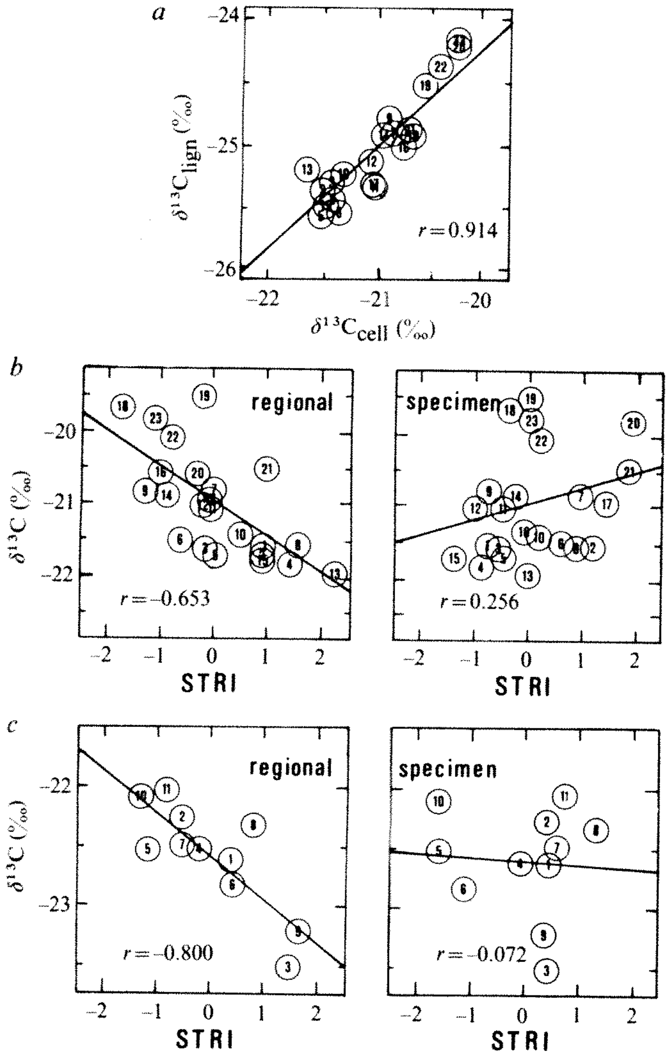

Fig. 2 Linear regressions (the figures within the circles represent sample numbers as given in Fig. 1). The *r* values adjusted for autocorrelations of first order are given in the text. *a*, δ^{13}C (cellulose) versus δ^{13}C (lignin) in ponderosa pine samples. *b*, δ^{13}C (cellulose) in ponderosa pine samples versus regional STRI (standardized tree-ring indices) for ponderosa pine. *c*, δ^{13}C (cellulose) in white fir samples versus regional STRI for white fir.

We have demonstrated a relationship between climate and stable carbon isotope values in tree rings. Cellulose is the most sensitive wood component, and in a single radius the time series variation are representative of climate. Stable carbon isotope analysis in tree rings may thus become an important method for extracting climate data from 'complacent' trees, those in which ring width variations are not responsive to climatic conditions (for example, trees tapping a permanent water source). In such a case, the isotope values of the wood should still record changes in the δ^{13}C values of the atmospheric CO_2 produced by fluctuations of the regional plant biomass. Moreover, from the above results, it seems that a single tree contains climate data equivalent to conventional dendroclimatology which, instead, uses the mean of several trees. Isotope dendroclimatology may thus be the proxy indicator that will help enlarge our data base for large scale climate models or simulations, and be also of benefit to archaeologists for local palaeoclimate reconstructions[28].

This research was funded by the NSF Climate Dynamics Program, and by the State of Arizona. We thank P. E. Damon, B. Bannister, J. Dean, H. C. Fritts and W. Robinson for useful discussions. The tree-ring samples were prepared by T. Harlan, Laboratory of Tree-Ring Research; chemical treatment and mass spectrometer analyses were performed by J. LoFaro and G. Hennington.

Electrophoretic evidence for two species of *Anguilla* leptocephali in the Sargasso Sea

Antonio Comparini & Emanuele Rodinò

Istituto di Biologia Animale, Università di Padova, 35100 Padova, Italy

Schmidt[1,2] produced indirect evidence that in order to reproduce the European eel (*Anguilla anguilla*) migrates to a definite zone of the Sargasso Sea, contiguous and partially overlapping the breeding area of the American eel (*Anguilla rostrata*). The two forms were recognized as distinct species on the basis of differences in meristic characters[3,4]. Later, Tucker[5] proposed that the two Atlantic eel populations originate from the same gene pool and are not distinct species but merely eco-phenotypes, their distinguishing characters being environmentally determined. More recent electrophoretic analysis has favoured the existence of two distinct species[6–9] and of particular significance from a genetic point of view is the very marked difference in malate dehydrogenase (MDH) allele frequencies between samples of American and European eels (refs 8, 10–12, Table 1*a*). However, inferring genetic isolation from genetic differentiation in eels is difficult[13,14], because of the possibility of differential selection. We report here the first observations on variability at four polymorphic loci in young *Anguilla* larvae caught in the breeding area. The observed genotype distribution and allele frequencies, particularly at the MDH-2 locus, definitely confirm the presence of two species of *Anguilla* leptocephali in the spawning zone of the Sargasso Sea.

The aim of the cruise of the FRV 'Anton Dohrn', from 19 March (Bermuda) to 9 May (Bremerhaven) (1979), was to resolve problems of sampling technique and egg and larval identification. During the period 21 March to 15 April, in the middle of spawning[1,4], more than 1,800 leptocephali of *Anguilla* were captured in different stations between 22–29° N and 55–70° W, in and near the spawning areas defined by Schmidt[1,2]. As expected, the captured leptocephali were mainly of the O-group (first year larvae) 7–25 mm in length and no more than a few weeks old[4]. Details of the fishing technique, place of capture and larval distribution are reported elsewhere[15]. Most of the larvae were preserved for myomere counts in the laboratory; 121 individuals of the O-group and five of the I-group (about 40 mm) were analysed on board by starch gel electrophoresis. Myomere counting on board was very rough due to local conditions and was later shown to be not completely reliable (for details, see ref. 16).

Total	126		252	

Only genotypes and alleles common to both species are reported in full.

* Totals are obtained by pooling unpublished genotype distributions observed in samples of *A. anguilla*[11,12].

† Pooled data from Williams *et al.*[10].

‡ Observed number of other genotypes also fitted well with Hardy–Weinberg distribution.

§ Frequencies of 'other' alleles: $b = 0.047$; $d = 0.025$; $e = 0.088$; three very rare alleles = 0.009.

‖ 'Other' observed genotypes: $bb = 1$; $bc = 3$; $cd = 2$; $ce = 5$.

For (*b*), $\chi^2_{(3)} = 78.3$, $P \ll 0.01$.

Among enzyme systems reported polymorphic in elvers and older eels[8,10–12], only three showed enough activity or clear enough electrophoretic patterns for a reliable genetic interpretation—MDH, phosphoglucose isomerase (PGI) and lactate dehydrogenase (LDH). Special attention was given to the scoring of MDH because of the previously reported difference in allelic frequencies between the two populations.

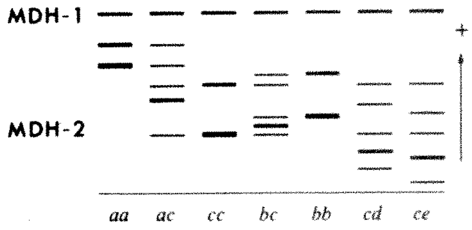

Fig. 1 Schematic representation of the MDH electrophoretic patterns observed in the leptocephali sample and genetic interpretation of variability at the MDH-2 locus. It is assumed that polypeptide products of the two loci randomly assemble to form homodimers and intralocus and interlocus heterodimers of intermediate electrophoretic mobility. Following our previous convention[17], the alleles are indicated by *a*, *b*, *c*, *d*, *e* in the order of the anodic mobility of the respective homodimer bands. Previous laboratory analysis of the MDH pattern in a sample of American eels has shown that the common MDH-2 allele of *A. rostrata* (named *a* by Williams *et al.*[10]) has the same electrophoretic mobility as the fast allele *a* previously reported in *A. anguilla*[11,12,17]; the rare allele *b* of *A. rostrata*[10] corresponds to the common allele *c* of *A. anguilla*[11,12,17].

* The genetic interpretation of the electrophoretic patterns and the electrophoretic methods are reported in refs 11, 17, 20.

† Species identification on the basis of MDH-2 genotypes.

‡ P values are computed with contingency χ^2 tests on the number of alleles, and with a weighted homogeneity test for allele frequencies[21].

The larval MDH electrophoretic patterns (Fig. 1) correspond closely to those previously described in elvers and adults of *A. anguilla* (Fig. 2) and *A. rostrata*[10]; as in other teleosts[18] they are genetically explicable assuming the presence of two MDH loci, one of which is polymorphic in the *Anguilla* species. The observed and expected genotype distribution and the allele frequencies for the polymorphic locus MDH-2, in the whole larval sample, are reported in Table 1*b*. The observed genotype distribution shows a very strong homozygote excess as compared with that expected according to the Hardy–Weinberg law.

Excluding inbreeding and selection against heterozygotes in a sample consisting mostly of very young larvae, the homozygote excess most probably results from the sampling together of individuals originating from two distinct populations with appreciable difference in allele frequencies (the Wahlund effect). This is consistent with the view that the sample was made up of groups of larvae belonging to both *Anguilla* species having respectively the same, or very similar, allele frequencies to those reported for samples of elvers and older eels 'recruits' and 'residents', respectively[10].

If this is true, then the MDH-2 genotype can also be useful in young leptocephali as a diagnostic character of the species, easier to recognize and more reliable at this stage than the rough myomere count made on board[15,16]. Indeed, in pooled samples of recruits and residents, on the basis of the reported MDH-2 allele frequencies (Table 1*a*), the probability of correct diagnosis of the species is more than 0.998 (as calculated applying the Ayala and Powell[19] statistics) if the *aa* homozygotes are scored as *A. rostrata*, the heterozygotes showing the 'ambiguous' genotype *ac* are not considered and all the other genotypes are scored as *A. anguilla*.

With the use of this parameter and omitting the eight observed *ac* individuals, the remaining 118 leptocephali analysed on board can be separated into 72 *A. rostrata* (*aa* genotypes) and 46 *A. anguilla* (*cc* and other genotypes). Laboratory myomere counts of preserved larvae, now in progress, are indeed showing that in the main batch of leptocephali *A. rostrata* larvae were the more abundant (F.-W. Tesch, personal communication).

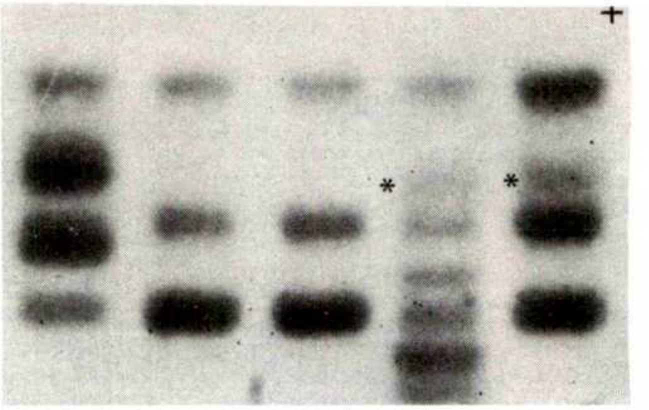

Fig. 2 Photograph of some MDH electrophoretic patterns observed in specimens of *A. anguilla*. The MDH-2 genotypes, from left to right, are: *ac*, *cc*, *cc*, *ce*, *cc*. Asterisks indicate bands corresponding to the mitochondrial MDH activity which appear in frozen specimens. Horizontal electrophoresis in 11.5% starch gel was carried out using electrode buffer 0.18 M Tris-citrate, *p*H 7.5, 1:15 diluted in the gel. The staining solution was: neutralized L-malic acid (10^{-2} M), NAD (10^{-3} M), monotetrazolium salt (10^{-3} M), phenazine methosulphate (10^{-4} M) in 0.05 M Tris-HCl, *p*H 8.

On the basis of the previous assumption, we report in Table 2 the genotype distribution at the PGI-1, PGI-2 and LDH-2 loci for the two larval groups. The observed numbers are in each case near to the expected assuming Hardy–Weinberg equilibrium. Comparison of allele numbers and of allele frequencies with statistical tests showed significant differences at the PGI-1 and LDH-2 loci, supporting the genetic separation of the two groups. Table 3 shows the allele frequencies at the same loci for both groups, in comparison with those observed in pooled samples of *A. anguilla*[11,12] and *A. rostrata*[14], respectively.

In *A. anguilla*, there is no appreciable difference, at these loci, between larvae caught in the spawning zone and eels caught in different European coastal waters[11]. It seems, therefore, that there is no differential selection at these loci during the years of larval drift; this is in accord with our previous observations of a lack of genetic differentiation among samples of recruits from different parts of Europe[11,12,20].

Table 3 Allele frequencies at PGI-1, PGI-2 and LDH-2 loci in samples of *A. anguilla* and *A. rostrata* leptocephali (L). For comparison, data from pooled samples (P) of both eel species are reported.

* Pooled data from our previous paper[11,12].

† Pooled data for 'recruits' only from Koehn and Williams[14].

‡ P values are computed according to Workman and Niswander test[21].

In *A. rostrata*, comparable data are available only for the PGI-2 locus. There is a very significant difference in allele frequencies between the larval sample and that reported for recruits of the North American shore. Moreover, in resident eels of this species, a latitudinal cline in allele frequencies at this locus was observed, while recruits were genetically homogeneous[10]. This pattern was demonstrated to be temporally constant[14]. The higher frequency of the common allele *b* (>0.9, and close to that found in leptocephali) was obtained in the northern part of the sampled range (Halifax, Nova Scotia; St John's, Newfoundland). It is perhaps premature to make the hypothesis of a temporal or geographical subdivision in the spawning of *A. rostrata* adults coming from different parts of the American coast; however, we note that some doubts still remain about the extension of the spawning place of this species[22].

In conclusion, observation on the genetic variability of some enzyme loci in a sample of young *Anguilla* leptocephali caught in the spawning ground have shown the existence in this zone of larvae from two different gene pools, thus definitively confirming Schmidt's theory of the existence of two distinct Atlantic *Anguilla* species.

The cruise was sponsored by the International Council for the Exploration of the Sea as a preliminary part of the International Eel Expedition[23]. This work was also supported by the Italian National Research Council through funds granted to the Institute of Marine Biology of Venice. We thank Dr F.-W. Tesch (Biologische Anstalt Helgoland, Hamburg) for enabling A.C. to participate in the cruise and for his help, Professor B. Battaglia for discussions and Professor J. A. Beardmore for help with the manuscript and English text.

Following the demonstration that hybrids between normal B-lymphocytes and myeloma cell lines continue to secrete antibodies with the same specificity as those produced by the parental B-cells[1], many groups have tried to use this approach to obtain cell lines expressing T-lymphocyte functions by crossing thymoma lines not expressing any measurable activity with various types of T-cell populations. Although there have been reports that hybrids could be isolated which secrete T-cell products with immunological activity[2–5], efforts to produce functionally active hybrids from cytolytic T-cells have all been unsuccessful (refs 6, 7, and M. N. and H. D. Engers, unpublished). We have fused an established, T-cell growth factor (TCGF)-dependent murine cytolytic T-lymphocyte (CTL) line with a mouse thymoma line and have obtained hybrids with cytolytic activity when we selected the hybrids in TCGF-containing medium, while hybrids isolated in the absence of growth factor showed no detectable cytolytic potential.

Recently, clonable murine T-cell lines with cytolytic activity have been derived from normal CTL populations cultured in medium supplemented with TCGF-containing supernatant from concanavalin A (Con A)-stimulated spleen cells (CS)[8,9]. Such CTL lines remain strictly dependent on CS medium for growth, but share many characteristics with permanent cell lines derived from other tissues[10]. B6.1.2 is a cloned CTL line obtained from spleen cells of a female C57Bl/6 mouse activated against syngeneic male cells. At the time of its isolation, it was cytolytically active against lipopolysaccharide-activated spleen cells (LPS-blasts) from male mice carrying the H–2D^{b} allele as well as from H–2D^{d} mice of either sex[11]. A mutant, TG14.OU5, was derived from this line, which is resistant to both 6-thioguanine (TG^{r}, 10^{-4} M) and ouabain (OU^{r}, 10^{-3} M), by two cycles of mutagenesis with ethyl methane sulphonate, followed by single-step selection with one of the drugs[10]. The resistant phenotype of this mutant has remained stable for 8 months of growth in the absence of either drug. The parental cells and the mutant show comparable lytic activity against the BALB/c myeloma S194, but both lines today display only marginal activity against LPS-blast targets.

B6.1.2 and TG14.OU5 have a near-diploid karyotype with several abnormal metacentric chromosomes[10] (Table 1). The cells have an irregular shape and grow mainly in suspension with only a slight tendency to adhere (Fig. 1). CSP.2 is a CTL line derived from C3H/HeJ (H–2^{k}) cells activated against syngeneic spleen cells haptenated with 3-(p-sulphophenyldiazo)-4-hydroxyphenylacetic acid (SP)[10]. In its lytic activity this line is hapten specific and H–2 restricted (Fig. 4): it will lyse SP-coupled LPS-blasts from B10-A (H–2K^{k}D^{d}) mice but shows no significant activity against hapenated B10.AQR (H–2K^{q}D^{d}) target cells.

B6.1.2, TG14.OU5 and CSP.2 all express the Thy-1.2 alloantigen. The thymoma lines used in the experiments described here, AKR-A (from Dr R. Herberman, NCI) and a TG^{r}OU^{r} BW5147 subline (from Dr. R. Hyman, Salk Institute) express the Thy-1.1 allele. They grow in suspension, in medium with or without CS, and show no detectable lytic activity against S194 or LPS-blasts, even when Con A is added to overcome the requirement for specific target-cell recognition[12]. AKR-A has a near-tetraploid karyotype and most cells carry one characteristic metacentric chromosome (Table 1).

Cells of the parent lines were mixed and fused, and plated out in different media (see Fig. 2 legend for details). Two to three weeks after fusion the plates were scored for growth: no growth was detected in plates with or without CS seeded with PEG-treated cells of only one of the parental lines or with untreated cell mixtures. In plates seeded with mixtures of AKR-A and TG14.OU5 cells treated with 50% polyethylene glycol

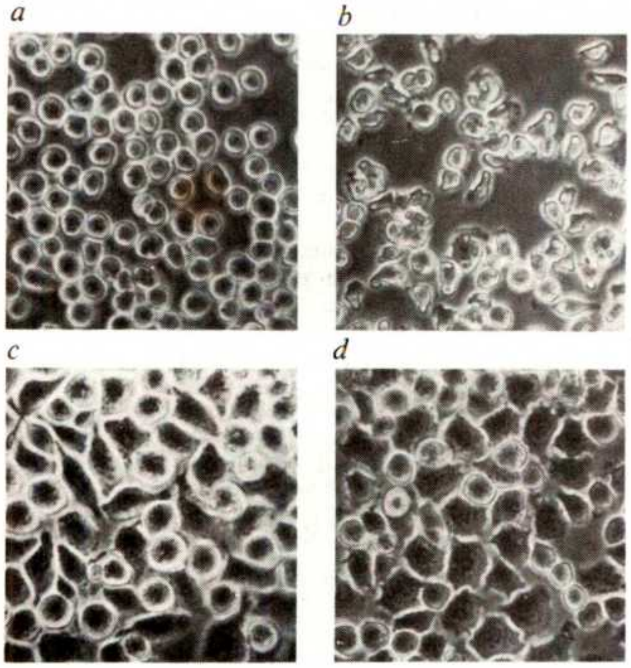

Fig. 1 Morphology of parental cell lines, AKR-A (*a*) and B6.1.2 TG14.OU5 (*b*) and two cytolytically active hybrid clones, MN9.19.7 (*c*) and MN9.20.2 (*d*). Phase-contrast micrographs of living cells.

(PEG), vigorous growth was observed in 70 of 96 wells not containing CS, and in 95 of 96 wells with CS. The cells growing in the absence of CS were round or slightly irregular and resembled the thymoma parent. They showed no tendency to adhere to the plastic surface and piled up to form regularly shaped colonies. The same cell type was found in many wells containing CS, but in addition most of the latter wells contained colonies formed by cells with a morphology quite distinct from that of either parent (Fig. 1): these cells were very large and flat and adhered quite strongly to the plastic surface. Size and shape varied somewhat from colony to colony, and although they clearly showed a strong tendency to adhere they could form multiple layers.

Table 1 Chromosome constitution of parental cells and two hybrid clones

	Total	Biarmed	Markers		
			AKR-A	TG14.OU5	
AKR-A	77.5(71–79) ±2.3	1.8(0–2) ±0.4	9/10	0/10	0/10
TG14.OU5	32.2(28–34) ±1.7	8.1(8–9) ±0.3	0/14	14/14	14/14
MN9.19.7	126.7(93–144) ±15.8	11.4(9–14) ±1.4	8/12	12/12	12/12
MN9.20.2	89.3(81–105) ±21.9	8.1(6/9) ±1.3	10/10	10/10	9/10

Chromosomes were prepared using the ASG-banding technique[17] and classified according to Nesbitt and Franke[18]. Chromosome number (range) ± s.d. was determined and the same metaphases were screened for the presence of marker chromosomes characteristic for the parental cell lines. Almost all MN9.19.7 metaphases contained two copies of each of the TG14.OU5 markers. TG14.OU5 lacks recognizable chromosomes 6, 7 and 8, whilst AKR-A and the hybrids contain several copies of these chromosomes.

We found that none of 34 populations selected in the absence of CS displayed any cytolytic activity whereas 60 of 79 presumptive hybrids selected in the presences of CS gave more than 10% specific lysis in the presence of Con A (Fig. 2). When the morphology of the latter hybrids was scored, it became apparent that all of the populations from the six wells containing only or almost only thymona-like cells gave less than 10% lysis. Ten independent (uncloned) populations, selected in the presence of CS, were expanded and maintained in CS medium containing HAT and ouabain (HOS medium). Their growth rate is comparable to that of the CTL parent line. Two of these populations consisted entirely of cells with the thymoma-like morphology. All 10 populations expressed both parental Thy-1 alleles: more than 90% of the cells were lysed when treated with monoclonal anti-Thy-1.2 or anti-Thy-1.1 antibodies and complement. Background lysis was less than 10%. The cytolytic activity of these hybrids against S194 varied (Fig. 3). The two thymoma-like hybrids had no detectable activity, even in the presence of Con A. The adherently growing hybrids all expressed some activity in the presence of the lectin and all except one showed some lysis also in its absence.

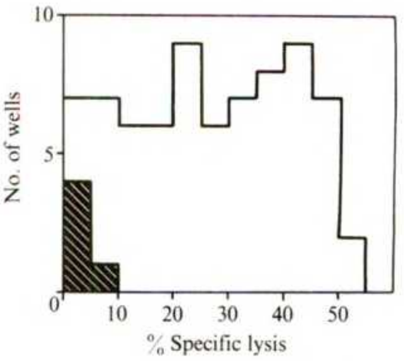

Fig. 2 Cyolytic activity of AKR-A × TG14.OU5 hybrids selected in medium supplemented with Con A supernatant. Before fusion the drug-resistant parents were grown for two passages in medium containing thioguanine and ouabain to eliminate any revertants. 1×10^7 cells of either parent were mixed and fused using 50% PEG (molecular weight 1,000) in a procedure essentially identical to the one described by Galfré *et al.*[14]. The fused cells were plated out at a density of 1×10^4 per cell type per well per 100 μl in flat-bottom microtitre plates (96 wells, Costar) in MLC medium or in MLC medium supplemented with 30% CS[8]. 100 μl of the same medium containing 10^{-4}M hypoxanthine, 5×10^{-7} M amethopterin, 1.6×10^{-5} M thymidine (HAT)[15] and 2×10^{-3} ouabain were added to each well on the next day. (This medium selects for cells in which the codominant ouabain resistance marker of one parent is complemented with the wild-type hypoxanthine phosphoribosyl transferase gene of the other.) One week later about two-thirds of the medium was replaced, keeping the HAT and ouabain concentration constant. 24 days after fusion cells were detached by vigorous pipetting with a multichannel micropipette (Flow) and transferred to round-bottom 96-well microtitre plates (Greiner). They were washed once and 10^4 ^{51}Cr-labelled S194 target cells and Con A (10 μg ml^{-1} final concentration) were added, all in Dulbecco's minimal essential medium with 5% fetal bovine serum. Plates were spun for 1 min at 1,000 r.p.m. and incubated for 6 h at 37°C. Specific isotope release into the medium was determined according to Brunner *et al.*[16]. Spontaneous release was 12%. Hatched bars show activity of populations from wells containing only thymoma-like cells.

Several of the independent cytolytically active hybrids were cloned, by plating cells at limiting dilutions (0.3 cells per well in HOS medium on feeder layers of irradiated peritoneal C3H cells[8]). Two independent clones have now been maintained in continuous culture for three months and are still cytolytically active, although the activity of one of them has declined considerably. Seventy days after fusion these two clones were

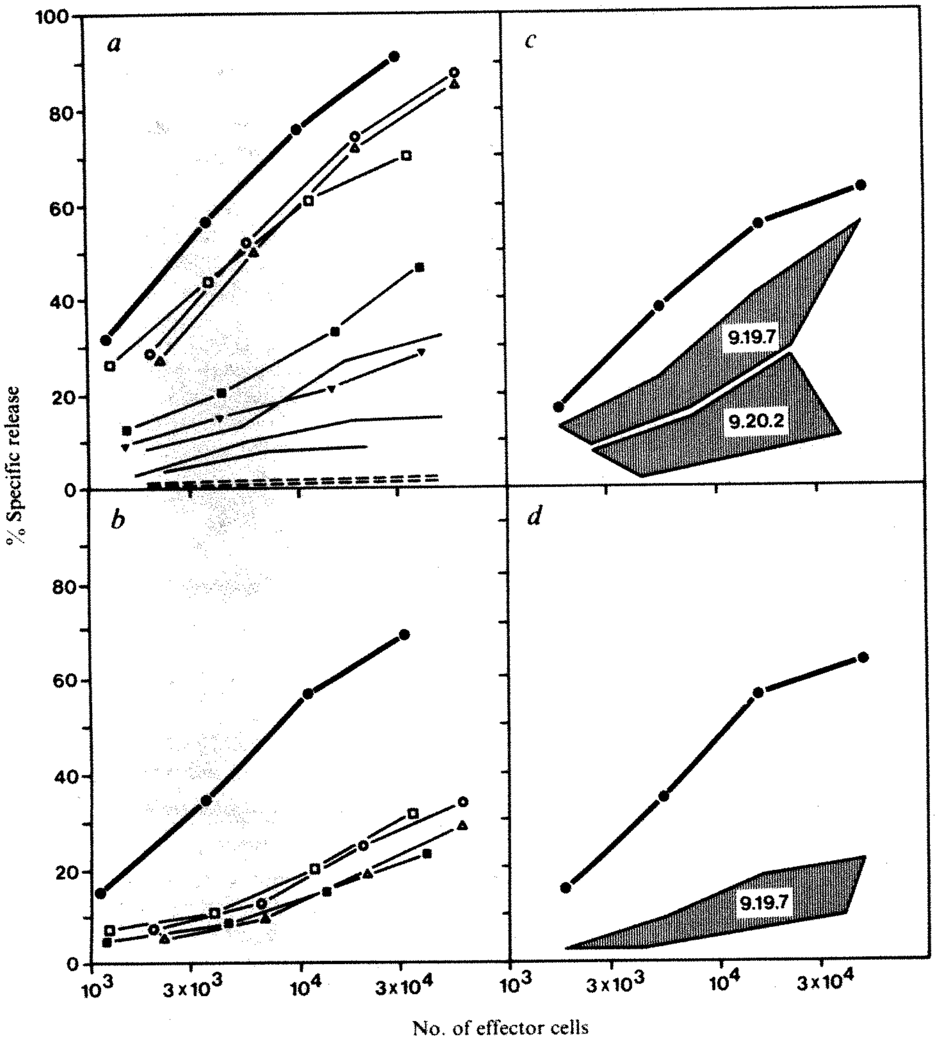

Fig. 3 Cytolytic activity (^{51}Cr release) of independent uncloned populations of AKR-A × TG14.OU5 hybrids (*a*, *b*) and individual clones (*c*, *d*), assayed in presence (*a*, *c*) and absence (*b*, *d*) of Con A. Targets: 10^4 S194 cells. Effector cells were collected during exponential growth. Adherent populations were detached with 0.02% EDTA in phosphate-buffered saline. ●, TG14.OU5. In *a* and *b*: ——, adherently growing hybrids; — — —, thymoma-like hybrids; ■, MN 9.19; ▼, MN9.20. In *c* and *d* the shaded areas indicate the range of activities of subclones derived from two cloned hybrids: MN9.19.7 (five subclones) and MN9.20.2 (four subclones). In *b* and *d* only significant activites are plotted. All subclones of 9.19.7 were active.

subcloned. All of the tested subclones gave significant lysis when tested in the presence of Con A, but most of the clones derived from the weaker line had only marginal activity (Fig. 3). Karyotype analysis of these two lines demonstrates that one of them contains approximately one set of each of the parental chromosomes, whilst the other carries two sets of TG14.OU5 chromosomes and one from the thymoma parent (Table 1).

It is very difficult to determine whether the AKR-A × TG14.OU5 hybrids described above express determinant-specific recognition structures, because, in the absence of Con A, the CTL-line parent as well as the hybrids show significant lytic activity only against tumour cell targets and, as we have argued elsewhere[10], such targets are not adequate for a specificity analysis of established CTL lines.

We therefore crossed the TG^{r}OU^r BW5147 thymoma line with CSP.2 using an essentially identical procedure. The results of this fusion were very similar to those of the AKR-A × TG14.OU5 cross[13], except that the morphological differences between the hybrids selected in the presence and those selected in the absence of CS were less obvious. We tested four hybrid populations selected without CS and seven selected in the presence of CS for expression of parental Thy-1 alleles and specific cytolytic activity. More than 90% of the cells of all populations were lysed by both anti-Thy-1.1 and anti-Thy-1.2 antibodies and complement. None of the CS-independent populations showed any lytic activity whilst all of the populations selected in CS lysed SP-coupled but not unhaptenated H-2^k LPS-blasts. Several of the active hybrids were tested against targets of different H-2 haplotypes and their activity was

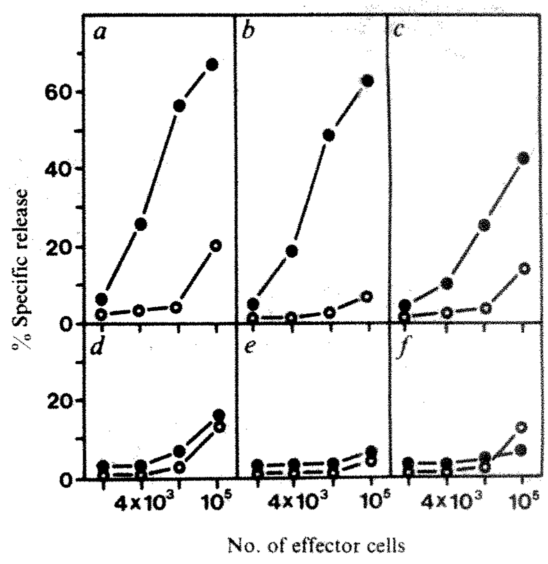

Fig. 4 Specificity and H-2 restriction of hybrids between BW5147 and CSP.2. Targets: LPS-blasts, untreated (○) or haptenated with 50 mM 3-(*p*-sulphophenyldiazo)-4-hydroxyphenylacetic acid (●), from B10.A mice (*a*, *b*, *c*; H-2 haplotype K^{k}I-A^{k}I-C^{d}D^d) or B10.AQR (*d*, *e*, *f*; qkdd). Effector cells: *a* and *d*, CSP.2; *b* and *e*, hybrid MN12.18.17; *c* and *f*, hybrid MN12.7. 3-h assay with 10^4 targets, spontaneous release ranged from 13–15%.

found to be H-2 restricted (Fig. 4). Active clones were obtained by limiting dilution and have maintained their specific activity for several months of continuous culture.

Our findings suggest that the earlier failures to obtain cytolytically active CTL-thymoma hybrids were due to the fact that such hybrids share the requirement for TCGF with their CTL parents and were not detected because all selections were carried out in the absence of CS. However, alternative explanations are possible. Clearly, our results suggest a relationship between TCGF dependence and expression of cytolytic competence. But, at present, we cannot decide whether the cytolytically incompetent, TCGF-independent thymoma-like hybrids are derived from active, growth factor-dependent cells, for example, by segregation of a particular CTL-line chromosome or whether the active hybrids have lost a thymoma chromosome carrying a gene (or genes) suppressing the CTL phenotype in the inactive hybrids. Other, less attractive possibilities have to be envisaged: (1) the two types of hybrids may be derived from different variants co-existing in the thymoma or the CTL lines. This interpretation is made unlikely by the very similar results obtained in three different crosses involving two thymomas and three CTL clones[13]. (2) Alternatively, the manifestation of the CTL phenotype in a hybrid may depend on a single stochastic event occurring early after fusion or it may be determined, for example, by the stage of the cell cycle in which the cells giving rise to a hybrid clone are at the moment of fusion.

Whatever the answers to these questions may be, it appears likely that cytolytic T-cell hybrids will provide us with new efficient tools for a genetic analysis of the control of the expression of T-cell functions.

This work was supported, in part, by grants from the Swiss NSF (to M.N.), the Schweizerische Krebsliga (to M.N. and A.C.) and the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 37-B9 to J.J.). M.C. is recipient of an EMBO fellowship. We thank Drs F. Fitch and M. Gefter for gifts of monoclonal antibodies.

Control of natural resistance to *Salmonella typhimurium* and *Leishmania donovani* in mice by closely linked but distinct genetic loci

Alison D. O'Brien,* David L. Rosenstreich† & Benjamin A. Taylor‡

*Department of Microbiology, Uniformed Services University of the Health Sciences, Bethesda, Maryland, 20014

‡Jackson Laboratory, Bar Harbor, Maine, 04609

Inbred strains of mice vary in their sensitivity to infection with both *Salmonella typhimurium*[1,2] and *Leishmania donovani*[3]. In both cases, this differential susceptibility is genetically controlled. Resistance to the intracellular parasite *L. donovani* is determined by a single locus on chromosome 1, designated *Lsh* (ref. 4). The primary regulator of resistance to *S. typhimurium* is a single, dominant autosomal gene, named *Ity* (for immunity to *typhimurium*)[5], and it has also been recently mapped to chromosome 1 (ref. 6). In addition, two other genetic loci regulate resistance to *S. typhimurium* in mice. These genes, *Lps*^{d} and *xid*, are mutant alleles that render C3H/HeJ and CBA/N mice, respectively, salmonella susceptible[7,8]. Both Bradley and his colleagues[3,4], and Plant and Glynn[2,6], noted similar patterns of resistance or susceptibility of inbred strains of mice to *L. donovani* and *S. typhimurium*, and therefore suggested that *Lsh* and *Ity* might be the same gene. Mapping of both genes to the same region of chromosome 1 supported this hypothesis but no linkage studies have been used to test it. Since recombinant inbred (RI) mouse strains are, in effect, permanent segregant populations[9], they are ideal for determining linkage between resistance genes to two different pathogens. Therefore, we determined the *S. typhimurium* susceptibility of five sets of RI mouse strains that had been previously typed for *Lsh*[4] and conclude that *Lsh* and *Ity* are closely linked but distinct genetic loci.

Mice from 25 BXD RI and their salmonella-resistant (DBA/2J)[5] and -susceptible (C57BL/6J)[5] progenitor strains (Jackson Laboratory) were injected subcutaneously (s.c.) with approximately 25 *S. typhimurium* organisms of the virulent TML strain[10]. The actual number of organisms administered was determined by plate count. The cumulative 28-day mortality was then assessed. For each strain at least two separate experiments were performed and progenitor strain controls were always included. In addition, the geometric mean number of *S. typhimurium* per spleen for each RI strain was ascertained[7] at day 9 after s.c. infection of mice with 10^3 TML.

The number of viable organisms per spleen of animals which died from salmonellosis before day 9 was estimated as 10^8 based on spleen counts in highly moribund mice. A comparison of the *Lsh* type, as previously reported by Bradley *et al.*, and the *Ity* types derived from our experiments, is shown in Table 1. RI strains were classified as *Ity*^{s} if $\geq$60% of the animals in a group died and if the $\log_{10}$ geometric mean counts per spleen were >5.0, whereas strains were considered *Ity*^{r} if mortality was $\leq$40% and if the $\log_{10}$ geometric mean counts were <4.50. The viable count limits for assigning an *Ity* type were chosen on the basis of the 99.9% confidence limits on the geometric means of the progenitor control strains. For those RI strains with lethality between 40 and 60% (that is, BXD-22, -19, -29, -25 and -8), *Ity* types were determined by spleen counts only because this single criterion was used by Plant and Glynn[6] for mapping the *Ity* locus. The *Ity* types of two RI strains (BXD-28 and BXD-31) were not designated because >60% of the animals died although their geometric mean spleen counts were in the resistant range. The discrepancy between these two parameters in BXD-28 and BXD-31 mice and the intermediate lethality (40–60%) for five BXD RI strains suggest that another gene(s), distinct from *Ity*, is influencing the outcome of infection. This is supported by our observations that the s.c. LD_{50} of *S. typhimurium* for BXD-28 mice was only 20 (compared with <2 for C57BL/6J mice and 5×10^4 for DBA/2J mice) but the F_1 progeny of BXD-28 and C57BL/6J parents were clearly *Ity*^{r} by spleen counts ($\log_{10}$ geometric mean count for four mice was 2.69). The origin of this hypothetical salmonella sensitivity gene(s) is not clear because progeny from the progenitor strains,

that is (C57BL/6J × DBA/2J)F_1 mice, were salmonella resistant (0/4 dead by day 28 when challenged s.c. with 10^3 TML) and were able to restrict early *S. typhimurium* net growth in their spleens ($\log_{10}$ geometric mean count for 10 mice was 3.27). As our criteria for *Ity* typing emphasized spleen counts, the influence of this undefined gene(s) on data interpretation was minimized. Moreover, it is clear that the major gene controlling *S. typhimurium* sensitivity is one closely linked to *Lsh*, since the *Lsh* and *Ity* genotypes were concordant in 21 of the 24 typable BXD RI strains. However, the two genes do not appear to be identical because three strains (BXD-18, -20 and -29) had different responses to *S. typhimurium* and *L. donovani*.

Genetic studies were performed to verify the *Ity* types of two of these strains. The progeny of crosses between BXD-18 and C57BL/6J mice were tested for salmonella sensitivity and the extent of *S. typhimurium* multiplication in their spleens. We reasoned that if BXD-18 mice are salmonella susceptible as a consequence of Ity^s expression, then no gene complementation should be observed in (C57BL/6J × BXD-18)F_1 mice. Thus, our findings that these F_1 mice were sensitive to *S. typhimurium* (4/4 deaths after s.c. infection with 25 organisms) and were unable to control early salmonella growth in their spleens (geometric mean count for nine mice was 6.18) confirm the Ity^s genotype of BXD-18 mice. To verify the Ity^r genotype of BXD-29 mice, we assessed the spleen counts of individual mice derived from crosses of (C57BL/6J × DBA/2J)F_1 female mice with BXD-29 male mice. Because Ity^r is dominant[2,5,6], 100% of [(C57BL/6J × DBA/2J) × BXD-29] F_1 mice should be Ity^r if BXD-29 animals are Ity^r, whereas only 50% should be of this genotype if BXD-29 animals are Ity^s. Since all eight of the [(C57BL/6J × DBA/2J) × BXD-29]F_1 mice had spleen counts $<10^5$, the Ity^r genotype of BXD-29 mice was verified. The salmonella responses of the BXD RI strains therefore suggest that *Lsh* and *Ity* are closely linked, but non-identical, genes. Further studies with LXB6, 58NXL, BRX58N and BXH RI strains confirmed this linkage. No crossovers between *Ity* and *Lsh* or discrepancies between lethality and spleen counts were observed among the 17 strains of LXB6, 58NXL and BRX58N mice tested (Table 2). Experiments with BXH RI strains were complicated by the expression of the defective lipopolysaccharide response gene (Lps^d) in some of these strains. As mentioned above, this gene (or one closely linked to it) renders mice susceptible to salmonellae. Moreover, mice homozygous for this allele (Lps^d/Lps^d genotype) are susceptible to murine typhoid regardless of their *Ity* type[7]. Thus, we expected that all BXH mice of the Lps^d/Lps^d genotype would be susceptible to infection, and, in fact, all mice of the BXH-2, -3, -4, -6, -7, 8 and -12 strains, which are LPS unresponsive[11], died following s.c. infection with approximately 25 *S. typhimurium*. Interestingly, Lps^d does not influence the response of mice to leishmaniasis because both Lsh^r and Lsh^s types occur among these strains[4]. To determine the *Ity* type of some of these LPS-low responder strains, we crossed mice of BXH-3, -4, -6, -7, and -8 with LPS-responsive (Lps^n) C57BL/6J mice. As Lps^d is recessive and as C57BL/6J mice are Ity^s, Lsh^s, we were able to use these F_1 mice for *Ity* typing. Such typing was based solely on lethality data because when these experiments were done we did not routinely perform splenic analyses. As indicated in Table 3, the *Ity* and *Lsh* types were concordant in these five hybrid strains. Moreover, the *Ity* and *Lsh* types were also concordant in the two LPS-responsive BXH strains examined (Table 3).

These data provide the first direct evidence for linkage between the chromosome 1 loci, *Lsh* and *Ity*. In only three of 48 *S. typhimurium*-typable strains was there apparent recombination between these markers. Thus, the estimated recombination frequency between *Ity* and *Lsh*, as calculated by the equation of Haldane and Waddington[12], is 0.02 ± 0.01 (s.e. of the estimate). It seems unlikely that the close association of *Ity* and *Lsh* evolved by chance when the 2% recombination frequency is viewed in terms of the entire mouse genome. The advantage of maintaining these loci in close proximity during the evolutionary process is not clear because neither organism appears to be a natural pathogen of feral mice. Nevertheless, the linkage does suggest that the functions of the products of the genes may be related. Since macrophages are critical in the control of both *L. donovani*[12] and *S. typhimurium*[13] infections, it seems reasonable to presume that these gene products are involved in some phase of the uptake or killing of the organisms by macrophages. One may also speculate, based on such analogous genetic loci as the H-2 and HLA complexes of mice and men, respectively, that man too may have genes which regulate his response to intracellular microbial infections. The concept of a human genetic complex analogous to the murine *Lsh-Ity* complex is not only intriguing but would also have far-reaching clinical implications. Since Ity^s mice cannot be protected from murine typhoid by immunization with standard vaccines[14], protection of humans with similar genetic defects may require the development of new vaccines designed specifically to overcome such deficiencies.

Human B lymphocytes are immortalized by Epstein–Barr virus (EBV, ref. 1). The virus can be used to establish lymphoblastoid cell lines that produce and actively secrete specific antibodies[2]. The original method, which we have used for various antigens[2–4] is based on selection of the specific surface antigen receptor-positive lymphocytes from the peripheral blood lymphocytes of a donor who was previously sensitized to the corresponding antigen. Furthermore, by cloning the polyclonal anti-NNP cell line we have produced human monoclonal antibodies for the first time *in vitro*[5]. About 5–20 μg ml^{-1} stably produced[5] specific antibody is obtained in the supernatant of the cell lines. This approach can be used for the *in vitro* production of monoclonal human autoimmune antibodies by EBV-immortalized lymphocytes from patients with autoimmune diseases. We demonstrate the continuous production *in vitro* of a monoclonal IgM anti-IgG antibody (rheumatoid factor, r.f.) by a lymphoblastoid cell line established from a patient with rheumatoid arthritis.

Rheumatoid factors that occur in the sera of patients with rheumatoid arthritis are antibodies that react with antigenic determinants on the Fc portion of human IgG. They are heterogeneous with respect to their antigen specificity and can belong to the IgM, IgG or IgA class. In rheumatoid arthritis, rheumatoid factors are usually polyclonal in nature while monoclonal rheumatoid factors have been described in infectious mononucleosis and lymphoproliferative disorders[6].

We have isolated the lymphocytes from a 15-ml blood sample from a patient (A.N.) with classic rheumatoid arthritis. Standard agglutination tests of the patient's serum using sensitized sheep erythrocytes with rabbit amboceptor (Rose Waaler test) and latex suspension coated with human IgG, gave titres of 1:1024 and 1:80 respectively. Selection and isolation of the antigen receptor-positive cells was carried out by rosetting the lymphocytes[7] with a 10-fold excess of human IgG coated on erythrocytes and subsequently separating them on a Ficoll–Isopaque gradient (density 1.077)[5]. The rosette-containing pellet was infected with a B958-derived EBV[1]. The infected cells were incubated in RPMI 1640 in 20% fetal calf serum (FCS) at 37 °C, 5% CO_2. The emerging cell line contained 0.6% cells that rosetted with human IgG-coated erythrocytes. This very low percentage was apparently due to the fact that in the initial selection stage not only antigen receptor-positive lymphocytes were rosetting with the IgG-coated erythrocytes but also non-related B lymphocytes that had Fc receptors. However, lymphoblastoid cell lines have very weak Fc receptors and usually do not form rosettes with IgG-coated erythrocytes[8]. Therefore we re-selected the emerging line by two subsequent re-rosettings. The outcoming cell line (r.f.-A.N.) is 100% EB nuclear antigen positive[9]. It has a 2-day doubling time and has now been maintained in tissue culture for more than 12 months.

The cells are surface and cytoplasmic IgM λ positive, IgA, IgD and κ negative as shown by staining of live and fixed cells with fluorescein isothiocyanate (FITC)-conjugated rabbit anti-human immunoglobulins (Table 1). The nonconcentrated culture supernatant of growing cells (up to 7×10^5 cells ml^{-1}) agglutinated human IgG and rabbit IgG-coated erythrocytes up to 1/128–1/512 dilution; the agglutination was inhibited by 2-mercaptoethanol. A 100-fold concentrated medium of 10^6 cells growing for 24 h in RPMI with 1.25% FCS had a specific agglutination titre of 1:16,000. By indirect staining of rabbit-IgG-coated erythrocytes previously incubated with the cell line supernatant (Table 1) the specific antibody was identified as an

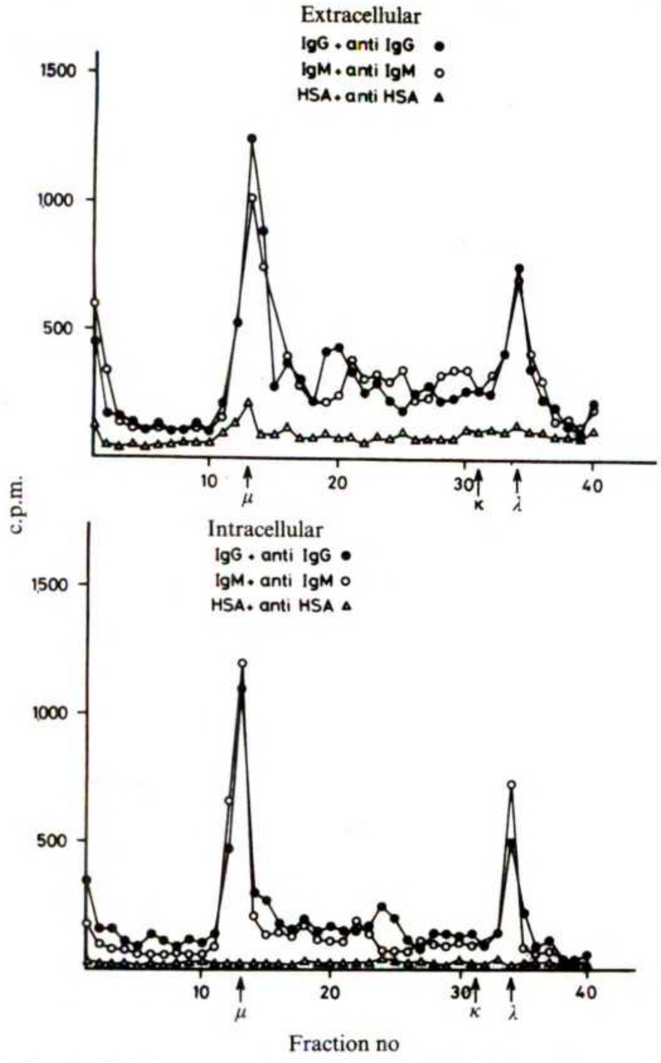

Fig. 1 Gel electrophoresis of immunoglobulins produced by r.f.-A.N. cell line. 12×10^6 r.f.-A.N. cells were incubated in 8 ml of RPMI, amino acid-free medium with 15% dialysed FCS with 40 μCi ml^{-1} of ^{3}H-labelled amino acid mixture (Amersham) for 24 h. Supernatant was collected, and cells were washed twice and lysed in 2 ml Triton 1%. Both supernatant and cell lysate were dialysed. The supernatant was concentrated 10 times. Aliquots (0.1 ml) of each sample were co-precipitated in a final volume of 0.5 ml with the following antisera and the corresponding antigen in the equivalence zone: rabbit anti-human IgG (Dakopatts) and human IgG; goat anti-HSA (Meloy) and HSA; rabbit anti-human IgM (Dakopatts) and human IgM. The precipitate was washed four times, lysed with 0.1 ml of 1% SDS and SDS-PAGE was performed on 12% acrylamide gels for 4 h (4 mA per tube). The positions of the control markers are indicated by arrows. Cell lysate analyses are shown on the left-hand traces; culture supernatant analyses are shown on the right-hand traces.

IgM, λ. The contrast between the polyclonal anti-IgG that characterizes the patient's serum (A.N.) and the monoclonal type of the anti-IgG of the r.f.-A.N. cell line is evident (Table 1). 65 ± 10% of the r.f.-A.N. cells form specific rosettes with human or rabbit but not goat IgG-coated erythrocytes or human IgM-coated erythrocytes. The erythrocytes used were: (1) $CrCl_3$-IgG coated, (2) O, Rh$^+$ coated with human IgG anti-D (Ortho), (3) A, Rh$^+$ and (4) B, Rh$^+$ coated with sub-agglutinating titres of IgM anti-A and anti-B antibody-containing sera.

The high percentage of rosettes is comparable with the specific rosette percentage that characterized the cloned anti-NNP lines[5], which also never reached 100%.

Instead of a plaque assay we developed a method to identify the class of the specific antibody and also the number of cells secreting this antibody, based on the observation of Lubbe *et al.*[11]. These workers demonstrated the formation of a multilayer cluster of antigen-coated erythrocytes around a specific antibody-producing mouse lymphocyte by adding an allogeneic anti-mouse immunoglobulin serum. Table 2 shows that on mixing r.f.-A.N. lymphoblastoid cells with an 100-fold excess of human IgG-coated erythrocytes and diluted rabbit antisera to different classes of human immunoglobulins we detected giant multi-layer clusters. These clusters were formed only in the mixtures containing anti-human total immunoglobulins, IgM or λ chains. No clusters were formed when anti-IgG, -IgA and κ-chains or uncoated erythrocytes were used, and cluster formation was totally inhibited by sodium azide. These results demonstrate that the cells are actively secreting IgM, λ antibodies against human IgG. The significant information this assay provides and the simplicity of its performance make it preferable to the conventional plaque-forming assay.

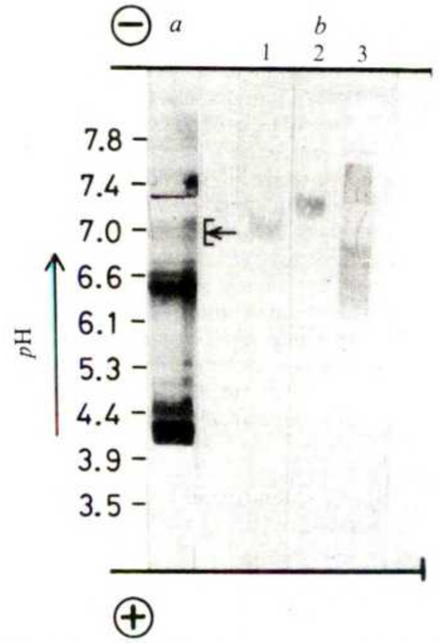

Fig. 2 IEF and immunofixation patterns. *a*, IEF of a concentrated (×1,000) culture supernatant of the cell line r.f.-A.N. Concentration was performed by precipitation with 50% saturated $(NH_4)_2SO_4$ followed by dialysis against H_2O; the resulting euglobulin was dissolved in 1 ml saline. IgM concentration was 150 μg ml^{-1}. *b*, Immunofixation patterns obtained with goat anti-human IgM, μ-chain specific serum (Hyland): lane 1, concentrated culture supernatant of the cell line r.f.-A.N.; lane 2, Waldenström' macroglobulinaemia serum (Meloy A 204; 80, 891) diluted 1 : 75 in saline; lane 3, serum from patient A.N. (undiluted). In all cases 20 μl of the samples soaked into Paratex filter pieces (LKB) were applied on the gel surface. Guiding *p*H values of the gradient are shown. Agarose IEF was performed in Isogel agarose gel 0·5% (Marine Colloids Division; FMC Corp.) in the presence of a 2% final concentration of Ampholine (LKB) *p*H 3.5–9.5, supplemented as required by Ampholines with the *p*H range 2.5–4.0 and 5.0–8.0. The dimensions of the agarose plates were 110 × 125 mm. The runs were performed in an LKB Multiphor at 5 °C. The current was kept at 10 mA for 10 min, then the Paratex pieces were removed and focusing was continued at 6.25 W constant power (1,000 V limiting) for 1 h. Immunofixation was carried out essentially as described by Pedersen and Axelsen[16].

To characterize the cells and their immunoglobulin product further, they were incubated for 24 h with radioactive amino acid mixture. Both the cell lysate and the culture supernatant were assayed for labelled anti-IgG immunoglobulins by co-precipitation in the presence of human IgG and rabbit anti-human IgG (Fig. 1). The radioactivity is clearly restricted to μ and λ chains. In parallel, co-precipitation of another sample of the same culture supernatant and cell lysate in the presence of human IgM and rabbit anti-human IgM was qualitatively and quantitatively identical to the corresponding co-precipitation with human IgG and rabbit anti-human IgG. This indicates that all the IgM secreted into the culture medium has anti-IgG activity and that apparently the line is monoclonal.

No radioactive precipitation occurred when goat anti-human serum albumin (HSA) and HSA were added to samples of the cell lysate and the culture supernatant. This is due to the fact that the *in vitro*-produced antibody does not react with goat IgG (see also Table 1).

The clonality of the immunoglobulin product synthesized by the established cell line has been tested by isoelectric focusing (IEF, Fig. 2) in agarose gels, followed by immunofixation. Since the r.f. antibody studied belongs to the IgM class, agarose gels with negligible sieving effects and minimal electroendoosmosis were used[13].

The pattern obtained using the concentrated culture supernatant showed a limited microheterogeneity characteristic for monoclonal IgM antibodies[13]. The pattern is similar to that obtained when a serum from a patient with Waldenström's macroglobulinaemia has been tested in the same run. This provides additional evidence of the monoclonal origin of the r.f. synthesized by the cell line r.f.-A.N.

The presence of a few closely spaced bands in IEF, when the sample containing the intact antibody was analysed (Fig. 2, *a*, *b* 1) and of a single peak corresponding to the L-chains derived from the same antibody in SDS-polyacrylamide gel electrophoresis (PAGE) (Fig. 1) are stringent criteria for monoclonality[14]. We should mention that the samples tested were crude preparations and that specific procedures to purify the r.f. antibody were not used so as to avoid the selection of a homogeneous population of antibodies.

This is the first time that specific r.f.-producing B cells from rheumatoid arthritis patients have been isolated, immortalized and established as a permanent autoimmune antibody-producing cell line. The availability of such cells can contribute to the understanding of the nature of the cells involved in autoimmune diseases. In addition, this defined product of the cell line is preferable to the unpredictable supply of polyclonal r.f. which is usually used in the radioimmunoassay for detecting immune complexes[15].

Gilliland *et al.*[17] established a cell line with no pre-selection from the synovium of a patient with rheumatoid arthritis that synthesized predominantly IgG, and that had an r.f. activity associated with IgG and IgM. These workers succeeded in establishing such a line after 100 unsuccessful trials from different synovial fluids. Our results suggest an approach to establish autoimmune antibody-producing cell lines that can be extended to other autoantibodies, such as anti-DNA, anti-T.

We have not studied the antigenic specificity of the *in vitro* produced r.f. in relation to the IgG molecule. The *in vitro* produced antibody can be used as an additional tool for understanding the structure and genetics of IgG molecules.

We thank Professor Dov Sulitzeanu for fruitful discussions. This work was carried out with the support of a Volkswagen Stiftung grant Az: I/36 120-121.

Relationship between increased aerobic glycolysis and DNA synthesis initiation studied using glycolytic mutant fibroblasts

J. Pouysségur, A. Franchi & P. Silvestre

Centre de Biochimie, Université de Nice, Parc Valrose,
06034 Nice, France

Reports from several laboratories have suggested that increased rates of glycolysis play an essential part in the initiation of DNA synthesis. This is based on observations that aerobic glycolysis: (1) occurs at low rate in resting mammalian cells and at very high rate in tumour cells[1–3]; (2) increases rapidly after DNA synthesis is initiated by addition of serum or purified growth factors[4,5], and (3) correlates with the expression of the transformed phenotype[6]. Also, specific inhibitors of aerobic glycolysis prevent the initiation of DNA synthesis[4]. To determine whether the rapid activation of phosphofructokinase—and therefore glycolysis—by purified growth factors[7] is necessary for the initiation of cell proliferation, we have isolated and studied two classes of glycolytic mutants. The first, isolated from Chinese hamster fibroblasts, has a total block in the glycolytic pathway[8]. The second, from hamster and Fisher rat fibroblasts maintains a permanent high rate of glycolysis. We have found that both classes of mutants retain normal control of DNA synthesis in response to serum. This dissociation indicates that growth-factor-stimulated glycolysis is not involved in the control of initiation of DNA synthesis and cell proliferation.

We used two fibroblast lines requiring serum for growth. The first, 023 which can grow in agarose, is a subclone of Chinese hamster lung fibroblasts (CC139 of ATCC). In spite of a spontaneously-transformed phenotype, its DNA synthesis is dependent on the addition of serum (Fig. 1, inset) or purified growth factors[9]. When CC139 cells are deprived of serum, DNA synthesis is arrested. As with normal cells, DNA synthesis and cell division can be reinitiated by addition of serum. A minimum of 8–10 h is required for the first cells to enter S phase (Fig. 1). The cell population doubles 20 h after stimulation by serum.

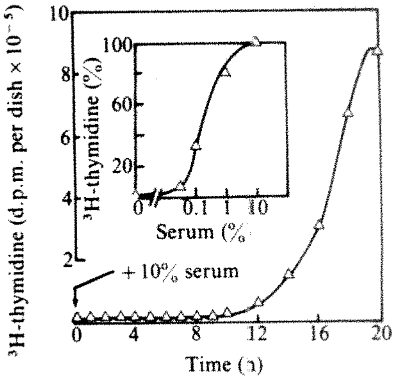

Fig. 1 Re-initiation of DNA synthesis by serum to Chinese hamster fibroblasts. Confluent cultures of Chinese hamster fibroblasts (35-mm dishes) were washed twice with Dulbecco's medium to remove residual serum and then incubated for 29 h in a mixture (1 : 1) of Dulbecco's and F12 medium (Gibco) deprived of serum. DNA synthesis was re-initiated by addition of 10% fetal calf serum (FCS) and its rate was measured as follows. Cells in duplicate dishes were pulsed for 1 h at 37 °C with 1 ml of culture medium containing 10% serum and ^{3}H-thymidine (5 μCi ml^{-1}). The cells were then washed twice with phosphate-buffered saline and fixed (60 min at 0 °C) with 1 ml of trichloroacetic acid 10% containing 1 mM thymidine. Radioactivity of the acid-precipitable fraction was measured after solubilization in 0.1 M NaOH. The inset shows the rates of DNA synthesis to different concentrations of serum, following 29 h of serum starvation. DNA synthesis was measured after incubation for 24 h with ^{3}H-thymidine (0.5 μCi *ml*$^{-1}$). Values are expressed relative to the thymidine incorporation obtained with 10% FCS.

Table 1 Glucose transport and glycolysis in Chinese hamster and Fisher rat fibroblasts and mutant derivatives

	Cell line	Origin	Phenotype	Glucose transport (3-*O*-MGlc) (nmolmg^{-1} min^{-1})	Glycolysis (lactate formed) (μmol per mg protein per h)
Chinese hamster fibroblasts	023	CC139 (ATCC)	Wild type	0.110 (100%)	1.4 (100%)
	DS7	023	Glycolysis$^-$ (pgi$^-$)	0.027 (25%)	0.08 (5%)
	GSK3	023	Respiration	0.430 (390%)	3.8 (260%)
Fisher rat fibroblats	FR3T3	(ref. 10)	Wild type	0.17 (100%)	0.65 (100%)
	GSR16	FR3T3	Respiration$^-$	0.35 (200%)	4.0 (610%)
	FR3T3-Py	FR3T3	Transformed by polyoma virus	0.30 (180%)	2.3 (350%)

All cells were grown in Dulbecco's modified Eagle's medium supplemented with 10% fetal calf serum. 023 Is a ouabain-resistant clone derived from the Chinese hamster fibroblasts CC139 (ATCC). DS7 and GSK3 were derived from 023 cells after mutagenesis with ethylmethane sulphonate as described for DS7[8]. The selection of the respiration-deficient mutants, GSK3 and GSR16 has been described elsewhere[13]. Cells were planted in 35-mm dishes, cultured to near confluency in 2–3 days, and assayed for 3-*O*-methyl D-glucose. For 3-*O*-MGlc transport studies, cells were precharged with 50 mM 3-*O*-MGlc before transport and assayed with 50 μM 3-*O*-MGlc. Rates of transport are the average of duplicate determinations with time points of 15, 30 and 60 s. Rates of glycolysis were calculated from the linear kinetic (lactic acid produced into the medium) obtained with time points of 30, 60 and 90 min.

Therefore, as with normal cells, growth-factor deprivation reversibly arrests these Chinese hamster cells in the G_0/G_1 phase of the cell cycle. The second cell line was isolated by Seif and Cuzin[10] from Fisher rat embryo fibroblasts. This diploid line, FR3T3, is anchorage-dependent, non-tumorigenic and dependent on serum for growth.

To analyse the relationship between increased glycolysis and the initiation of DNA synthesis, we searched for a class of mutants in which glycolysis is supressed and another in which it is permanently derepressed. We used tritium 'suicide' to select these mutants. From hamster fibroblasts treated with ^{3}H-labelled 2-deoxyglucose we selected DS7, a mutant lacking phosphoglucose isomerase activity. (Details of the selection are given elsewhere[8].) By a similar method, but using [6-^{3}H]-D-glucose, we isolated GSK3 from hamster cells and GSR16 from rat fibroblasts. Some of the clones surviving ^{3}H-glucose 'suicide' had a specific defect in the oxidation of glucose by the Krebs cycle. This was due to a block in respiration that resulted in a decrease in oxygen uptake. One consequence of this mutation is a decrease in ATP derived from oxidative metabolism; this in turn triggers a permanent activation of glycolysis to compensate for the deficit in energy.

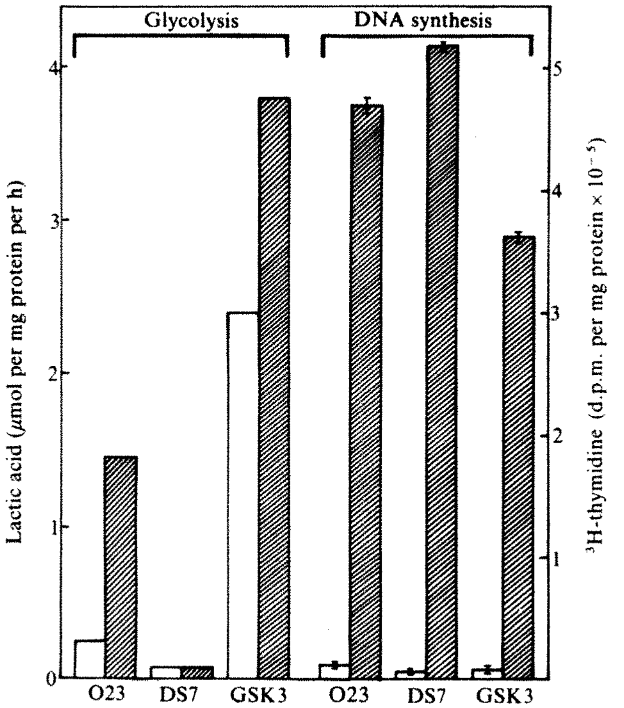

Fig. 2 Rates of glycolysis and DNA synthesis in serum-starved and serum-refed Chinese hamster fibroblasts. Wild type (023) and mutant (DS7 and GSK3) cells were grown for 2 d in media containing 10% FCS (10^6 cells per 35-mm culture dish). The cells were then washed (twice to remove residual serum) and incubated for 29 h in the mixture (1:1) of Dulbecco's and F12 medium. At the end of the starvation period, media were renewed and half of the cells were supplemented with 10% FCS (hatched bars). Rates of glycolysis were measured as the amount of lactic acid produced during the first hour after starvation (see legend to Table 1). Rates of DNA synthesis were determined by the incorporation of thymidine into acid-precipitable material after 24 h of incubation in the presence (hatched columns) or absence (open columns) of 10% serum and ^{3}H-thymidine (0.2 μCi ml^{-1}).

Table 1 summarizes rates of glucose transport and glycolysis in the two cell lines and their mutant derivatives. The rate of glycolysis is decreased 20-fold in DS7, whereas it is increased six-fold in GSR16 (compared with the corresponding parental lines). Interestingly, in conjunction with a block in glycolysis, DS7 has low glucose transport activity, whereas derepression of glycolysis in GSK3 or GSR16 is accompanied by increased glucose transport. The biochemical basis for this co-regulation will be discussed elsewhere[11]. It is also interesting that the respiration-deficient mutation introduced into FR3T3 activates glycolysis and glucose transport to values higher than those observed in the highly transformed polyoma virus derivative, FR3T3-Py (Table 1).

Figure 2 shows that re-initiation of G_0/G_1-arrested wild type 023 cells by serum rapidly stimulates (sixfold) glycolysis. In contrast, as would be expected, serum cannot stimulate glycolysis in the deficient mutant DS7. However, re-initiation of its DNA synthesis is not prevented by the glycolytic defect. Even in conditions of serum starvation, GSK3 sustains levels of glycolytic activity 10 times higher than those in wild-type arrested cells, and even higher than in serum-stimulated 023 cells. Although serum starvation fails to reduce rates of glycolysis and glucose transport to low levels, DNA synthesis is arrested in GSK3 cells (Fig. 2).

Results obtained with the untransformed cell line FR3T3 and its derivatives are shown Fig. 3. As with GSK3, when the respiration-deficient mutant GSR16 is starved of serum for 48 h, its rate of glycolysis is not reduced to low levels: indeed it is slightly higher than in polyoma-virus transformed FR3T3 and 10 times higher than in normal FR3T3. However, Fig. 3 shows that in contrast to FR3T3-Py in which DNA synthesis cannot be arrested, GSR16, like the parent FR3T3 line, has normal control of DNA synthesis and cell division.

Thrash and Cunningham[12] have demonstrated a dissociation of increased transport from initiation of fibroblast proliferation. Our studies extend this dissociation to aerobic glycolysis and support their report because DS7 and GSK3 have a 15-fold difference in glucose transport (Table 1), yet they both show normal control of DNA synthesis.

Zielke *et al.*[13] have reported that human fibroblasts can undergo one to two cell divisions in the absence of glucose, provided that the anabolic function of glucose required for nucleic acid synthesis is substituted by the addition of purines

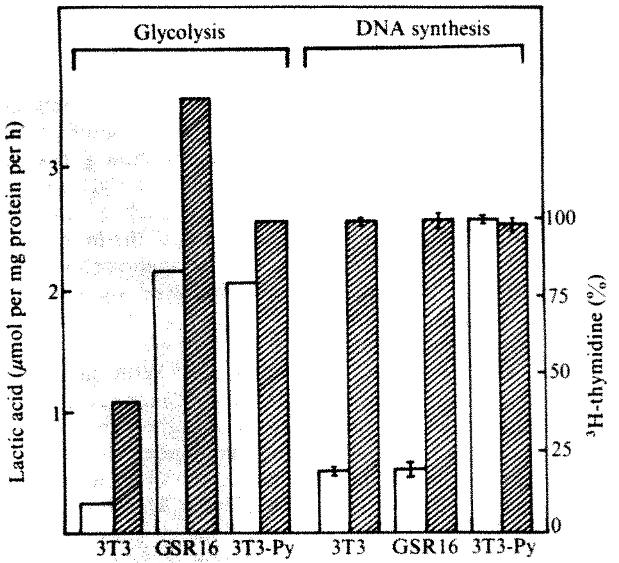

Fig. 3 Rates of glycolysis and DNA synthesis in serum-starved and serum-refed Fisher rat fibroblasts. FR3T3, GSR16 and FR3T3-polyoma transformed cells (10^5 per 35-mm dish) were grown for 2 d in 10% FCS and then starved of serum for 48 h in the mixture (1 : 1) of Dulbecco's and F12 medium. Then half the cells were supplemented with 10% FCS. Rates of glycolysis and DNA synthesis were measured as for Fig. 2. Open columns, cells starved of serum; hatched columns, cells with 10% serum added.

and pyrimidines to the medium. Therefore, one may ask whether a possible role of glucose metabolism in controlling DNA synthesis or cell proliferation *in vivo* has been masked in *in vitro* studies, in which a rich medium (DMEM/F12) containing nucleic acid precursors was used. There are two lines of evidence against this possibility. (1) The results shown in Fig. 2 for 023 and DS7 were also observed when the cells were serum-starved and serum-stimulated in Dulbecco's medium alone (not containing the nucleic acid precursors of the F12 medium). In this situation the anabolic function of glucose is required and the pentose-phosphate shunt, still functional in DS7, facilitates the re-initiation of DNA synthesis. (2) We have shown that the glycolytic block in DS7 cells does not prevent their capacity to form tumours[8] and therefore to proliferate *in vivo*.

In conclusion, the properties of GSK3 and GSR16 indicate that the loss of growth regulation of transformed or tumour cells is not linked to their high glucose metabolism. Also it seems clear from the study of the glycolysis-deficient mutant DS7 that growth factor-activated glycolysis or glycolysis *per se*, is not necessary for the initiation of DNA synthesis and cell division.

We thank Dr Rolando Pêrez for stimulating discussions; Professor Gérard Ailhaud for support; Dr Mary Murphy for reading the manuscript and Mrs Geneviève Oillaux for typing it. This work was funded by CNRS (LP 73-00), DGRST (Membranes Biologiques, no. 77-7-1269) and by INSERM (ATP no. 82-79-114).

Single Na^+ channel currents observed in cultured rat muscle cells

Frederick J. Sigworth & Erwin Neher

Max Planck Institut für biophysikalische Chemie,
D-3400 Göttingen, FRG

The voltage- and time-dependent conductance of membrane Na^+ channels is responsible for the propagation of action potentials in nerve and muscle cells. In voltage-step-clamp experiments on neurone preparations containing 10^4–10^7 Na^+ channels the membrane conductance shows smooth variations in time, but analysis of fluctuations[1,2] and other evidence[3] suggest that the underlying single-channel conductance changes are stochastic, rapid transitions between 'closed' and 'open' states as seen in other channel types. We report here the first observations of currents through individual Na^+ channels under physiological conditions using an improved version of the extracellular patch-clamp technique[4–6] on cultured rat muscle cells. Our observations support earlier inferences about channel gating and show a single-channel conductance of approximately 18 pS.

Our cell preparations were myoballs[7,8] prepared from 19–20-day old rat embryos. After fusion to form myotubes the cells were treated for 2 days in 10^{-6} M colchicine, which caused them to assume a spherical shape, and then returned to the normal growth medium (Dulbecco's minimal essential medium with 10% fetal calf serum) for 2–5 days before use. As excitable cells, myoballs were advantageous for several reasons. First, Na^+ channels in frog muscle show longer activation time constants than those in frog nerve, and we observe slower activation in myoballs than in mammalian nerve[9]. The long time constants reduce the time-resolution requirements of the recording system. Second, the absence of connective tissue in the cell culture allows direct access to the sarcolemma without enzyme treatment[5]. And third, the spherical shape of the cells allows the use of a conventional, two-microelectrode voltage clamp for measurement of the whole-cell currents. In contrast to the recent recordings from K^+ channels in squid axons by Conti and Neher[10], we were also able to use physiological ionic solutions for our experiments. We did, however, cool the cells to room temperature (19–22 °C) to slow the channel kinetics.

The recording method (Fig. 1) represents an order-of-magnitude improvement in resolution over previous results from the patch recording technique. The basis of the improvement is an increase from 10^8 to 10^{10} Ω of the seal resistance that electrically isolates a small patch of membrane for current measurement[6]. The higher resistance introduces less thermal noise (which in the past was the predominant noise source) allowing a wider recording bandwidth to be used. It also allows voltage steps to be applied to the patch without the necessity of voltage-clamping the entire cell with microelectrodes. A seal is formed by applying gentle suction in the pipette which is pressed against the cell membrane. In two experiments we estimated the membrane patch area to be 2 and 10 μm^2 from transfer capacitance measurements on cells that were also voltage-clamped with microelectrodes. This area is large in view of the 0.3–0.5 μm diameter of the opening in the pipette tip, and suggests that part of the membrane is drawn into the pipette, forming an omega shape (Fig. 1).

The size of the peak Na^+ currents recorded with the microelectrode clamp in these cells varied from essentially zero to about 1 mA per cm^2 of surface area; this latter current density corresponds to about 10 channels per μm^2 surface area. Capacitance measurements[7] suggest that the total membrane area is much larger than the surface area, as would be expected from transverse tubules or extensive membrane infolding. The

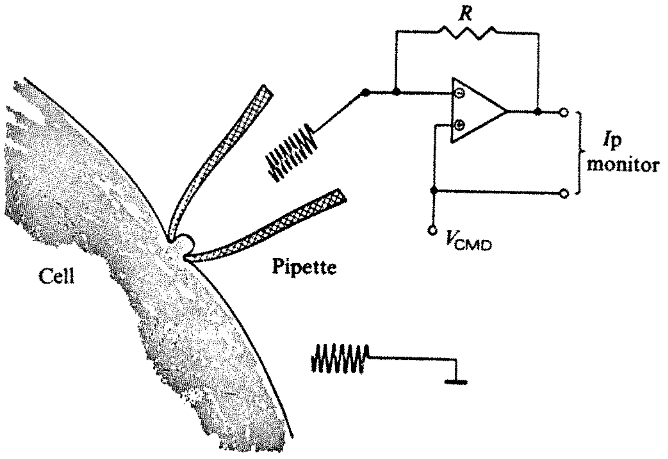

Fig. 1 Recording system. Details of pipette fabrication and use are given in ref. 6. Briefly, a freshly fire-polished glass pipette with inner opening diameter ~0.3–0.5 μm is filled with modified Ringer solution and pressed against a myoball (cell diameter 30–80 μm). Suction (5–50 cm H_2O) is applied to the inside of the pipette for 5–30 s until the sealing resistance, measured as the current response to small voltage pulses at V_{CMD}, suddenly increases to > 1 GΩ. Ag–AgCl electrodes are used in the pipette and for the reference electrode in the bath. The patch clamp circuitry resembles that described previously[5], but was modified to exploit the high seal resistance. The current measuring resistance R was increased to 10 GΩ, and frequency-response corrections were applied in a later amplifier stage to maintain flat response in the current monitor signal to 7 kHz. The operational amplifier is a Burr–Brown 3523J. As the input shunt capacitance ($\simeq 3$ pf) causes the voltage noise of the amplifier to predominate at high frequencies, we coat the pipettes with wax or Sylgard to reduce the wall capacitance. The potential inside the pipette is controlled by V_{CMD}; this also provides very good control of the potential of the membrane patch since the pipette access resistance is < 10 MΩ and the patch currents cause negligible changes in the resting potential of the cell. The bathing Ringer solution contained (in mM): 140 NaCl, 1.4 KCl, 2.0 $MgCl_2$, 1 $CaCl_2$ and 20 HEPES at *p*H 7.4. The pipette solution was the same with 0.2–1 $\mu g\ ml^{-1}$ α-bungarotoxin added to block acetylcholine receptors. Both solutions were filtered (0.2 μm pore size) immediately before use. Occasionally 5 mM TEA Cl (replacing NaCl) was also present to block K^+ channels; this had no obvious effect on the patch current recordings.

small number of channels in a patch—at most 3–5 channels were simultaneously active—is consistent with this. Also, voltage clamp of the cells sometimes showed large, tetrodotoxin (TTX)-sensitive regenerative responses at small depolarizations, characteristic of a large membrane component under poor voltage-clamp control. No responses of this kind were seen in the patch clamp recordings, however.

Figure 2*c* shows a series of current records from a membrane patch, obtained by successive depolarizations to $V = 10$ mV, where V is the displacement from the resting potential. Discrete current pulses of varying duration appear after the start of the depolarizations; inactivation of the currents appears as a reduction in the frequency of appearance later in the depolarizations. In roughly half of the records no channel events were seen; in two records of the 300 taken in this run two overlapping events were seen.

Conditions known to reduce the Na^+ current also affect these current pulses. When two-thirds of the Na^+ in the pipette was replaced with the impermeant substitute tetramethylammonium ion (TMA), the discrete currents were reduced in size (Fig. 2*d*). In other experiments the sensitivity to block by TTX was tested statistically. For these we used two culture dishes of cells 5 days after colchicine treatment because at this later stage the channel density seems to be more uniform[11], as reflected by the fraction of patches that contain channels. In each dish four recordings were made, three with Ringer solution in the pipette and one with 1 μM TTX added. Channel activity was present in all six patches in the absence of TTX, and not present in TTX, showing that TTX blocks at least some of the channels ($P < 0.05$, Fisher test).

Assuming that the Na^+-channels in these cells are identical and function independently, one expects that the sum of many current records from a few channels should show the same properties as the sodium current measured in a conventional voltage-clamp from thousands of channels. Such an average time course derived from 300 depolarizations of the membrane patch is shown in Fig. 2*b*. It shows the typical kinetic behaviour[12] with a rapid ($\tau_m \simeq 0.8$ ms) activation followed by a slower ($\tau_h \simeq 2.6$ ms) inactivation process.

Averages and representative single records are also shown in Fig. 3 for variously sized depolarizations. With increasing depolarization the peak inward current first increases, as the probability that channels are open rises, and then decreases as the single-channel currents become small near the reversal potential. The mean channel open time, τ, shows the qualitative behaviour expected from Hodgkin–Huxley kinetics[12] where $\tau = 1/(3\beta_m + \beta_h)$. At small depolarizations τ increases with depolarization as the closing rate constant β_m decreases. At larger depolarizations the increasing inactivation rate β_h shortens τ. There is, however, a quantitative disagreement, with τ not differing significantly from τ_m in the data of Fig. 2 and in two other experiments at $V = 10$ and 20 mV. At such small depolarizations, where activation is small, τ would be near $\tau_m/3$ in the Hodgkin–Huxley theory. The channel lifetimes are consistent, on the other hand, with the kinetic theory of Armstrong and Gilly[13] in which the final opening step of the channel is rate limiting in channel activation.

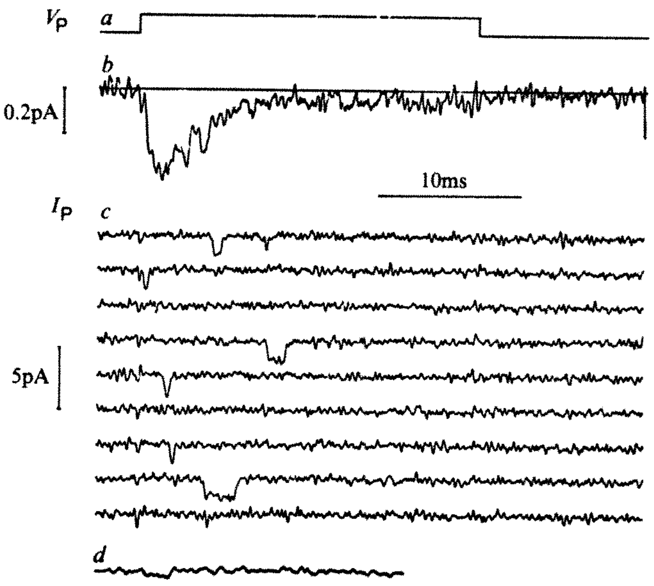

Fig. 2 Single-channel currents during 10 mV depolarizations. *a*, Imposed patch membrane potential. The patch was held hyperpolarized by 30 mV; 40 mV depolarizing pulses were given at 1-s intervals. *b*, Average of a set of 300 current records elicited by these pulses. *c*, Nine successive individual records from this set. The mean channel current was −1.6 pA, and lifetime was 0.7 ms. *d*, Example of a current record obtained in another experiment where two-thirds of the Na^+ in the pipette was replaced with tetramethylammonium ion. The record was plotted on the same scale as *c* but additional filtering was used to reduce the noise level. Leakage and capacitance currents were subtracted in each case using means of responses to symmetrical hyperpolarizing pulses; to remove a residual capacitance artefact in *b* and *c* a mean time course was computed from records in which no channel activity was visible, and this mean was subtracted from individual records. Filtering of the data resulted in effective system risetimes of 300, 180 and 300 μs in *b*, *c*, and *d*, respectively. The patch apparently contained 2–3 active channels, as estimated from responses to larger depolarizations. The solution in the pipette contained 5 mM TEA. Cell 3.1; temperature, 18 °C.

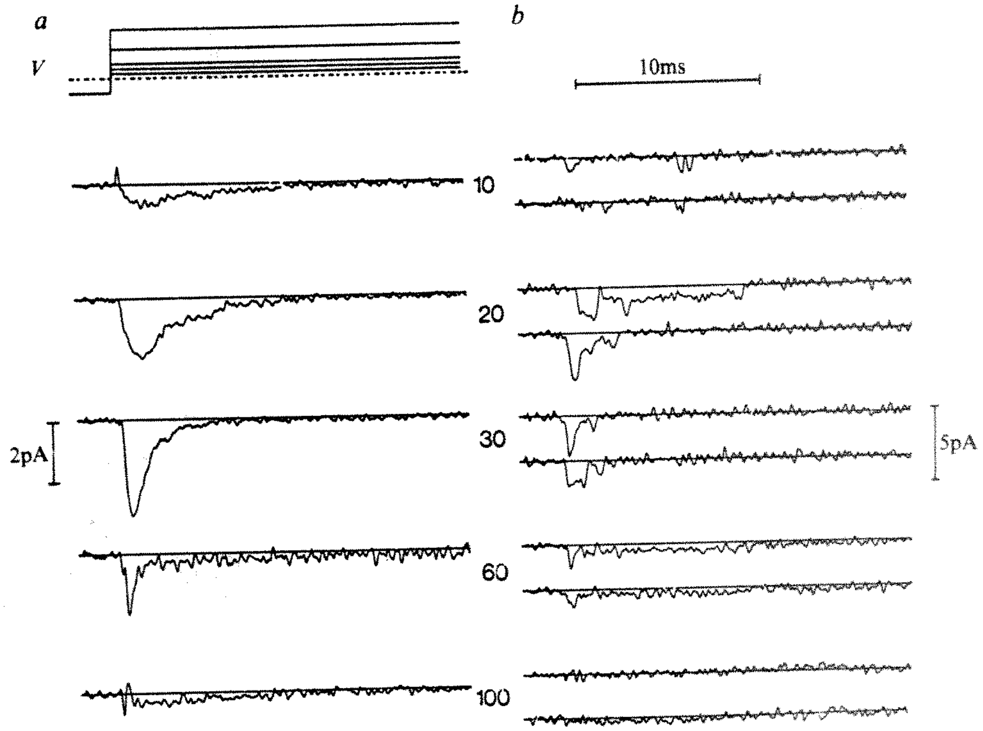

Fig. 3 Patch currents obtained with depolarizations to the various potentials V shown. a, Means calculated from 24–104 current records; b, representative individual records at each potential. Overlapping currents from 2–3 channels can be recognized at $V = 20$ and 30 mV. Note the decrease in current size near the reversal potential (approximately $V = 100$ mV). Leakage and capacitance currents were subtracted with averages from symmetrical hyperpolarizations. Recording system risetime was 220 µs. Cell 7.1, 3 days after colchicine treatment. Temperature, 22 °C.

Estimates of the cell resting potentials allow us to express values of V in terms of absolute membrane potential. Impalements with microelectrodes showed maximum resting potentials in the range −60 to −70 mV. h_∞ curves from averaged patch currents showed $h_\infty = 0.5$ in the range $V = 0$ to −15 mV whereas measurements with the microelectrode voltage clamp showed corresponding absolute potentials of −80 to −95 mV. We conclude therefore that the resting potentials were in the range −60 to −80 mV. This places the apparent reversal potential $V_{Na} \simeq 100$ mV in Fig. 3 in the absolute membrane potential range of +20 to +40 mV.

The size of the single-channel currents corresponds to a single-channel conductance $\gamma = 18$ pS. This value is at first sight surprisingly large, as γ estimates for frog nerve Na^+ channels, based on current fluctuation analysis, are in the range 6–8 pS (refs 1, 2). These values become twice as large, however, when they are corrected to the temperature and higher sodium concentration used in our experiments, assuming[14] $Q_{10} = 1.3$ and a linear concentration dependence of conductance.

The extracellular patch clamp as used in this work promises to be a powerful electrophysiological technique for tissue-cultured cells. The ability to clamp and change the potential in small patches of membrane now allows voltage-clamp studies to be performed on cells that are too small or have unsuitable geometries for microelectrode work.

We thank Drs B. Sakmann and O. Hamill for advice and help in getting the seals to work, and H. Karsten for preparing the myoballs. F.J.S. is a fellow of the Alexander von Humboldt Stiftung.

The glucose analogue 2-deoxyglucose (2-DG) can be used quantitatively to measure metabolic activity[1] and is widely used qualitatively for mapping functional activity in the brain[2–4]. The resolution (meaning the full width at half maximum of the grain density distribution around a line source) of the technique using [^{14}C]-2-DG and X-ray film is limited to about 100 µm[5]. Attempts have been made to improve the resolution using [^{3}H]-2-DG (ref. 6) and cellular resolution has been achieved in the goldfish retina[7] and with cultured mouse neurones[8]. An anatomical technique for mapping the metabolic activity of individual neurones would be useful for studying invertebrate central nervous systems, which are relatively simple and stereotyped compared to vertebrate brains. The [^{3}H]-2-DG technique was applied to an invertebrate in a study of the *Drosophila* visual system[9], though without cellular resolution. We present here modifications of the [^{3}H]-2-DG technique to demonstrate localization of 2-DG in single neurones of *Limax maximus*, a gastropod mollusc, with a resolution of less than 1 µm.

Glucose and 2-DG compete both for transport into and out of a cell and for phosphorylation by hexokinase inside the cell. Once 2-DG is phosphorylated to 2-deoxyglucose-6-phosphate (2-DG-6-P), it is not metabolized further and accumulates in the cell. In the conventional [^{14}C]-2-DG technique[1], the tissue is frozen, sectioned on a cryostat, picked up on a warm coverslip

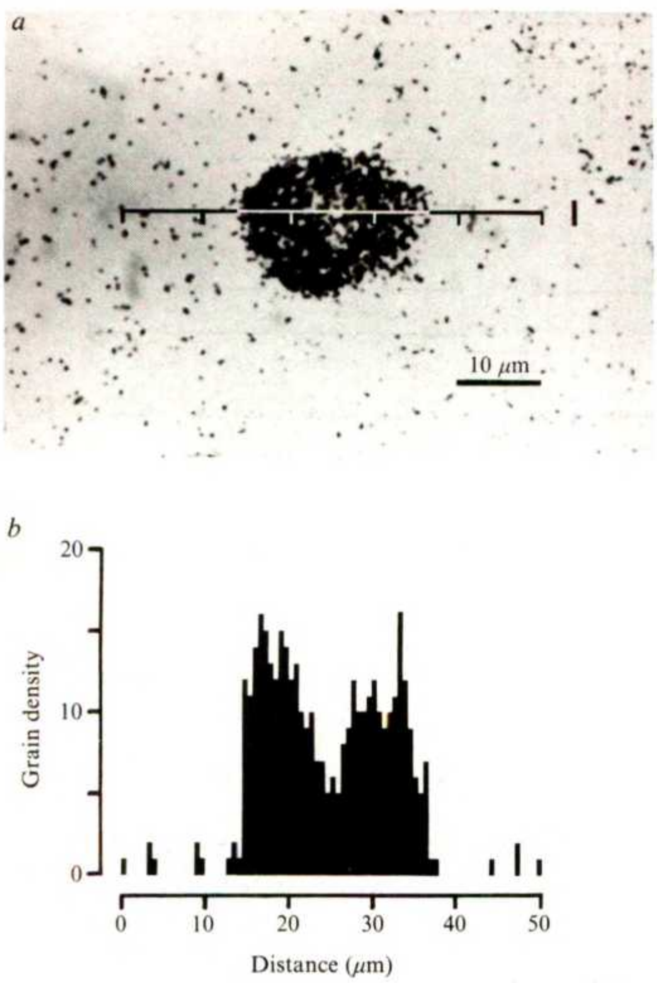

Fig. 1 Measurement of silver grain density over a single cell body in a buccal ganglion. *a*, Light-microscopic autoradiograph from a preparation incubated in [^{3}H]-2-DG for 45 min and freeze-substituted with acetone at −70 °C. During the incubation, a neurone in the buccal ganglion was stimulated with an intracellular electrode to elicit action potentials at the rate of 2 s^{-1}. Several cells in the buccal ganglion were labelled. Scale bar, 10 μm. *b*, A reticle with 100 lines was superposed over the cell at high magnification and the silver grains were counted by focussing through the emulsion of the autoradiograph. The number of silver grains between reticle lines (in a rectangle (0.63×4.6 μm) as shown to the right of the cell) is plotted as a function of distance along the line drawn through the cell body in *a*. The drop in density of silver grains over the centre of the cell occurs over the nucleus. The density of silver grains over the cytoplasm is 4.1 μm^{-2}, which is 40 times the average background density over the tissue surrounding the cell and 290 times the background density in the emulsion.

and dried on a hot plate, during which the 2-DG and 2-DG-6-P can freely diffuse and interfere with the localization of the label within cells. One way to prevent diffusion is to replace the water in the cell with a solvent in which 2-DG and 2-DG-6-P are insoluble and to exclude water from the tissue in all subsequent steps. We have localized [^{3}H]-2-DG using two methods: in the first, the tissue was frozen and freeze-substituted[10] with acetone at −70 °C, and in the second, the tissue was dehydrated in dry acetone at 4 °C.

The buccal ganglion of *L. maximus* innervates the animal's feeding musculature and contains several large identifiable neurones as well as several hundred smaller cells[11,12]. The stereotyped structure of the ganglion, its small size (about 1 mm in diameter) and its accessibility to electrophysiological techniques make it suitable for studying the uptake of 2-DG by single neurones. In each experiment, a pair of buccal ganglia was dissected and placed in saline modified by lowering Ca^{2+} to 0.07 times its normal concentration and raising Mg^{2+} by five times to reduce transmission at chemical synapses. (The composition of the solution was 56 mM Na^+, 4.2 mM K^+, 0.5 mM Ca^{2+}, 23 mM Mg^{2+}, 104 mM Cl^-, 0.2 mM $H_2PO_4^-$, 2.5 mM HCO_3^- and 5 mM dextrose.) Approximately 100 μCi ml^{-1} of 2-[1,2-^{3}H]-deoxy-D-glucose (New England Nuclear NET-549, specific activity 40 Ci mM^{-1}) was added to the bath and the ganglia were incubated for 1 h or less, depending on the experiment. Afterwards, the ganglia were rinsed in five washes of fresh saline over 30 min. For freeze-substitution, the ganglia were then rapidly frozen in Freon 22 cooled to −160 °C with liquid nitrogen, placed in a vial containing 20 ml dry acetone and 1 g of Al_2O_3 (Brockman grade 1), and kept at −70 °C for 48 h. For acetone dehydration, the ganglia were placed in an identically prepared vial and kept at 4 °C overnight. No fixatives were used. (Fixation with glutaraldehyde[6,7] results in a loss of over 90% of the radioactivity from the tissue[7,8].) After either freeze-substitution or dehydration, the tissue was gradually warmed to room temperature and embedded in Araldite to which 1% by weight Dow-Corning silicone fluid[13] had been added. The embedded

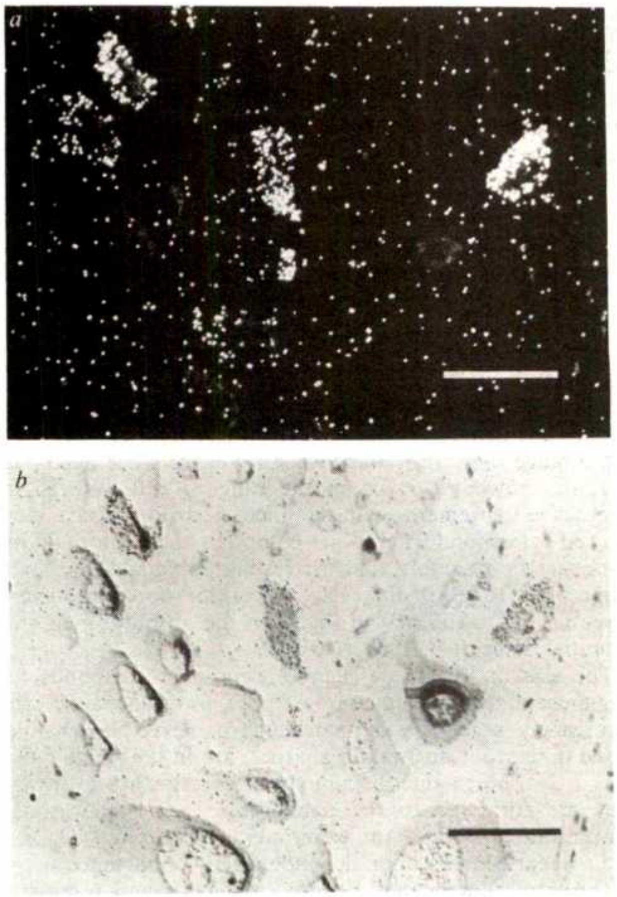

Fig. 2 Light-microscopic autoradiograph of several labelled cell bodies in a buccal ganglion. The ganglion was incubated in [^{3}H]-2-DG for 20 min and dehydrated in dry acetone at 4 °C. During the incubation a neurone was stimulated with an intracellular electrode to elicit action potentials at the rate of 2 s^{-1}. The sections were lightly stained with methylene blue. *a*, Five labelled cells (dark-field illumination). The cell bodies could be traced in serial sections through the ganglion. The nuclei of the two labelled cells on the far left and the cell on the far right were not labelled above background. The average density of silver grains over the labelled cells was 0.1 μm^{-2}–0.5 μm^{-2}, which was approximately 10–50 times the background density over surrounding tissue. *b*, The same section in *a*, photographed using Nomarski differential interference contrast optics. Scale bar, 40 μm.

tissue was then dry-sectioned at 2–4 μm on an ultramicrotome and placed on a slide coated with a thin layer of anhydrous glycerol. The glycerol was evaporated by setting the slide on a hot plate at 110 °C. The slides were then dipped in Kodak NTB-2 nuclear emulsion, dried, exposed at 4 °C for 2–4 weeks, developed in Kodak D-19 at 16 °C for 6 min, washed and stained with either 1% methylene blue or 1% toluidine blue.

Scintillation counting was used to determine the uptake of [^{3}H]-2-DG by ganglia during incubation and the loss of label during subsequent processing. The amount of radioactivity left in the acetone following either freeze-substitution or dehydration was less than 0.5% of the total radioactivity remaining in the ganglion. The loss of label during autoradiography was not quantitatively assessed, but it was probably low because spreading of label around the edges of the section or around discretely labelled structures within the section was never seen.

Autoradiographs of buccal ganglia incubated in [^{3}H]-2-DG revealed labelled individual neurones in all preparations. No cells were labelled in control ganglia incubated without [^{3}H]-2-DG, thus ruling out positive chemography. In seven heavily labelled cells from three preparations, the density of silver grains over cell bodies was between 0.1 μm^{-2} and 4.5 μm^{-2}, which was 10–50 times the mean background density over adjacent tissue. The glucose utilization is therefore 10–50 times greater within some cells than without. The localization of [^{3}H]-2-DG in a single heavily labelled buccal neurone is shown in Fig. 1*a*. The density of silver grains drops sharply at the boundary of the cell body, with the transition from maximum grain density to background occurring in less than 1 μm (Fig. 1*b*). The resolution of the technique appears to be limited by the size of a developed silver grain, which has a diameter of 0.5 μm. Whenever the stained cell membrane of a labelled cell is visible, the grain density drops abruptly at the cell membrane. In some labelled cells, such as those shown in Fig. 2, the grain density also drops abruptly at the nuclear membrane, with much lower labelling over the cell nucleus than the cytoplasm. In addition to labelled cell bodies, labelled structures could also be detected in the neuropil.

The high resolution obtained with this technique is probably the result of removing water from the tissue. During freeze-substitution, the maximum concentration of water at the interface between ice and acetone is 4% at −70 °C (ref. 14). Thus, molecules insoluble in acetone diffuse very little from the site at which they were immobilized during freezing. For example, freeze-substitution has been used to localize Ca^{2+} in subcellular compartments[15]. More diffusion of 2-DG and 2-DG-6-P occurs within the cell with acetone dehydration at 4 °C than with freeze-substitution at −70 °C. However, the labelling of single cell bodies using acetone dehydration had the same resolution as with freeze-substitution. We can therefore conclude that both freeze-substitution and acetone dehydration are effective in localizing [^{3}H]-2-DG within single neurones.

The [^{3}H]-2-DG technique presented here can be used to measure the qualitative change in the distribution of label under different conditions. Preliminary experiments indicate that the labelling of single neurones demonstrated here is correlated with spontaneous and stimulated electrical activity in the ganglion[16]. The technique could be useful in studying networks of neurones underlying behaviour in the isolated central nervous system[17]. In particular, the participation of small neurones, which are difficult to study electrophysiologically, can be monitored as easily as large neurones. It may also be possible to measure the metabolic activity of axon terminals in the neuropil. As the resolution reported here is close to the limiting resolution of light microscopy, further improvement will require the use of electron microscopy.

This investigation was supported by NIH postdoctoral fellowships MH07670 (T.J.S.) and NS05188 (S.C.R.). Repeated tricyclics induce a progressive dopamine autoreceptor subsensitivity independent of daily drug treatment

Louis A. Chiodo & Seymour M. Antelman*

Psychobiology Program, Department of Psychology,
University of Pittsburgh, Pittsburgh, Pennsylvania 15260

Dopamine (DA) has largely been ignored in considering possible mechanisms underlying the therapeutic effects of tricyclic anti-depressants (TCA)[1–3]. Most previous work done has focused on the ability of some TCAs to block the *in vitro* re-uptake of DA[1]—an effect which unfortunately requires very high doses. Recently, however, Serra *et al.*[3] proposed that TCAs may exert their therapeutic effects by inducing a subsensitivity of presynaptic receptors located on the dendrites and soma of DA neurones (DA autoreceptors). This hypothesis was directly tested by examining the influence of TCAs on the demonstrated ability of the DA agonist, apomorphine, to depress selectively the spontaneous activity of single DA cells. We now report that repeated administration of both typical and atypical TCAs induces a progressive subsensitivity of DA autoreceptors, and that this gradual augmentation of DA autoreceptor subsensitivity depends on the passage of time rather than daily TCA administration. The latter finding suggests that daily drug administration may not be therapeutically necessary.

The 53 male albino rats (200–250 g; Zivic Miller) used in these studies were housed two per cage with free access to food and water and maintained on a 12 h light/dark cycle. Animals were handled and weighed daily for 2 weeks before experiments began. All experiments were done in double-blind conditions. After a period of drug treatment (specified below) the animals were anaesthetized with chloral hydrate [400 mg per kg, intraperitoneally (i.p.)], mounted in a stereotaxic apparatus and the spontaneous discharge rates of single DA neurones located within the zona compacta of the substantia nigra (SNC; coordinates: anterior 1,300–2,400 μm, lateral 1,300–2,400 μm [ref. 4]) were monitored as previously described[5,6]. Briefly, extracellular electrical activity was recorded through glass micropipettes filled with 2 M NaCl which was saturated with fast green dye (tip size 1–3 μm, *in vitro* d.c. impedance of 4–12 MΩ). Neuronal signals were fed into a high input–impedence differential amplifier (bandpass filters: 100 Hz and 3 kHz) whose output was led into a window discriminator, a signal integrator and digital frequency meter. The femoral vein was catheterized for the intravenous (i.v.) administration of all pharmacological agents. All drug doses are based on the weight of the salt. At the termination of each experiment the recording

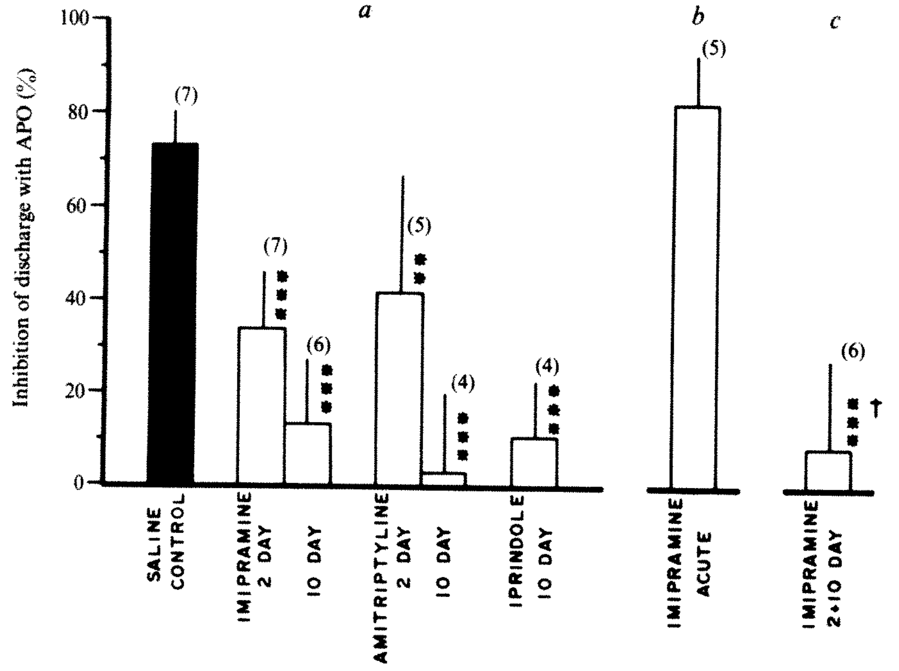

Fig. 1 The effects of various TCA treatments on the apomorphine-induced (APO; 0.004 mg per kg, i.v.) inhibition of the spontaneous activity of zona compacta DA neurones. See text for doses and details. $^{***}P<0.001$, $^{**}P<0.02$; two-tailed *t*-test, $\dagger P<0.05$ relative to 2-day imipramine group. Number tested in parentheses.

site was marked by passing a 40-μA negative current for 10 min which results in the injection of the dye[7]. The animals were then perfused and the brain sliced and stained. All neurones reported in this study were histologically located in the zona compacta region of the substantia nigra.

Single DA neurones were located on the basis of the previously described electrophysiological criteria of Bunney and Aghajanian[8]. That is, DA cells within the SNC spontaneously discharged at rates of 1–9 Hz, had biphasic action potentials (+/−) with amplitudes of 0.4–1.5 mV and typically displayed a train of action potentials or 'burst' on discharge. All cells also met the pharmacological criteria for identifying DA neurones established by these investigators[8,9]. Spontaneous activity was inhibited by the administration of a presynaptic dose of apomorphine and increased by the DA antagonist, haloperidol. To avoid contaminating any of our results, verification of the effects of haloperidol always took place immediately before terminating the recording session.

In the first experiment we investigated whether repeated injections of both typical (imipramine and amitriptyline) and atypical (iprindole) TCAs could alter DA autoreceptor sensitivity. Animals were placed into one of the following treatment groups: (1) 2 days of imipramine; (2) 10 days of imipramine; (3) 2 days of amitriptyline; (4) 10 days of amitriptyline; (5) 10 days of iprindole; and (6) 10 days of saline vehicle. All drugs were administered intraperitoneally in a dose of 10 mg per kg twice daily. Forty-eight hours after cessation of drug treatment the animals were recorded from as described above. Once a DA neurone was located its spontaneous activity was monitored for a minimum of 4 min to establish a reliable baseline rate. Apomorphine was then administered. Since a 0.004 mg per kg (i.v.) dose of apomorphine has been shown to inhibit DA neuronal activity by stimulating only DA autoreceptors located within the SNC[10], we used the degree of inhibition obtained with this dose as our index of DA autoreceptor sensitivity. The present results indicate that repeated TCA injection induces a subsensitivity of presynaptic DA autoreceptors (Figs 1*a*, 3). All TCA treatments resulted in a significant attenuation of the ability of apomorphine to inhibit the spontaneous discharge of DA neurones. Ten days of TCA administration resulted in a greater degree of DA autoreceptor subsensitivity than 2 days of treatment. Although TCA treatment also produced a tendency toward an overall increase in baseline firing rates, relative to saline controls this difference was not statistically significant.

To determine the possible functional significance of TCA-induced DA autoreceptor subsensitivity we examined the responsiveness of subsensitive cells to tail pressure, a mildly activating, non-painful stimulus. We have previously shown that tail pressure induces DA-dependent behaviours and also alters the activity of midbrain DA neurones[5,6]. All TCA treatments increased the ability of tail pressure to alter the spontaneous discharge of DA neurones (Fig. 2). This effect was significantly different from saline controls in both the 2- and 10-day imipramine groups as well as the 10-day amitriptyline group ($P<0.05$ for all three). Interestingly, the 10-day amitriptyline group, which showed the greatest degree of DA autoreceptor subsensitivity, was the group most responsive to tail-pressure induced changes in discharge. The fact that some of the groups (that is, the 10-day iprindole) did not reach statistical significance is probably due to a combination of relatively small group size and a large degree of group variance.

To investigate the possibility that residual TCAs might simply be competing with apomorphine for autoreceptor binding and, in so doing, reduce its effectiveness, we examined the effects of acute administration of imipramine (0.4 mg per kg, i.v.) on the subsequent injection of apomorphine (0.004 mg per kg, i.v.). Acute imipramine had no effect on the ability of apomorphine to inhibit DA neuronal discharge (Fig. 1*b*). It also failed to alter the spontaneous activity or responsiveness to tail pressure of these neurones relative to controls (Fig. 2).

The augmentation of DA autoreceptor subsensitivity seen after 10 days of imipramine and amitriptyline treatment is reminiscent of the progressive behavioural sensitization that can occur following the administration of amphetamine and other stimulants[11,12]. Although stimulant sensitization is usually induced by repeated drug treatment it is not dependent on such treatment and long-lasting effects have been observed following only a single amphetamine injection[13]. These findings raise the question of whether the progressive DA autoreceptor subsensitivity that occurs between 2 and 10 days of TCA treatment actually depends on administering these agents for 10 days.

To answer this question we ran an additional group of animals which received 2 days of imipramine (10 mg per kg, i.p. twice a day) followed by 10 drug-free days. Thus, this group was tested for subsensitivity at the same time as the group receiving 10 days of imipramine followed by 2 drug-free days. This treatment produced the same degree (actually 32% greater) of DA autoreceptor subsensitivity as the 10-day imipramine group

(Fig. 1c). Consistent with these data, 2 days of imipramine followed by 10 drug-free days (2+10 day group) resulted in significantly greater subsensitivity than an equal number of injections followed by only 2 drug-free days (2+2 day group). That is, the administration of the presynaptic dose of apomorphine inhibited the spontaneous activity of DA cells by only 9.2±19.0% in the 2+10 day group but by 34.1±12.4% in the 2+2 day group ($P<0.05$, see Fig. 1). This experiment clearly demonstrates that the TCA-induced progression in DA autoreceptor subsensitivity is not dependent on repeated daily drug treatment. Moreover, these data provide an additional and definitive argument against explaining subsensitivity in terms of direct competition between TCAs and apomorphine. That is, maximal subsensitivity was observed at a time (10 days after cessation of injections) when little if any residual imipramine would be expected in the brain.

The present study provides the first electrophysiological demonstration of DA autoreceptor subsensitivity. Moreover, the fact that both classical and newer TCAs induce progressive subsensitivity within the same time frame as their antidepressant effects suggests that DA autoreceptor subsensitivity must be considered as a possible mechanism underlying the therapeutic effects of these agents. Finally, and perhaps most significantly, we have found that the progressive augmentation of DA autoreceptor subsensitivity induced by TCAs is not dependent on repeated daily drug administration. Thus, short-term drug treatment seems to be sufficient to trigger a subsensitivity which then undergoes a progressive enhancement as a function of time regardless of whether TCAs are again administered. This finding may be clinically relevant in several respects. If presynaptic DA autoreceptor subsensitivity is critical for the therapeutic efficacy of TCAs, then our data suggest that daily treatment with these agents may not be necessary for the amelioration of depression. The same data also provide a possible explanation of the delayed therapeutic onset of TCAs—it may reflect the time necessary for the development of a critical degree of receptor subsensitivity as well as the build-up of TCAs to steady-state therapeutic concentrations[14]. It would be interesting to know whether TCA-induced changes in noradrenaline[15,16] and serotonin[17] receptors are also independent of repeated drug treatment.

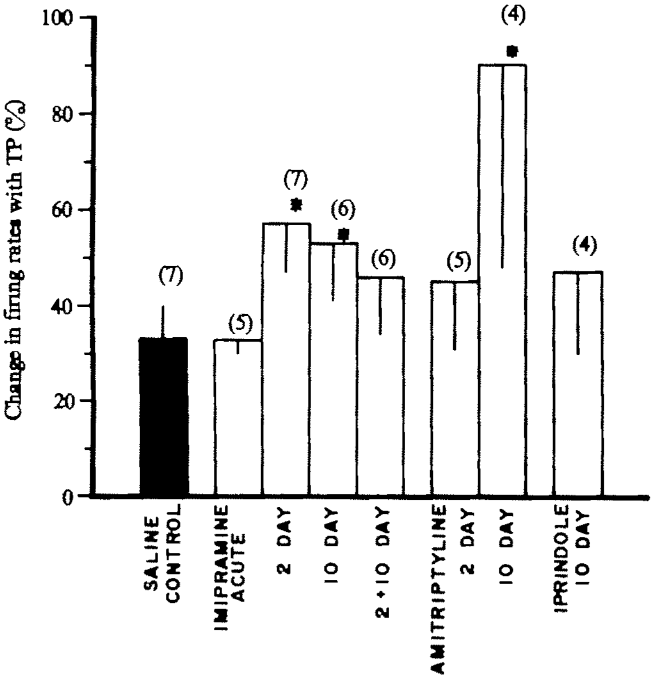

Fig. 2 TCA potentiation of tail-pressure induced (TP) changes in DA neuronal discharge. Data from same animals represented in Fig. 1. *$P<0.05$, two-tailed t-test. Number tested in parentheses.

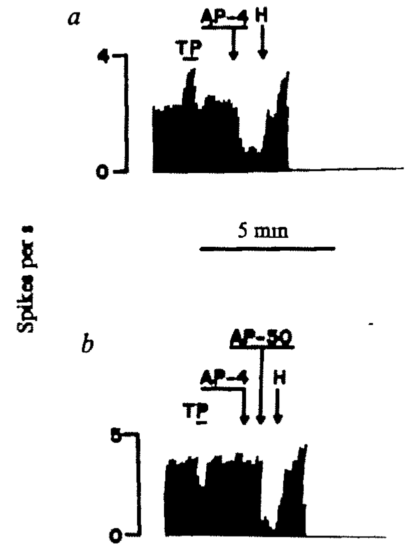

Fig. 3 Cumulative histograms of DA neurones located in the zona compacta demonstrating the effects of repeated TCA treatment on the ability of a presynaptic dose of apomorphine (APO-4; 4 μg per kg, i.v.) to inhibit the spontaneous firing of these neurones. *a*, Saline-treated control cell. A presynaptic dose of apomorphine produced an 81% inhibition of neuronal activity. Haloperidol (HAL; 0.2 mg per kg, i.v.) reversed this effect. *b*, Cell from an animal treated with imipramine for 10 days. A presynaptic dose of apomorphine had no effect on the spontaneous activity of this cell however, the subsequent administration of a postsynaptic dose of apomorphine (APO-50; 50 μg per kg, i.v.) was able to inhibit neuronal discharge by 86%. Haloperidol (0.2 mg per kg, i.v.) again reversed this effect. Horizontal bars represent the duration of the sensory stimulus, mild tail pressure (TP). Arrows indicate the i.v. administration of pharmacological agents.

The possible functional significance of subsensitive DA autoreceptors is reflected in our finding that animals showing such a subsensitivity also demonstrate an enhanced responsiveness to an activating environmental stimulus (tail pressure). Enhanced responsiveness to environmental stimuli is essentially the functional definition of successful TCA treatment.

Although TCA doses used in these experiments are about four times those used clinically this is not likely to explain our findings as preliminary data from our laboratory indicate similar effects with electroconvulsive shock, a non-pharmacological antidepressant treatment. This raises the question of whether our findings are specific to treatments having an antidepressant effect. In this regard, it should be noted that perturbation of DA autoreceptors does not invariably give rise to subsensitivity. Using a similar procedure Gallager *et al.*[18] have shown that repeated treatment with haloperidol induces DA autoreceptor supersensitivity.

We can only speculate about the mechanisms underlying TCA-induced subsensitivity of DA autoreceptors. First, a blockade of dendritic DA uptake[19] would result in overstimulation of DA autoreceptors which might then compensate by the induction of subsensitivity. Second, by analogy to the finding that repeated TCA administration produces a decrease in the number of cortical β-adrenergic receptors[16], it is possible that a similar decrease in the number of DA autoreceptors underlies our effects. Finally, it is important to note that our data are not incompatible with the induction of noradrenergic subsensitivity[15,16] which has been reported to follow repeated TCA treatments. Our noradrenaline–dopamine interaction hypothesis[20,21] indicates that decreased noradrenaline activity actually results in an increase in DA functioning. For instance, interference with noradrenaline activity either by inhibiting synthesis, stimulating presynaptic α-receptors or postsynaptic

α-receptor blockade can reverse the behaviourally suppressive effects of postsynaptic DA receptor antagonists (ref. 20, and unpublished observations).

We thank Dr J. Perel for comments on this manuscript. This work was supported by MH-32306 and RSDA MH-00238 (to S.M.A.), MH-16581, and training grant 5T32-MH-14634.

Interferon treatment inhibits glycosylation of a viral protein

Earlier, we reported[1] a 30–200-fold reduction in the yield of infectious vesicular stomatitis virus (VSV) released from L cells treated with 10–30 reference units ml^{-1} of interferon (IFN); however, in these cultures virus particle production, as measured by VSV particle-associated viral RNA, virus nucleocapsid protein and viral transcriptase, was inhibited less than 10-fold. There was biochemical and morphological evidence of a significant reduction in glycoprotein (G) and membrane protein (M) of VSV particles released from IFN-treated cells[2,3]. We compare here the effects of tunicamycin (TM) and IFN in L cells. Treatment with TM or IFN reduced the production of infectious VSV particles, decreased the amount of G and M proteins in VSV released from treated cells, and inhibited an early step in the formation of asparagine-linked oligosaccharide chains, the incorporation by membrane preparations from treated cells of *N*-acetylglucosamine into glycolipids with the properties of dolichol derivatives.

It is known that G protein of VSV contains two 'complex' type asparagine-linked oligosaccharide chains[4]. The role of polyisoprenoid glycolipid intermediates in the biosynthesis of *N*-glycosidically bound oligosaccharides is well established[5–8], and work by several groups[9–11] has implicated dolichol-linked oligosaccharides in the glycosylation of the G protein of VSV. TM, a glucosamine-containing antibiotic produced by *Streptomyces lysosuperficus*[12], inhibits the lipid intermediate pathway by blocking the transfer of *N*-acetylglucosamine-1-phosphate from UDP-*N*-acetylglucosamine to dolichyl monophosphate (Dol-P)[13–19]. Treatment with TM inhibited the formation of glycosylated G protein in VSV-infected BHK cells[20–22].

The Indiana strain of VSV used in this work was plaque purified and passaged at low multiplicities. Virus titre was assayed as 50% tissue culture infectious doses ($TCID_{50}$) by observation of virus-induced cytopathic effect in Vero cells grown in microtitre plates, or by a plaque titration method as PFU ml^{-1}; the titre was 2×10^9 $TCID_{50}$ ml^{-1}. The mouse L cell (from Dr D. Burke) was very sensitive to the virus growth inhibitory effect of mouse IFN. Mouse IFN was prepared and partially purified on an antibody affinity column[23]. The specific activity of this preparation was greater than 4×10^7 international mouse reference units (r.u.) per mg protein.

Table 1 Effect of IFN and TM on the production of VSV

VSV released from L cells treated with:	Virus titre (PFU ml^{-1})	Inhibition ($\log_{10}$)
Control for IFN (no treatment)	8.0×10^7	—
IFN (30 r.u. ml^{-1})	7.5×10^5	2.1
Control for TM (no treatment)	3.0×10^7	—
TM (0.5 μg ml^{-1})	4.0×10^6	0.90
TM (1.0 μg ml^{-1})	4.0×10^5	1.90

L cells were grown in 150 cm^2 flask (2×10^7 cells) and treated with 0–30 r.u. per ml of interferon for 14 h; the cell monolayers were washed three to four times to remove the residual interferon. All monolayers were then infected with VSV at a multiplicity of five plaque-forming units (PFU) per cells. TM (0.5 or 1 μg ml^{-1}) was added to cells after 1 h of VSV infection. All monolayers were further incubated for 20 h. The supernatant fluids were then collected and sedimented at 10,000*g* to remove cell debris. Virus titre in these supernatant samples were quantified by a plaque titration method.

There was a 200-fold decrease in infectious virus titre in VSV released from L cells treated with IFN (30 r.u. ml^{-1}). TM (0.5–1 μg ml^{-1}) inhibited the infectious virus production in the range of 10–80-fold (Table 1). Purified virus samples with the same amount of protein or radioactivity were applied to SDS-polyacrylamide gel electrophoresis (PAGE) slab gels[24]. After electrophoresis, the gels were stained, dried and exposed to Kodak X-OMAT film. When the incorporation of radioactive precursor was quantified by fluorography[25], three proteins (G, N and M) were clearly visible in samples of virus not treated with TM; however, in VSV released from TM (0.5–1 μg ml^{-1})-treated cells there was a dose-dependent decrease in G protein; also, a faster moving band appeared between G and N proteins. This band could not be labelled by glucosamine, suggesting that this was an unglycosylated G protein (Fig. 1, lane 3); the M protein was also inhibited in samples treated with TM. In VSV released from IFN-treated cells, there were also three proteins (G, N and M) clearly visible; however, the G and M proteins were reduced in amount compared to VSV released from cells not treated with IFN (Fig.1, lane 7). When the G protein was labelled with glucosamine and an equal amount of protein loaded on gels, we observed that in VSV released from IFN-treated cells, there was a very significant inhibition of glucosamine incorporation. Electron microscopic studies revealed that VSV particles released from cells treated with either TM or IFN lacked glycoprotein spikes. These effects of TM on released VSV were very similar to those observed in VSV released from cells treated with IFN (30 r.u. ml^{-1}) and suggested that in VSV released from cells treated with IFN, there was a deficiency in G protein compared to VSV released from untreated cells.

Since lipid-linked oligosaccharides are involved in the glycosylation of VSV glycoprotein G[9–11], we carried out preliminary studies to see if IFN treatment affected the biosynthesis

0028–0836/80/400454—03$01.00

of *N*-acetylglucosaminyl derivatives of dolichol. When membranes from IFN-treated cells were incubated with UDP-*N*-acetyl-[^{14}C]glucosamine, only 18% as much label was incorporated into glycolipid as compared to the preparations from untreated cells (Table 2). When the assays were carried out in the presence of 10 nmol of exogenous Dol-P, the labelling of glycolipid was stimulated in both preparations, but the rate of synthesis of glycolipid was still substantially higher in membranes from untreated cells. This result indicated that the reduction in glycolipid formation by IFN-treated cells was probably not due to a deficit in endogenous acceptor lipid. The direct addition of IFN to the incubation mixture had no effect on the labelling of the glycolipid fraction. The observations that the labelling of *N*-acetylglucosaminyl lipid was stimulated by exogenous Dol-P, was inhibited by TM$^{13-18}$ (data not shown), and that *N,N′*-diacetyl-[^{14}C]chitobiose was released by mild acid (0.01 M HCl, 100 °C, 15 min) treatment of the glycolipid fraction, strongly suggest that the glycolipids labelled in these experiments were *N*-acetylglucosaminyl derivatives of dolichol involved in lipid-mediated protein glycosylation. More detailed studies on the characterization of the glycolipids synthesized by this *in vitro* system are in progress.

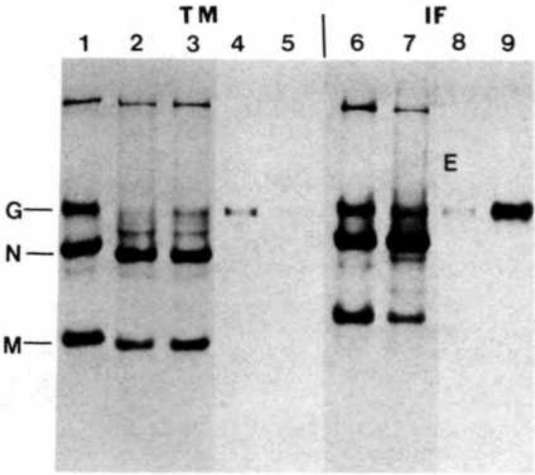

Fig. 1 L cells were treated with IFN or TM as described in Table 1. After virus adsorption and incubation for 2 h, the monolayers were washed with methionine-free medium and then ^{35}S-methionine (20 μCi ml^{-1}, specific activity, 800 Ci mmol^{-1}, Amersham) was added to monolayers in special minimal essential medium (MEM) devoid of cold methionine and supplemented with 2% dialysed fetal calf serum (FCS). After 6 h of incubation, 2 ml of regular MEM supplemented with 5% FCS was added to each culture and cells were incubated overnight. For labelling of glycoprotein (G), monolayers were infected with VSV for 2 h and the cultures were washed with glucose-free MEM. All cultures were refed with 15 ml of special medium (glucose-free MEM) containing 20 Ci ml^{-1} of ^{3}H-glucosamine for 6 h and then 2 ml of regular MEM was added to each culture and cultures were incubated overnight. The supernatant fluids were collected and clarified at 10,000*g* for 15 min to remove cellular debris. The clarified supernatant fluids were centrifuged at 42,000*g* for 2 h. The pellet was resuspended in a small volume of TES (Tris-EDTA-sodium chloride) buffer (*p*H 7.2) and was further purified by banding on 20–50% (w/w) equilibrium sucrose gradients for 16 h at 72,000 *g*. Proteins were analysed by SDS-PAGE^{24}. Purified VSV proteins with equal amount of radioactivity were applied to the gels except those in which G protein was labelled with ^{3}H-glucosamine where equal amounts of protein were added. The gels were subjected to electrophoresis and then stained with Coomassie brilliant blue R. After destaining they were impregnated with 2, 5-diphenyloxazole (NEN), dried, and exposed to Kodak X-OMAT X-Ray film. Phosphorylase B (molecular weight 92,500), bovine serum albumin (molecular weight 69,000), ovalbumin (molecular weight 46,000), carbonic anhydrase (molecular weight 30,000), and cytochrome *c* (molecular weight 12,300) were used as reference protein molecular markers. TM lanes: (1), proteins labelled with ^{35}S-methionine of VSV from cells not treated with TM; (2), proteins of VSV from cells treated with TM (1 μg ml^{-1}); (3), proteins of VSV from cells treated with TM (0.5 μg ml^{-1}); (4), G protein of VSV labelled with ^{3}H-glucosamine and released from cells not treated with TM; (5), G protein of VSV released from cells treated with TM (1 μg ml^{-1}). IFN lanes: (6), proteins labelled with ^{35}S-methionine of VSV from cells not treated with IFN; (7), proteins of VSV from cells treated with IFN (30 units ml^{-1}); (8), G protein of VSV labelled with ^{3}H-glucosamine and released from cells treated with IFN (30 r.u. ml^{-1}); (9), G protein of VSV released from cells not treated with IFN. Three VSV proteins, G, N and M, are visible on gels.

Inhibition of the synthesis of *N*-acetylglucosaminyl lipids with properties of dolichol derivatives, that serve as precursors for the dolichol-bound oligosaccharide lipid intermediates in protein glycosylation, was lower by membrane preparations from IFN-treated cells as compared to membrane preparations from untreated cells and could also be partially responsible for results obtained with VSV released from L cells treated with IFN; such virions were selectively deficient in G and M protein$^{1-3}$. It might also explain results on Moloney murine leukaemia virus (MMLV) from IFN-treated TB cells, where virus with markedly decreased infectivity was produced^{26}. The MMLV virions were also deficient in the viral envelope glycoproteins gp 69/71, so that the decreased amount of glycoprotein may be directly related to a slower rate of synthesis of *N*-acetylglucosaminylpyrophosphoryldolichol (GlcNAc-P-P-Dol) in IFN-treated cells.

Table 2 Effect of IFN treatment on transfer of *N*-acetylglucosamine from UDP-*N*-acetylglucosamine into glycolipid

Treatment of cells	Addition to incubation mixture	*N*-Acetyl-[^{14}C]glucosamine incorporated into glycolipid fraction (c.p.m. per mg membrane protein)
None	None	6,180
None	Dol-P(10 nmol^{-1})	20,700
IFN(30 r.u. ml^{-1})	None	1,130
IFN (30 r.u. ml)	Dol-P(10 nmol)	2,680

L cells were grown in Petri plates to confluency (1 × 10^{7} cells) and were treated with 30 r.u. per ml of interferon overnight. All cell monolayers were washed with saline three times, scraped, and centrifuged at 1,500 r.p.m. for 10 min. The cell pellets were suspended in 4 vol of ice-cold buffer consisting of 0.1 M Tris-HCl (*p*H 7.0), 0.25 M sucrose, 1 mM EDTA and homogenized. After homogenization, the suspensions were clarified by centrifugation at 8,500*g* for 5 min. The supernatant fluids were pelleted at 39,000*g* for 20 min and the pellets (crude particulate fraction) were resuspended in homogenization buffer. The protein content was measured by the Lowry procedure^{28}. Each reaction mixture contained crude particulate enzyme preparation; 50 mM Tris-HCl (*p*H 8.0); 0.125 M sucrose; 0.5 mM EDTA; 15 μM UDP-*N*-acetyl-[^{14}C]glucosamine (620 c.p.m. pmol^{-1}); 10 mM $MgCl_2$ and 0.02% Triton X-100 in a total volume of 0.1 ml. Dolichyl monophosphate was dispersed by ultrasonication in 0.1% Triton X-100 and 10 nmol were added where indicated. Following an incubation at 37 °C for 10 min the amount of *N*-acetyl-[^{14}C]glucosamine incorporated into the glycolipid fraction was assayed as described elsewhere^{17}. Lipid-phosphorous was determined by the Bartlett procedure^{29}. Dol-P, dolichyl monophosphate.

It will be interesting to determine whether the synthesis of GlcNAc-P-P-Dol is generally sensitive to IFN-treatment in a wide variety of animal cells. If glycosylation of asparagine residues in viral membrane glycoproteins is critical for the assembly of infectious particles of some viruses, inhibition of the enzymatic transfer of *N*-acetylglucosamine-1-phosphate from the nucleotide derivative to Dol-P would be an effective means of impeding viral production. The effects on glycosylation may also be pertinent to the varied activities of interferons on cell growth and on the immune system^{27}.

We thank Ms S. Harrell and F. Mottram for technical help, and Dr D. Epstein for many helpful discussions.

Integration of Moloney leukaemia virus into the germ line of mice: correlation between site of integration and virus activation

Detlev Jähner & Rudolf Jaenisch

Heinrich-Pette-Institut für Experimentelle Virologie und
Immunologie an der Universität Hamburg,
Martinistrasse 52, 2000 Hamburg 20, FRG

Endogenous avian[1–3] and murine[4–9] C-type viruses are genetic elements which are transmitted at several distinct chromosomal loci. Different patterns of virus activation have been observed in a variety of different mouse strains[10–12]. However, because there are multiple copies of closely related endogenous viruses in every mouse strain, the genetic basis of the differential expression of these genes is poorly understood. A new substrain of mice, BALB/Mo, was derived previously[13] carrying the exogenous Moloney leukaemia virus (M-MuLV) genome on chromosome 6 (ref. 14). Virus activation occurs in lymphatic tissues of all BALB/Mo mice soon after birth[12]. We report here the derivation of three new substrains of mice each carrying a single M-MuLV genome on different chromosomal integration sites. Each locus was associated with a distinct phenotype of virus expression. Evidence is presented that apparently identical viral genomes show differences in spontaneous virus activation and that defective viral genomes can be carried in the germ line of mice.

Four to eight cell embryos were isolated from pregnant mice, treated with pronase to remove the zona pellucida and cultivated *in vitro* as described previously[13,15]. For infection with M-MuLV the embryos were co-cultivated overnight with subconfluent Cl 1A cells[16]. They developed into blastocysts and were subsequently transferred into the uterus of a pseudopregnant female. Of 28 mice derived in this way, 12 were viraemic when tested by radioimmunoassay for p30 at the age of 4 weeks. One viraemic male (no. 62) of ICR origin was selected. When mated with normal females, 20 of his 75 offspring were viraemic at 4 weeks of age. This paternal transmission of virus suggests that M-MuLV was integrated into cells of the germ line of male 62. The fraction of viraemic offspring observed (26%) deviates from the mendelian expectations for transmission of a single dominant gene and suggests 'germ-line mosaicism'[13]. Biochemical evidence (Fig. 1) indicates that male 62 was not only mosaic in the germ line but also in somatic tissues (see below). In contrast, his viraemic sons transmitted viraemia to approximately 50% of their offspring. This mendelian transmission indicates that they were heterozygous for a single viraemia-inducing genetic locus and indicates that the exogenous M-MuLV had been converted to an endogenous virus in these mice.

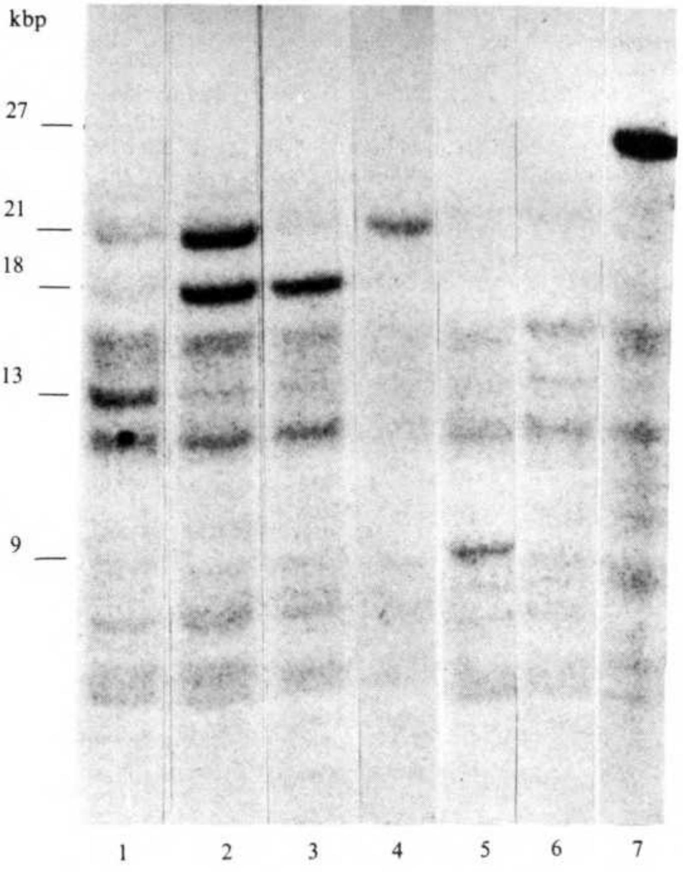

Fig. 1 Restriction enzyme analysis of mouse liver DNA. High molecular weight DNA from liver biopsies was digested with *Eco*RI, separated on agarose gels, transferred to nitrocellulose filters and hybridized to M-MuLV-specific cDNA as described[19]. *Eco*RI-digested λ DNA was used as a size marker. Lane 1, DNA from male 62; lanes 2–5, DNA from individual N-1 animals; lane 6, ICR control; lane 7, BALB/Mo DNA. The size and position of M-MuLV-specific fragments is indicated on the left. kbp, Kilobase pairs.

The integration site of M-MuLV in the DNA of male 62 and his offspring was analysed with the restriction enzyme *Eco*RI using the technique of Southern[17]. This enzyme has no recognition site in the viral genome[18]. M-MuLV-specific sequences were detected above the background of endogenous murine viruses by using an M-MuLV-specific probe[19]. Figure 1, lane 7, shows a single M-MuLV-specific fragment with a molecular weight of 27 kilobase pairs in BALB/Mo liver DNA which was run as a control. This band represents the endogenous M-MuLV copy in BALB/Mo mice[19,20]. Multiple bands with much lower relative intensities than the M-MuLV-specific bands are present in all mouse DNAs and are due to residual cross-homology of our specific probe with endogenous murine viruses. Three new M-MuLV-specific fragments not present in the uninfected control (lane 6) with molecular weights of 21, 18 and 9 kilobase pairs, respectively, were detected in the offspring of male 62 (lanes 2–5). The liver of male 62 (lane 1) carries all three

Table 1 Characterization of genetically transmitted M-MuLV sequences and phenotype of mice

Origin	No. of animals	M-MuLV in *Eco*RI fragment (size in kilobase pairs)	No. of M-MuLV copies per diploid genome equivalent	Expression of viraemia	Genetic locus
Male 62	1	21 18 13 9	2	+	–
N-1 of male 62	3	21	1–1.2	–	*Mov-2*
	5	18	0.9–1.2	+	*Mov-3*
	8	21 18	2–2.4	+	*Mov-2* *Mov-3*
	6	9	0.9–1.1	–	*Mov-4*
	8	–	0	–	–
BALB/Mo (heterozygous)	–	27	1	+	*Mov-1*

Backcross animals of the N-1 generation from male 62 were derived as described in the text. Viraemic and non-viraemic offspring were partially hepatectomized[21] and the liver DNA was subjected to restriction enzyme analysis and to quantitative hybridization using specific M-MuLV cDNAs as hybridization probes[19,22]. The size of M-MuLV-specific *Eco*RI fragments (see Fig. 1) and the number of M-MuLV-specific DNA copies per diploid mouse genome equivalent are given[22]. Animals were tested for viraemia at 3 weeks of age[13]. Designation of genetic loci is explained in the text. Data on BALB/Mo mice are taken from previous publications[19,20].

M-MuLV-specific bands found in his offspring and one additional band of 13 kilobase pairs. These band intensities are weaker than the respective bands in DNA of his offspring. Together with quantitative hybridization data (Table 1) detecting only two M-MuLV copies per genome equivalent, these results indicate that M-MuLV sequences were present in only part of the liver cells. Thus male 62 showed mosaicism in somatic tissues as well as in the germ line.

Restriction enzyme analysis of liver DNA revealed five genotypes among his offspring (Table 1). The 21- and 18-kilobase pairs M-MuLV-specific bands segregated independently and were found alone or in combination in individual offspring. This suggests that a single blastomere of male 62 was doubly infected with virus and gave rise to a clone of infected cells. Animals carrying the 9-kilobase pair band presumably originated from germ cells derived from a different infected blastomere. This interpretation is supported by the equal intensities of the 21- and 18-kilobase pair bands as opposed to the unequal intensities of the 13- and 9-kilobase pair bands, respectively, in the liver of male 62 (Fig. 1, lane 1).

Genetic segregation studies showed that the 21- and 18-kilobase pair fragments were transmitted at the expected mendelian ratio of approximately 50% to the N-2 generation (Table 2). Germ-line transmission was also found in animals segregating the 9-kilobase pair copy. Our results define three new genetic loci carrying M-MuLV-specific sequences, designated *Mov-2, Mov-3* and *Mov-4* corresponding to the M-MuLV-specific *Eco*RI fragments of 21-, 18- and 9-kilobase pairs length, respectively. The locus representing the M-MuLV gene in BALB/Mo mice has been designated previously as *Mov-1* (ref. 14).

The structures of the integrated M-MuLV genomes were analysed after digestion of cellular DNA with the restriction enzyme *Pvu*II (Fig. 2). Fragments *a, b, c, d* correspond to the 3′ half, the *pol* region, the *gag* region and the *pol–gag* junction, respectively, of the M-MuLV genome[23]. No difference was observed between the internal M-MuLV fragments generated from *Pvu*II cleavage of DNA from mice of genotype *Mov-1* (lane 2), *Mov-2* (lane 3) or *Mov-3* (lane 4). DNA from mice with genotype *Mov-4*, however, had lost the largest *Pvu*II fragment (lane 5), suggesting that the integrated M-MuLV in these mice contains a deletion in the 3′ half of the viral genome. Further analysis with *Sac*I confirmed this conclusion (data not shown). Our results show that no major rearrangements in the M-MuLV genomes carried in the latter three substrains of mice have occurred and that partially deleted viral copies can be present in the germ line of mice.

Table 2 correlates the genotype of the mice with the status of viraemia. Three different phenotypes were observed: (1) early development of viraemia in animals carrying the *Mov-3* gene; (2) no viraemia at 3 weeks of age but occasional activation of M-MuLV later in life in animals carrying the *Mov-2* gene; (3) no occurrence of viraemia in animals carrying the *Mov-4* gene. Viraemia in *Mov-3* animals occurred at age 3 weeks or younger and was followed by rapid development of fatal leukaemia at 2 to 4 months of age. The genetic transmission of the *Mov-3* gene correlates well with the occurrence of viraemia and supports the conclusion that the presence of this gene induces early virus expression. Mov-2 animals, however, occasionally activate virus later in life. Table 2 shows that 14 out of 150 N-2 animals which were derived from Mov-2 males bred with normal females developed viraemia at 2 to 4 months of age. As only 50% of the offspring are expected to carry the *Mov-2* gene, the incidence of virus activation is approximately 20%. When viraemic N-2 males were bred again with normal females, a similar incidence of viraemia in the N-3 generation was observed. In contrast to Mov-2 animals, none of 60 offspring of Mov-4 animals became viraemic.

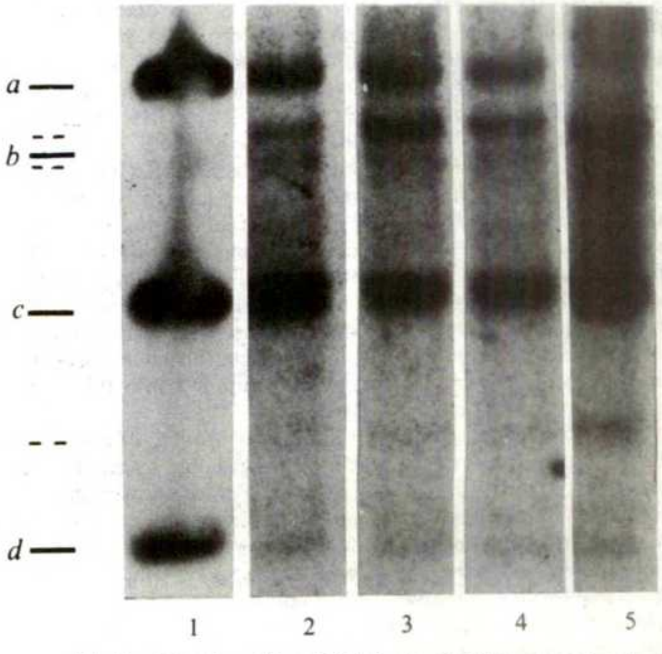

Fig. 2 Digestion of liver DNA by *Pvu*II. DNA was analysed as described in Fig. 1. Lane 1 shows a *Hin*dIII-*Pvu*II double digest of M-MuLV cloned in pBR 322 (provided by S. Goff). Lane 2, BALB/Mo DNA (Mov-1); lane 3, Mov-2 DNA; lane 4, Mov-3 DNA; lane 5, Mov-4 DNA. *a–d* Mark the positions of the M-MuLV fragments after *Pvu*II digestion as published[23].

Table 2 Genetic transmission of M-MuLV sequences and incidence of viraemia in second backcross generation

M-MuLV-specific *Eco*RI fragment in father	Locus	M-MuLV-specific sequences in DNA of N-2 mice/total tested	Viraemic N-2 animals/total tested	Percentage
18 Kbp	Mov-3	14/28	125/255*	49
21 Kbp	Mov-2	6/14	14/147†	9.5
9 Kbp	Mov-4	1/5	0/60	0

N-1 males of genotype Mov-2, Mov-3 and Mov-4 were identified after partial hepatectomy as described in Table 1. They were bred with normal females and some of the offspring were again partially hepatectomized and the presence of M-MuLV-specific sequences in the liver DNA determined by quantitative hybridization[22]. All animals were repeatedly tested for viraemia using the RIA for p30 (ref. 13).

* Animals segregating the *Mov-3* locus were viraemic at the youngest age tested (3 weeks).

† Animals segregating the *Mov-2* locus were non-viraemic at 3 weeks of age; some mice developed viraemia at later ages (between 2 and 4 months of age).

Having become viraemic, Mov-2 animals develop leukaemia quickly. The disease is indistinguishable by histological and molecular parameters from the leukaemia occurring in Mov-3 animals. The host range of the activated virus was determined. The virus grew equally well on NIH 3T3 and BALB 3T3 cells but did not replicate in CCl 64 cells. This phenotype bred true when cloned on either of the permissive cell lines. Thus the virus was NB tropic like the original virus used for infection of the embryos.

The sequence homology of Mov-2 and Mov-3 virus was analysed by molecular hybridization. RNA was isolated from NIH 3T3 cells which were infected with Mov-2 virus and from spleens of viraemic Mov-2 and Mov-3 animals. Each RNA preparation annealed to the same extent (95%) to M-MuLV cDNA at low C_rt values. In contrast, RNA of spleens from non-viraemic Mov-2 animals annealed to the same extent as RNA from control animals (15% annealing at a C_rt value of 10,000). Furthermore, when DNA from NIH 3T3 cells infected with virus activated from Mov-2 animals was digested with *Pvu*II, no differences in the cleavage pattern of integrated viral sequences were observed in comparison to Cl 1A virus, BALB/Mo virus or Mov-3 virus (data not shown). This suggests that Mov-2 animals activate NB tropic Moloney virus integrated into their germ line.

We chose Moloney leukaemia virus as a model system to establish the experimental conditions for integrating genetic material into the germ line of mice. The animal exposed to virus was a mosaic carrying viral genomes in part of his somatic and germ cells and genetically defined mouse strains were only obtained after segregating the genes in the next generation. As preimplantation embryos are not permissive for expression of viral functions[15], our experimental approach can be used to introduce other than viral genetic information into the germ line.

The M-MuLV genome carried at the *Mov-1, Mov-2* and *Mov-3* locus, respectively, was indistinguishable by all criteria used. Virus activation in the respective mice, however, was different. Thus, cellular sequences flanking an integrated viral genome may influence its expression by a *cis*-acting mechanism, as has been suggested[24,25]. The mechanisms by which animals have acquired endogenous viruses and the evolutionary forces that influenced virus expression are not known. Our results indicate that the endogenous viruses of mice may have entered the germ line by infecting early embryos and that the different phenotypes of virus expression observed in inbred mouse strains may depend on the chromosomal integration site of the virus. Our model system should facilitate investigations to understand the regulation of C-type virus expression during cellular differentiation and its possible role in evolution.

We thank Drs S. Goff, E. Gilboa and D. Baltimore for providing us with the M-MuLV clone and Dr J. Bilello and all members of the tumour virus laboratory for constructive criticism. The technical assistance of D. Grotkopp and E. Hoffmann is gratefully acknowledged. This work was supported by a grant from the Deutsche Forschungsgemeinschaft and by Research Contract NOICP 71008 from the NCI. The Heinrich-Pette-Institut is financially supported by Freie und Hansestadt Hamburg and by Bundesministerium für Jugend, Familie und Gesundheit, Bonn. This study was performed as part of the PhD study of D.J. at the University of Hamburg.

T-DNA of a crown gall teratoma is covalently joined to host plant DNA

***Agrobacterium tumefaciens* strains containing tumour-inducing (Ti) plasmids[1–3] incite cancerous growths called crown galls when inoculated into wounded dicotyledonous plants. Tumour tissue can be cultured axenically *in vitro*, and exhibits a transformed phenotype in the absence of the inciting bacterium. Transformed cells grow autonomously, are auxin and cytokinin autotrophic *in vitro*[4] and synthesize opines[5–8], novel amino acid derivatives dictated by Ti plasmid genetic information[9–11]. A small segment of the Ti plasmid, termed T-DNA is maintained in axenic tumour cells[12–19]. Mitochondrial and chloroplast DNA from a crown gall teratoma are free from T-DNA, whereas nuclear DNA contains T-DNA in amounts similar to that in total tumour cell DNA[20,21]. T-DNA appears to be attached to what is presumably plant DNA in the crown gall tumour cell: Southern blot analysis[22] of tumour DNA digested with restriction endonucleases reveals T-DNA fragments that are not fully homologous to Ti plasmid DNA[14,17,21]. We report here the isolation by molecular cloning of a 'border fragment' T-DNA and flanking plant DNA from the crown gall teratoma BT37 and show that T-DNA is covalently joined to a repeated DNA element of the tobacco nuclear genome.**

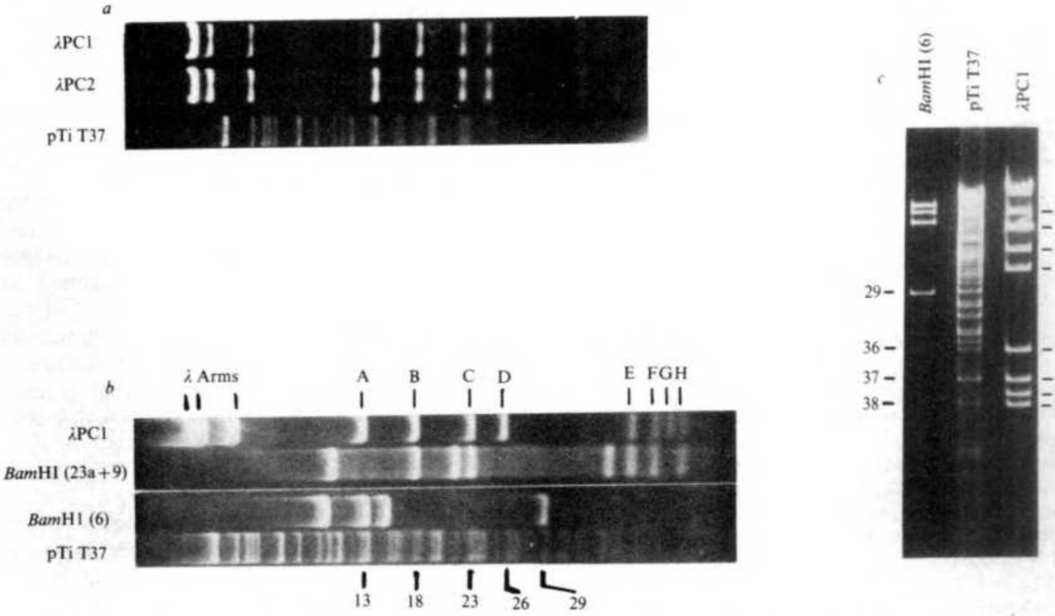

Fig. 1 *Eco*RI digests of DNA from λPC1 and λPC2, pTi T37 and cloned fragments of pTi T37. Charon 4A bacteriophage[30] DNA was digested with *Eco*RI and the vector arms separated from internal fragments by sedimentation through 5–20% NaCl linear gradients. Partial and complete *Eco*RI digests of BT37 tumour DNA, isolated as described in ref. 12, were fractionated in the same manner (F. Blattner, personal communication). Fragments 10–20 kilobases in size (correct for Charon 4A cloning inserts) were pooled. Phage arms (20 μg) and target fragments (7 μg) were incubated with T4 DNA ligase for 16 h at 4 °C (50 μl reaction volume). Packaging was performed by published procedures[23,24]. Phages were plated on 9.2 cm^2 Petri dishes at 20,000 plaques per plate. Lifts were prepared[25] and hybridized with pTi T37 DNA labelled *in vitro* by nick translation[26], in order to detect plaques containing T-DNA inserts. Two positive plaques, λPC1 and λPC2, were detected and purified. *a*, *Eco*RI digests of λPC1 and λPC2 DNA (isolated from CsC1 banded phage particles by phenol deproteinization and dialysis) and of pTi T37 DNA were fractionated by electrophoresis in a horizontal slab gel of 0.7% agarose as described previously[31]. The three largest molcular weight fragments in the phage DNA digests are Charon 4A arms. *b*, *Eco*RI digests of λPC1 DNA, pTi T37 DNA and two recombinant plasmids containing the left end of T-DNA from pTi T37 (see text and Fig. 2) were fractionated as described above in 1% agarose. c, *Eco*RI digests of λPC1 DNA, pTi T37 DNA and (as molecular weight marker) one recombinant plasmid from the left end of T-DNA were fractionated by vertical 1.5% agarose slab gel electrophoresis in TB buffer (10.8 g Tris base, 0.93 g disodium EDTA and 5.5 g boric acid per litre). Fragments of pTi T37 were numbered starting from fragment 29, which is also indicated in *b*. Fragment G is not an internal pT1 T37 fragment.

For molecular cloning of T-DNA fragments from BT37 tobacco teratoma DNA, we used the strategy of F. Blattner *et al.*[23]: shotgun cloning of a mixture of *Eco*RI partial and complete digest fragments of total tumour DNA into Charon 4A bacteriophage. Ligated DNA (see legend to Fig. 1 for details) was packaged *in vitro* into phage coats[23,24] and approximately 10^6 plaque-forming units were plated and screened by hybridization of plaque 'lifts'[25] with Ti plasmid DNA, labelled *in vitro* by nick translation[26] with $[\alpha\text{-}^{32}\text{P}]$deoxynucleotide triphosphates. Two positive plaques were picked and purified. The *Eco*RI cleavage patterns of the resulting two recombinant phage DNAs are presented in Fig. 1*a*. λPC2 possesses six of the eight *Eco*RI insert fragments contained in λPC1; the latter are designated A–H in decreasing order of molecular weight (Fig. 1*b*). To determine how many of the insert fragments were homologous to Ti plasmid DNA, a Southern transfer prepared from them was hybridized with ^{32}P-labelled[26] pTi T37 plasmid DNA. Autoradiography revealed that all insert fragments except the G fragment of λPC1 hybridized strongly (data not shown). Further studies used only λPC1 to determine whether any of its insert fragments were border fragments containing both Ti plasmid and plant DNA sequences.

A map of the part of pTi T37 detected in plant tumour line BT37[16,19–21] is presented in Fig. 2. Part of *Bst*I fragment 6 as well as the whole of 23A, 9 and 14A are detectable in the tumour DNA by Southern blot analysis[21]. Eight intact *Eco*RI fragments of the Ti plasmid are internal to this region and are also detectable by Southern blot analysis of BT37 tumour DNA[19,21]. To compare the insert fragments of λPC1 with the *Eco*RI fragments that map in T-DNA, we compared the single and multiple cleavage products of Ti plasmid fragments with those of λPC1. Because of the complexity of total Ti plasmid DNA, we used two clones of Ti plasmid DNA in the vector pBR322. One contained *Bst*I fragment 6, and the other contained a partial digest product, *Bst*I fragments 9 plus 23A plus the unnumbered small fragment between them. Figure 3 shows that *Eco*RI fragment 13 (cut from the appropriate *Bst*I clone) co-migrates with A, 18 with B, and 23 with C. Also, the two subfragments of D generated by *Bst*I/*Eco*RI double digestion of λPC1 correspond to *Bst*I/*Eco*RI double digest fragments of the appropriate *Bam*HI clones (data not shown). Confirmation of D as *Eco*RI fragment 26 was achieved by recloning D into pBR325 (ref. 27), labelling this recombinant plasmid and hybridizing it to a Southern blot of pTi T37 *Eco*RI fragments as well as λPC1 *Eco*RI fragments. The probe hybridized with D in the phage DNA digest as expected and with fragment 26, of identical electrophoretic mobility, in the Ti plasmid digest (data not shown).

The low molecular weight inserts E, F and H of λPC1 co-migrate with subfragments of the (23A+9) *Bst*I clone (Fig. 1*b*) and in the Ti plasmid *Eco*RI digest, fragment 36 co-migrates with E, 37 with F and 38 with H (Fig. 1*c*). Clearly fragment G is not an intact *Eco*RI fragment of the Ti plasmid: no *Eco*RI fragment of pTi T37 co-migrates with it (Fig. 1*c*).

Fragment G could be either a plant DNA fragment included in the original phage clone by coincidence, or a border fragment abutting A on the left or (less plausibly) F on the right. For DNA hybridization analysis, G was recloned into the *Eco*RI site of pBR325 (ref. 27), and an *Eco*RI digest of this clone, containing vector and G fragments, was used to prepare Southern blots. When duplicate tracks were hybridized with labelled pTi T37 DNA (Fig. 3*a*), fragment G hybridized weakly. G thus

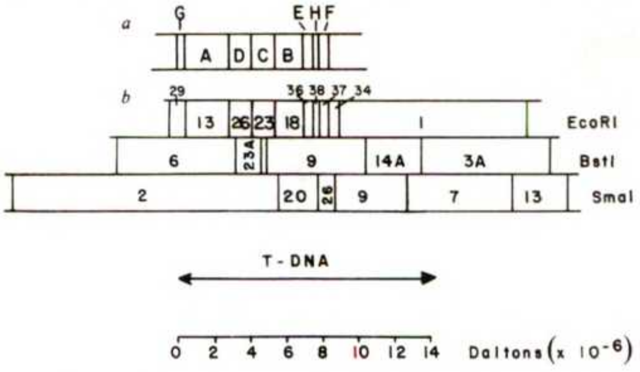

Fig. 2 Map of the T-DNA portion of pTi T37 and of the inserts of λPC1. For the *Sma*I fragment map and evidence see ref. 16. The *Bst*I fragments were mapped hybridizing isolated *Sma*I and *Hpa*I fragments to Southern blots[22] of *Bst*I digest fragments of pTi T37 as described previously[32]. *Bam*HI (a *Bst*I isoschizomer) fragments of partially digested pTi T37 were cloned into the *Bam*HI site of pBR322, and clones containing the following inserts were picked from a bank of 200 clones by colony hybridization[33]: fragment 6, fragments 9 and 23A and the small unnumbered fragment between them, fragment 14A and fragment 3A. Digestion of these recombinant plasmids with *Sma*I, *Hpa*I, *Bst*EII and combinations of these enzymes produced the fragments predicted by the map presented here and the published *Hpa*I and *Bst*EII maps[16]. Digestion of these recombinant plasmids with *Eco*RI alone and in combination with the other enzymes mentioned above allowed us to determine the *Eco*RI fragment map of pTi T37 shown above. The numbers assigned to the small fragments (34–37) were determined by the method described in Fig. 1*c* legend. *a*, The fragment map of the inserts in λPC1; *b*, the fragment map of pTi T37. Evidence for the arrangement of these fragments is based on the identification of their counterparts in the Ti plasmid digest as described in the text. Assignment of G to the left edge of the phage insert is based on its hybridization to Ti plasmid fragments mapping in this region (see text).

appeared to contain a short piece of Ti plasmid DNA. To determine whether G derived from the left edge of T-DNA, we hybridized Southern blots of Ti plasmid fragments generated by four different restriction enzymes (Fig. 3*b*). The G probe hybridized to *Bst*I fragment 6, *Eco*RI fragment 29, *Sma*I fragment 2 and *Hpa*I fragment 5 (see map in ref. 16), evidence that G is indeed from the left edge of T-DNA. *Eco*RI fragment 29 was recloned from *Bst*I fragment 6, and this recombinant plasmid also hybridized with G weakly (Figure 3*a*). We conclude that fragment G has weak homology with the leftmost edge of the T-DNA portion of the Ti plasmid. Much of G is not Ti plasmid DNA, for its hybridization with the Ti plasmid fragments is poor compared with homologous reactions run simultaneously.

Next we tested fragment G for homology with tobacco DNA. Normal tobacco leaf DNA and BT37 tumour DNA were cleaved with *Eco*RI or *Bst*I and the fragments immobilized by Southern blotting[22]. The cloned G fragment in the vector pBR325 was labelled by nick translation and used as probe. Figure 4 shows that this fragment hybridizes to a series of bands in the tobacco DNA digests. Two other fragments of λPC1 (A and D) cloned in the same vector and used as probes in parallel hybridization studies with tobacco DNA did not hybridize to such bands (data not shown). We conclude that fragment G is homologous to a family of repeated DNA sequences in the tobacco genome. The prominent pattern of *Eco*RI fragments of tobacco DNA to which G hybridizes suggests that this family is a 'clustered repeat'[28,29]. The smaller and simpler *Bst*I cleavage products to which G hybridizes suggest that there are *Bst*I sites internal to the repeat element. The role of such repeated DNA sequences in the eukaryotic genome is unknown. We note no significant difference in the intensity or pattern of bands in the tumour DNA digest compared with normal tobacco leaf DNA digest (Fig. 4 and other data not shown). Thus, the organization and copy number of the repeated DNA family to which G hybridizes is not altered grossly during tumorigenesis. Tumour DNA must contain one altered member of this family—the one into which T-DNA is inserted; however this member is not noticeable in Fig. 4, presumably because of the abundance of unaltered family members.

We conclude that the T-DNA found in BT37, a tobacco crown gall teratoma, is covalently joined at its left edge to plant DNA. Apart from this, the T-DNA fragments that we have isolated from this tumour line appear to be colinear with the corresponding region of the Ti plasmid: no noticeable alterations have occurred in this region of T-DNA whilst in the plant cell. Consistent with the location of T-DNA in the nuclear rather than chloroplast or mitochondrial DNA fraction[21], its left border fragment hybridizes to repeated DNA chracteristic of eukaryotic genomic DNA. It is not clear from this study whether T-DNA is an integral part of a tobacco chromosome in the transformed plant cell; it could constitute an extrachromosomal autonomously replicating DNA element. There is, however,

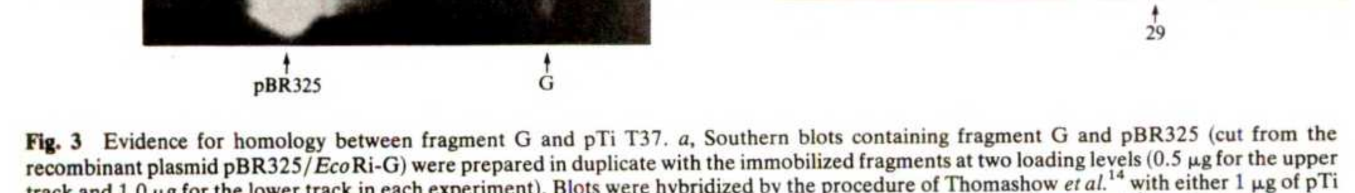

Fig. 3 Evidence for homology between fragment G and pTi T37. *a*, Southern blots containing fragment G and pBR325 (cut from the recombinant plasmid pBR325/*Eco*Ri-G) were prepared in duplicate with the immobilized fragments at two loading levels (0.5 μg for the upper track and 1.0 μg for the lower track in each experiment). Blots were hybridized by the procedure of Thomashow *et al.*[14] with either 1 μg of pTi T37 DNA (2.6×10^7 c.p.m. μg^{-1}) or 0.5 μg of recombinant plasmid pBR325/*Eco*RI-29 DNA (1.66×10^8 c.p.m. μg^{-1}) in 5 ml of reaction medium[14]. Probes were labelled by nick translation[26] with ^{32}P-labelled deoxynucleotide triphosphates. *b*, Southern blots[22] of pTi T37 digests produced by four restriction endonucleases (*Sma*I, *Hpa*I, *Bst*I and *Eco*RI) were hybridized[14] with 0.5 μg of recombinant plasmid pBR325/*Eco*RI-G (1.26×10^8 c.p.m. μg^{-1}). The numbers of the digest fragments to which the probe hybridized are indicated.

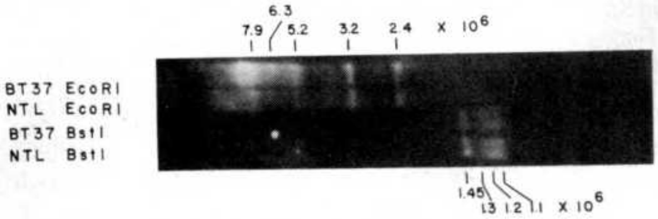

Fig. 4 Evidence for homology between fragment G and tobacco DNA. *Bst*I digests of 2.8 μg of normal tobacco leaf DNA isolated as described elsewhere[34] and of BT37 tumour DNA, in addition to *Eco*RI digests of 5.0 μg of the same two DNAs, were fractionated in horizontal slab gels of 0.7% agarose and blotted by Southern's procedure[22]. The blots were hybridized[14] with 1.5 μg of recombinant plasmid pBR325/*Eco*RI-G (5.4×10^7 c.p.m. μg^{-1}). The autoradiogram shown was exposed for 48 h (with two Dupont Cronex intensification screens) at −80 °C. Molecular weights of the bands in the autoradiogram were estimated from a calibration curve for the original gel based on digest fragments of known molecular weight. NTL, Normal tobacco leaf DNA, BT37, tobacco BT37 tumour DNA.

little precedent for the existence of such an element. Regardless of the physical situation of T-DNA our data make it clear that this foreign prokaryotic DNA element has become joined to eukaryotic DNA. The mechanism and specificity of such novel joining of phylogenetically alien DNAs may be revealed by analysis of DNA sequence at the border regions.

This work was supported by research grant NP194 from the American Cancer Society. M.E.T. was supported by a Damon Runyan–Walter Winchell Cancer Fund postdoctoral fellowship. We thank Drs Fred Blattner and Jerry Slightom for assistance in the cloning experiments.

Note added in proof: Similar results have been obtained for two T-DNA border fragments from an octopine-synthesizing tobacco crown gall tumour[35].

Many aspects of light energy transduction in photoreceptors are under study[1,2]. One important problem concerns the light-initiated primary event in rhodopsin and the identity of the primary photoproduct. It is usually assumed that the red-absorbing pigment bathorhodopsin[3] is the first photoproduct. In cattle rhodopsin, it is produced within 6 ps of excitation[4] and is stable at 77 K. However, Yoshizawa *et al.*[5–7] have found a blue-absorbing pigment, hypsorhodopsin, in photosteady-state mixtures formed with orange light at liquid helium temperatures (~5 K). On warming the hypsorhodopsin in the dark to liquid nitrogen temperatures (77 K), it converts to bathorhodopsin. These two results suggested that hypsorhodopsin might be a precursor of bathorhodopsin, but that presents difficulties. For example, hypso-type intermediates have not been seen for all visual pigments[6]. Moreover, when cattle rhodopsin was irradiated with blue light at liquid helium temperatures, it was converted to bathorhodopsin without forming detectable hypsorhodopsin[6,7]. Finally, rapid kinetic experiments to determine the time course of formation of bathorhodopsin and hypsorhodopsin have given ambiguous results[4,8–10]; this may be due to the use of rhodopsins from different species. Because squid rhodopsin seemed to have more hypsorhodopsin in photosteady states than cattle rhodopsin[7], we have studied the photo products of another cephalopod rhodopsin at carefully controlled low temperatures (±0.2 K). We report here that octopus rhodopsin has a hypso intermediate that is easily formed on irradiation but that the batho-product appears before significant amounts of the hypso-product accumulates. Moreover, the thermal conversion of hypsorhodopsin to bathorhodopsin must be fitted with two rate constants, and the activation enthalpy of the faster process is almost zero, that is, it is temperature independent over the range studied.

Octopus (Mizudako, *Paroctopus defleini*) microvillar membranes were prepared as previously described[11]. Rhodopsin was extracted from the membranes with a 2% digitonin solution, glycerol was added to the preparation to give a final concentration of 75%, and the samples were stored at −70 °C. The *p*H of the solution was adjusted to 10.5 with sodium carbonate buffer just before the start of an experiment, so that at room temperature any bleached rhodopsin would go to alkaline metarhodopsin ($\lambda_{max} = 376$ nm)[12].

On cooling to 10 K, the λ_{max} of octopus rhodopsin (476 nm at 10 °C) shifted to 486 nm (Fig. 1, curve 1). When the octopus rhodopsin was very briefly irradiated with 480 nm light at 10 K, the spectral change indicated the formation of a bathochromic product (octopus bathorhodopsin) (Fig. 1, curve 2). On further irradiation, the concentration of the bathochromically absorbing product increases (curve 3) and the appearance of a hypsochromically shifted photoproduct (octopus hypsorhodopsin) can also be seen (Fig. 1, curve 4). With further irradiation using 530 nm light, a photosteady state is formed which contains large amounts of hypsorhodopsin (56%), as well as rhodopsin (<4%) and isorhodopsin (>40%), with almost no bathorhodopsin. A detailed analysis of the spectra shows that hypsorhodopsin and bathorhodopsin appear concomitantly. Figure 1 strongly suggests that on irradiation of rhodopsin at

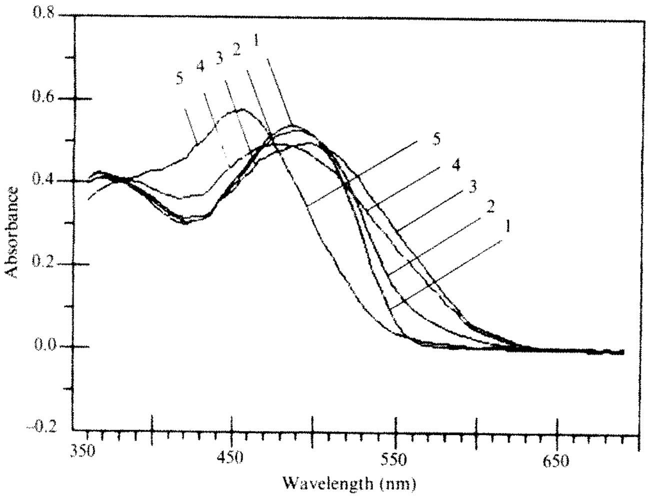

Fig. 1 Spectral changes observed in the conversion of rhodopsin to bathorhodopsin, hypsorhodopsin and isorhodopsin at 10 K. Curve 1, octopus rhodopsin in digitonin (*p*H 10.5) 10 K; curves 2–4, products of irradiation at 480 nm for successive periods of 8, 64 and 2,048 s; curve 5, photosteady state obtained by irradiation at 530 nm for 10 min. Curve 5 represents about 56% hypsorhodopsin, >40% isorhodopsin and <4% rhodopsin. This composition was determined as in ref. 7. All spectra were recorded with a Cary 14 using a Janis 10DT super Varitemp Optical Dewar.

10 K, the stable, blue-absorbing ground state species, hypsorhodopsin, is apparently not the precursor of the bathorhodopsin formed at this temperature.

On slowly warming up from 45 K, the spectrum of the photosteady-state mixture formed by irradiating octopus rhodopsin at 10 K shifted to longer wavelengths with sharp isosbestic points at 479 nm and 374 nm, as shown in Fig. 2. In the insert, the change in absorbance at 540 nm, indicating the formation of bathorhodopsin, is shown as a function of temperature. Judging from the similarity of their absorption spectra, the batho-product obtained by warming is identical to bathorhodopsin produced by irradiation of octopus rhodopsin at 80 K (B. Mao, M.T. and T.G.E., unpublished observations). Thus, the data of the insert show that hypsorhodopsin is converted to bathorhodopsin above 45 K. This transition temperature is much higher than that observed for the bovine[6] and squid[7] or frog[13] hypsorhodopsin → bathorhodopsin transition. There is no evidence of any stable intermediates between hypsorhodopsin and bathorhodopsin.

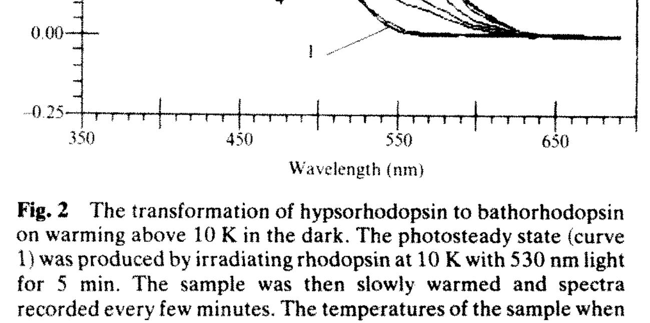

Fig. 2 The transformation of hypsorhodopsin to bathorhodopsin on warming above 10 K in the dark. The photosteady state (curve 1) was produced by irradiating rhodopsin at 10 K with 530 nm light for 5 min. The sample was then slowly warmed and spectra recorded every few minutes. The temperatures of the sample when the spectrum was measured are: (1) 10 K, (2) 40 K, (3) 50 K, (4) 55 K, (5) 60 K, (6), 65 K, (7) 70 K, (8) 80 K. Inset: absorbance at 540 nm (indicating the formation of bathorhodopsin) as a function of temperature.

We attempted to measure the enthalpy of activation in the thermal conversion of hypsorhodopsin to bathorhodopsin. At a given temperature, rhodopsin was irradiated with continuous yellow light ($\lambda > 490$ nm) for 3 min to reach the photosteady state. Immediately after the light exposure, the decay of hypsorhodopsin was monitored by the absorbance at 440 nm and the formation of bathorhodopsin by the absorbance at 550 nm. For temperatures between 53 K and 73 K, we plotted $\ln(A_t - A_\infty)$ as a function of time, where A_t and A_∞ are the absorbance at t min and infinity, respectively. The rates of both hypsorhodopsin and bathorhodopsin are non-exponential; both curves can be fitted fairly well by the sum of two exponentials. The temperature dependence of the two rates is plotted in an Arrhenius manner (ln K against $1/T$) in Fig. 3. The temperature dependence of the decay of hypsorhodopsin gives $\Delta H = 0.87 \pm 0.29$ kcal mol^{-1} and $\Delta H = 0.09 \pm 0.28$ kcal mol^{-1}. A similar pair of values are found for the formation of bathorhodopsin. The non-exponential character of the hypsorhodopsin decay processes implies that hypsorhodopsin is not a single homogeneous species. We are now studying the thermal decay process in more detail, in particular the nature of the component which seems to be almost temperature independent.

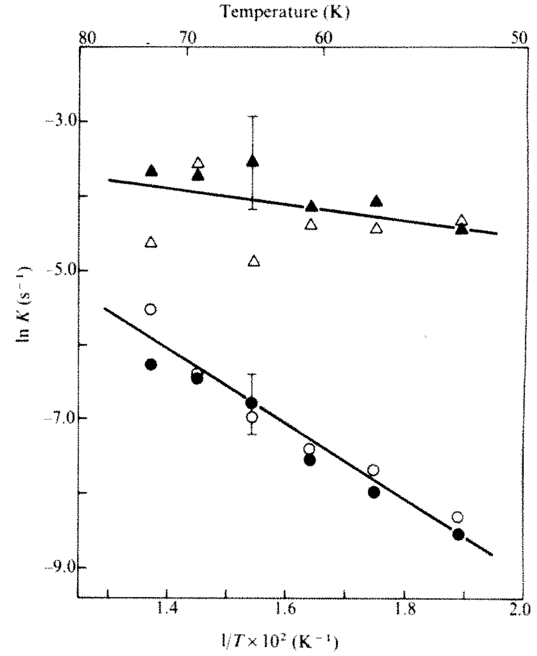

Fig. 3 Arrhenius plot of kinetic data for the decay of hypsorhodopsin (decrease in absorbance at 440 nm) and formation of bathorhodopsin (increase in absorbance at 550 nm). △, Faster phase; ○, slower phase in the decay of hypsorhodopsin. ▲, Faster phase; ●, slower phase in the formation of bathorhodopsin.

Contrast perception above threshold is only minimally impaired in human amblyopia

Robert F. Hess & Arthur Bradley*

Physiological Laboratory, University of Cambridge,
Cambridge CB2 3EG, UK

Amblyopia is a condition occurring at birth, or in early childhood, which affects up to 5% of the population and is characterized by degraded vision in one eye not able to be corrected by spectacles and having no observable lesion in the eye itself. Its cause is therefore uncertain, yet indirect evidence suggests a neural one, very likely in the visual areas of the brain. Ambyopia is usually associated with either a strabismus (eye misalignment) or anisometropia (unequal refractive error). Investigation into its neural basis has involved two approaches: psychophysical research in humans with amblyopia[1-6] has shown marked contrast deficits for threshold stimuli, suggesting deficient contrast coding at and above threshold in amblyopia. Neurophysiological research on animals deprived in early life with either a surgically induced squint or an optically induced anisometropia has suggested that 'blur' may be the common etiological basis for these two amblyopias[7]. We have investigated here whether amblyopes exhibit contrast deficiencies for other than threshold stimuli. Our measurements show that the threshold deficits measured in amblyopia bear no simple relationship to what happens above threshold. There is no contrast coding abnormality in amblyopia in the high-contrast range typical of everyday vision. We also give suprathreshold evidence for anisometropic and strabismic amblyopia having different neural bases.

Repetitive spatial patterns with a sinusoidal luminance profile were generated independently on each side of a video display. Using a partition and a motor-driven sectored disk (for alternate presentation of stimuli to each eye) an amblyope could be presented with the same pattern of independent contrast to each eye. Care was taken to ensure that all subjects were optically corrected. An experimental session began with the amblyope setting a contrast detection threshold for each eye at a particular spatial frequency. Gratings would then be set at any one of several contrasts above this threshold and presented to the amblyopic eye as the standard. The task was to adjust the contrast of the pattern seen by the good eye (variable) until it was perceptually equated to that seen through the amblyopic eye (standard). In some experiments this experimental protocol was reversed with the normal eye observing the standard contrast stimulus. Five settings were averaged for each contrast match using the method of adjustment.

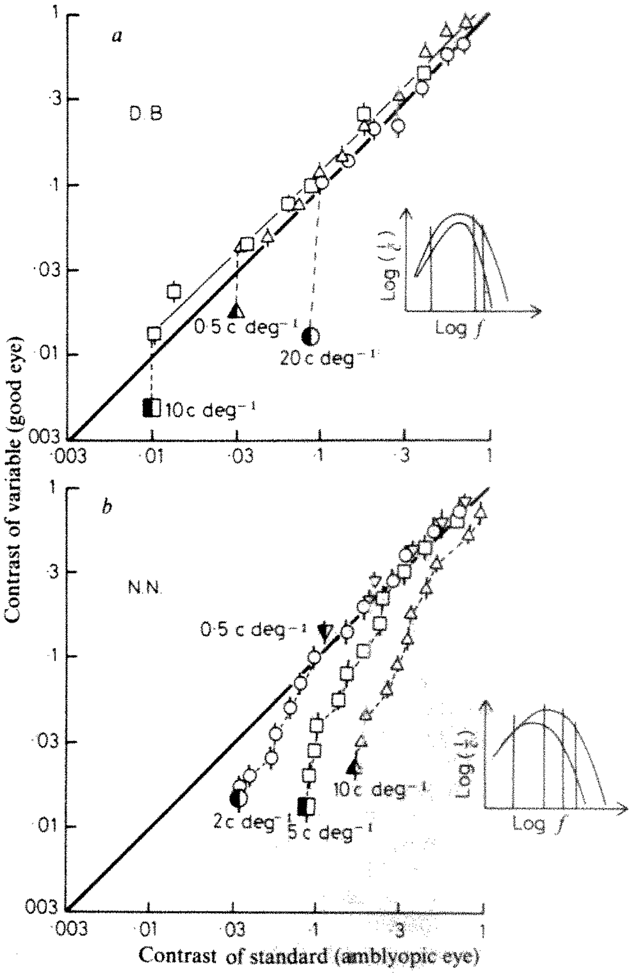

Fig. 1 Contrast matching results are displayed for three different spatial frequencies. The contrast of the standard grating shown to the amblyopic eye was matched by a variable grating of the same spatial frequency shown to the normal fellow eye. Each axis is logarithmic. Contrast thresholds are indicated by half-filled symbols. Inset is the form of the contrast threshold response for the normal and amblyopic eye. Strabismic (*a*) and anisometropic (*b*) amblyopia are compared. The gratings were displayed on a video screen for 500 ms. Field size of the stimulus was 10 deg, its mean luminance was 200 cd m^{-2} and its colour was green (P 36 Phosphor).

In both figures the matching results have been plotted on logarithmic coordinates. If contrast matches between the eyes are set to equality then the results will fit along the diagonal line with a slope of 1. This is true for normal observers. Figure 1*a* and *b* which show contrast matching data for a representative strabismic amblyope and for a representative anisometropic amblyope are very different. For the strabismic amblyope (Fig. 1*a*), once the target contrast is just slightly above its detection threshold it is perceived correctly by the amblyopic eye. This result is independent of the bar size of the target (spatial frequency). However, for the anisometropic amblyope (Fig. 1*b*), contrast perception is degraded over a substantial suprathreshold range (0.5 log unit–1 log unit). This range is dependent on the spatial frequency of the pattern. These results suggest that even if the threshold losses for these two forms of amblyopia look similar, their suprathreshold perception is dramatically different. This finding which has been confirmed for a group of strabismic and anisometropic amblyopes is summarized in Table 1 in terms of the contrast ratio between the eyes at threshold and at a contrast 3dB above threshold. An equivalent result is obtained when the contrast standard is shown to the normal eye. These results strongly suggest that strabismic and anisometropic amblyopes have different perceptual deficits.

These results also allow a better estimation of the type of neural dysfunction in human amblyopia. For example, strabismic amblyopia behaves as though the contrast range had been truncated to a different extent for each spatial frequency, thus maintaining normal suprathreshold contrast perception. Therefore, even though the contrast thresholds are raised in this form of amblyopia, this threshold disturbance has no suprathreshold relevance. It is as if a switch has been inserted somewhere in the amblyopic visual system to restrict the lower range of contrasts available to each set of frequency-specific neurones in the amblyopic visual system. To this extent the strabismic amblyope's system is well modelled by normal peripheral function. Figure 2*a* illustrates how normal contrast perception varies as a function of the position of a target in the peripheral field of vision for a normal subject. These results for normal peripheral viewing are very similar to that of the strabismic amblyope, supporting a more recent suggestion[8] based solely on

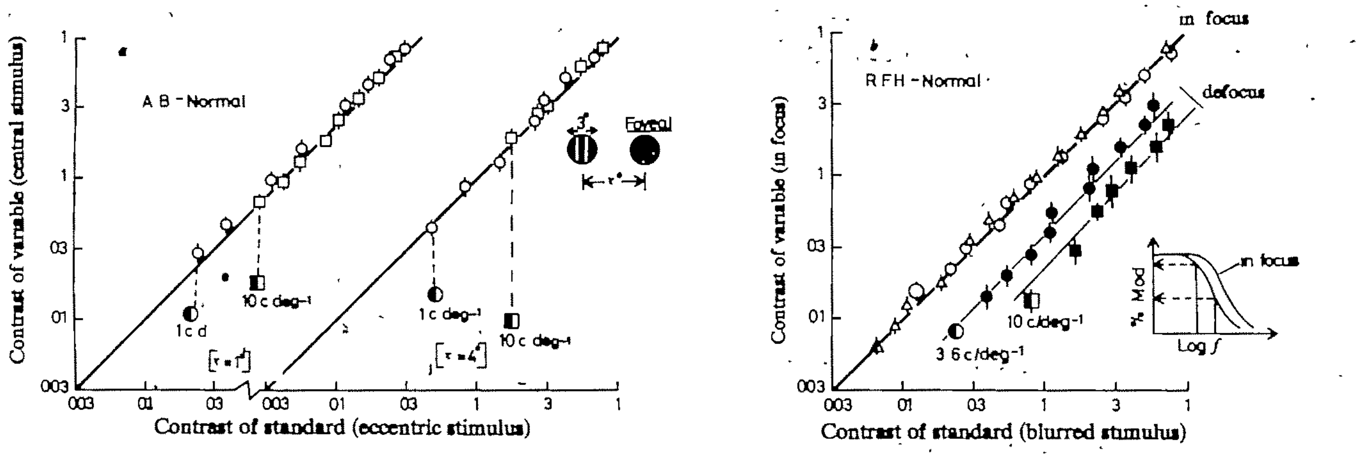

Fig. 2 Contrast matching results are displayed for a range of spatial frequencies. These results are plotted in an identical manner to those in Fig. 1. The contrast loss from two extents of eccentric viewing (1° and 4°) is displayed (*a*) as well as the contrast loss from optical blur (*b*). These should be compared with strabismic and anisometropic amblyopia (Fig. 1) respectively (see text).

threshold measurements that vision in strabismic amblyopia resembles that of the normal periphery.

The contrast matching abnormality is obviously different for the anisometropic amblyope (Fig. 1*b*); however the defective contrast perception does gradually diminish as the absolute contrast of the standard increases. Even for very fine targets (for example 10 c deg^{-1}) the defect at threshold is much larger than at high contrast levels (see also Table 1). It is interesting that the neural contrast deficit does not merely mimic the optical contrast loss due to the restricted (blurred) visual input present in early life. The contrast loss found with optical blur is displayed in Fig. 2*b* and this should be compared with the anisometropic result in Fig. 1*b*. Blur expected from a physical consideration should affect suprathreshold contrast perception as much as threshold perception (parallel displacement of the contrast matching line on log/log axes). Although optical blur (Fig. 2*b*) in early life may have originally produced the amblyopia seen in Fig. 1*b*, it remains possible that substantial neural compensation may have occurred by the amblyopic visual system in the higher contrast range (compare Figs 1*b* and 2*b* in the upper range). This neural compensation may explain why adult amblyopes do not accept that the degraded vision from their amblyopic eye looks like a defocused version of what they see through their fellow normal eye. This compensation is best thought of as a gain change of about a factor of 2 for all spatial frequencies. It is as if an extra stage of amplification is present somewhere in the amblyopic visual system to boost the neural suprathreshold contrast signal in only the upper part of the range. A similar contrast gain change has been reported[9] for the normal eye at high spatial frequencies and for some astigmatic subjects. These findings for contrast perception in subjects with abnormal vision are similar to those for loudness perception in subjects with peripheral damage to the auditory system. Within the auditory domain such a 'gain change' is referred to as 'recruitment'.

Table 1 Comparison of threshold and suprathreshold abnormality (3 dB above threshold) for strabismic and anisometropic amblyopes

Subjects	Spatial frequency (c deg^{-1})	Threshold contrast ratio	Suprathreshold contrast ratio (a contrast 3dB above threshold)
(*a*) Strabismic amblyopes			
D.B.	0.5	0.5	1.25

A.C.	1	0.3	0.5
	2	0.09	0.16
	3	0.017	0.1

In conclusion our results strongly suggest that the contrast coding abnormalities in amblyopia are mostly limited to threshold conditions and also that the neural basis of anisometropic and strabismic amblyopia is different. They also highlight the nature of the suprathreshold contrast deficit in each condition. Although it has been shown that human amblyopes do not exhibit deficits in contrast perception in the mid- to high-contrast range, they do experience difficulty in identifying such stimuli. This is due to a somewhat independent anomaly in spatial perception. They see targets 'distorted'[10], for example a simple black and white stripe pattern appears jumbled and twisted yet, as shown here, the individual components are perceived at their correct contrast. Clearly this spatial distortion is likely to be the main basis of amblyopia. The defining features reported here for the two main forms of human amblyopia should be amenable to neurophysiological assessment in animals which have been either strabismically or anisometropically deprived in the early months of life. Such assessment may indicate the relevance of animal models as well as the possible neural substrate for these human perceptual phenomena.

Murine neuroblastoma cells have been widely used as a model system for neuronal cells as they can be induced to differentiate in culture by various stimuli, such as dibutyryl cyclic AMP (dbcAMP)[1], prostaglandin[2], and serum starvation[3]. The cells respond with assembly of microtubules, leading to neurite outgrowth[4,5], with increased activity of neuronal-specific enzymes, tyrosine hydroxylase, choline acetyltransferase and acetylcholine-esterase[6,7], and synthesis of neurotransmitters[8]. The differentiated cells lose tumorigenicity[9]. Cell-to-substratum adhesion is evidently crucial for neurone extension *in vitro*[10]. Neurite outgrowth is induced by treatments that increase cell-to-substratum adhesion in some neuronal cell cultures[11,12]. We have now identified the major high molecular weight proteins synthesized and secreted by murine C1300 neuroblastoma cells as fibronectin, laminin and type IV procollagen, of which the latter two were also found to be deposited in pericellular matrix form.

The mouse neuroblastoma cells (C1300, clone NB41A3); American Type Culture Collection, CCL 147) were cultured in Eagle's medium supplemented with 10% fetal calf serum and antibiotics. To induce morphological differentiation, the neuroblastoma cells were plated sparsely and cultured in the presence of 1 mM dbcAMP. The polypeptides secreted into the culture medium by metabolically labelled (^{3}H-proline or ^{14}C-glycine) neuroblastoma cells were precipitated with ammonium sulphate and analysed by SDS-polyacrylamide gel electrophoresis. The major polypeptide as seen on autofluorograms migrated with an apparent molecular weight (MW) of 230,000 (Fig. 1, lanes 2 and 3). In addition, labelled polypeptides were seen with MWs of 400,000 and 170,000. These polypeptides were disulphide-bonded to each other since similar analysis of unreduced samples revealed a major polypeptide band with a MW of 440,000 and larger material (Fig. 1, lane 1). The overall pattern of protein secretion did not appreciably vary over a wide range of labelling times and was not affected by the presence of 1 mM dbcAMP in the cultures (not shown).

Several major bands could be identified as either fibronectin or laminin polypeptides by precipitation from the neuroblastoma cell extracts and culture media with the respective antibodies (Fig. 1, lanes 4 and 5). The fibronectin chains showed an apparent MW of 230,000, while laminin polypeptides could be visualized as a closely spaced doublet with MW of 215,000 together with a higher molecular weight (400,000) component. The radiolabelled laminin polypeptides co-migrated with protein-stained[13] components of authentic laminin purified from the mouse EHS sarcoma[14] (not shown).

Initial analysis of medium proteins produced in the absence of ascorbate failed to identify collagenous protein. Since laminin has so far only been found together with collagen type IV both *in vivo*[14,15] and *in vitro*[16,17], we also examined media of cell cultures labelled in the presence of sodium ascorbate and the cross-link inhibitor β-aminopropionitrile fumarate. Two new disulphide-linked polypeptides MWs 170,000 and 180,000 according to collagenous standards) were now secreted and were sensitive to a highly purified bacterial collagenase (Fig. 1, compare lanes 2 and 3; 6 and 7). These two polypeptides comprised about 16% of protein-bound ^{3}H-proline-derived radioactivity and could be specifically precipitated with antibodies to type IV collagen (Fig. 1, lane 8). Antibodies to interstitial procollagens or collagens did not precipitate protein-bound radioactivity (Fig. 1, lane 9). The type IV procollagen polypeptides were particularly rich in the matrix material attached to the growth substratum (Fig. 2*a*) at the expense of fibronectin polypeptides, which were abundant in the medium (Fig. 2*b*). Indirect immunofluorescence studies using previously described procedures[16] confirmed the presence of all three glycoproteins in the cells and deposition of laminin under the attached cells, as will be reported in detail elsewhere.

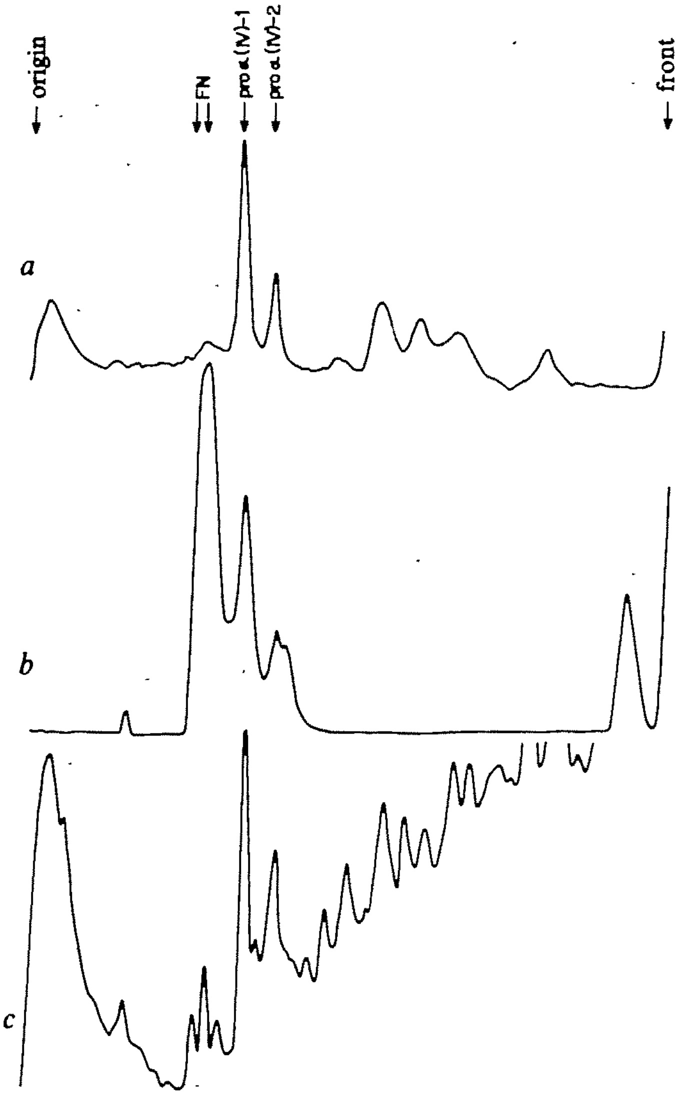

Fig. 1 Electrophoretic analysis[32] of metabolically labelled proteins secreted into the medium by undifferentiated C-1300 neuroblastoma cells. Lane 1 medium, non-reduced; lanes 2, 3 and 7, medium reduced with mercaptoethanol. The medium in lanes 3, 6 and 7 was obtained in the presence of ascorbate (30 μg m^{-1}) and β-aminopropionitrile fumarate (30 μg ml^{-1}); lane 6, medium after treatment with bacterial collagenase. Proteins were precipitated before analysis with ammonium sulphate (281 mg ml^{-1}) in the presence of gelatin carrier (50 μg ml^{-1}) and protease inhibitors[33]. Lanes 4, 5 and 8, identification of proteins by immunoprecipitation[16] with specific antibodies to laminin[14] (lane 4), fibronectin[18] (lane 5) and type IV collagen[34] (lane 8). Control precipitates in lane 9 were obtained either with anti-type II collagen or normal rabbit IgG. The polypeptides were visualized by fluorography[35]; lanes 4 and 5 were exposed for 6 d, the other lanes for 3 d. Except for lane 1 all samples were analysed in reducing conditions. Globular proteins as indicated by their molecular weights (left side) and type I collagen and procollagen chains (right side) were used for calibration.

0028-0836/80/400465—02$01.00

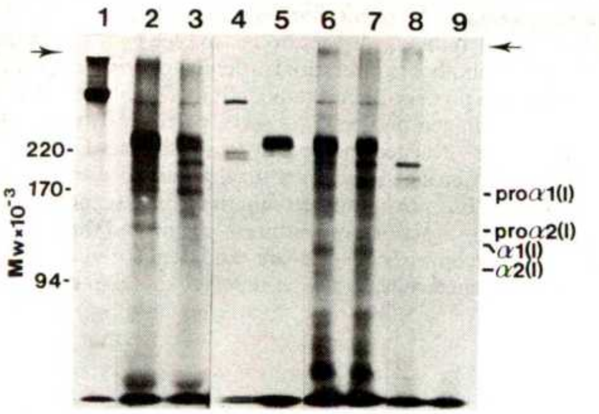

Fig. 2 Comparison of labelled proteins in the matrix (*a*), medium (*b*), and cell layer (*c*), obtained from undifferentiated C-1300 neuroblastoma cultures by densitometric scanning. Cell-free substrate-attached matrix was prepared using sequential extraction of cell layers with 0.5% sodium deoxycholate and hypotonic buffer in the presence of protease inhibitor[36]. Cell layer contained both intracellular and matrix proteins solubilized directly into electrophoresis sample buffer. The positions of fibronectin (FN) and type IV procollagen pro-α1 (IV) and pro-α2 (IV) chains are indicated by arrows. Electrophoresis was carried out in reducing conditions.

No distinct deposits of fibronectin or type IV procollagen could be detected in cultures of either attaching or differentiating cells, but the latter was identified by electrophoresis (Fig. 2*a*). Essentially similar results were obtained with the NB42B clone[5] of C1300 cells.

Several methods of determining the amounts of the major glycoproteins secreted by morphologically undifferentiated and differentiated C1300 cells gave no consistent differences between the two. This was the case when radioactivity in the high molecular weight peptide bands was plotted against cell number or amount of protein in the cell layer. Quantification of medium proteins by radioimmunoassay (RIA) using antibodies directed against human plasma fibronectin[18] or the large, pepsin-resistant fragment of laminin[19] gave similar values for both states, when corrected for the amount of cells in each culture. Nearly identical patterns for radioactive polypeptides were also observed in both cell layers, or isolated pericellular matrix material by electrophoresis followed by autofluorography or by RIA for pepsin-solubilized laminin.

These results show production of fibronectin, laminin and type IV collagen by two clones of a well-characterized line of murine neuroblastoma cells able to differentiate in culture. Cell-surface associated polypeptides of molecular weights similar to that of laminin and antigenically distinct from fibronectin have been detected both in N18 neuroblastoma[20] and in PC12 pheochromocytoma cell clones[21]. Furthermore, both nerve growth factor and dbcAMP have been found to induce alterations in protein secretion and substrate-attached material of PC12 cell structures[22], whereas dbcAMP and subsequent differentiation had no effect on protein secretion in the present study.

The only collagenous protein secreted by neuroblastoma cells was of the basement membrane type. Its polypeptide pattern was very similar to that of type IV procollagen secreted by murine parietal yolk sac cells *in vivo*[23] and tumour cells in culture[17]. Note that secretion of collagen by neuroblastoma cells was detected only in ascorbate-treated cultures. The significance of type IV collagen for neuroblastoma cells remains unknown. Our data demonstrate that neuroblastoma cells in culture produce proteins characteristically found in a wide variety of basement membranes. It is possible that this synthesis pattern is an example of the so-called retrodifferentiation of tumour cells[24] and represent the primitive ectodermal origin of the (neuroblastoma) cells[25]. Currently held views indicate that neurones lack adjacent basal laminae in the central nervous system[26,27] and that Schwann cells are responsible for matrix production in the peripheral nervous system[28,29]. Intraneuronal synaptic clefts[30] and neuromuscular junctions[31], however, contain matrix material. Thus it is also possible that basement membrane production by neuroblastoma cells, particularly in their differentiated state, reflects a similar *in vivo* activity.

Corrigenda

In the letter 'Discovery of a very distant supernova' by M. R. S. Hawkins, *Nature* **286,** 467–469, in Table 1 the epoch of J4394 is 29.7.78. In Fig. 1 the point with the same ordinate as the cross is spurious and in Fig. 3 two of the points in the top left-hand corner are spurious. The sentence in line 44 on p. 468 beginning 'Note that . . .' should read 'In particular, the fit was made without the last two observations, which after galaxy subtraction were the most uncertain.' In line 3 on p. 469, for 'non-expanding Doppler' read 'non-Doppler'.

The following acknowledgement refers to the letter 'Renin-like effects of NGF evaluated using renin-antagonists' by D. B. Avrith *et al.*, *Nature* **285,** 248–250. 'We thank Professor Vernon, Department of Chemistry, University College London, for the gift of immunologically pure β-subunit of NGF'.

Geological objections to an extensional origin for the Buchan and Witchground Graben in the North Sea

CHRISTIE AND SCLATER'S refraction results[1] corroborate our inference from regional gravity[2] that the crust under the Buchan and Witchground Graben area of the North Sea is anomalously thin (see Fig. 1). However, their mechanism[3] for the development of the grabens, invoking crustal stretching by a factor of ~2 during the late Jurassic to early Cretaceous, raises serious geological problems. (1) The structure of the inner Moray Firth at lower Mesozoic levels[4] precludes both N–S extension of more than a few per cent, and significant later transcurrent movement on the Great Glen fault[5]. How can Christie and Sclater reduce their supposed N–S crustal extension of at least 60 km, along the Greenwich meridian, to zero, 200 km to the west? Our gravity modelling shows that if gross crustal extension occurred at all, it was in a NE–SW to E–W direction below the Viking and Central grabens, and not in a N–S direction across the Moray Firth. (2) The thickening of the Palaeozoic layer from near zero, at either end of their refraction profile, to about 4 km in the centre, implies up to 4 km of pre-late Permian erosion, and/or a Palaeozoic depositional basin. In contrast, their upper crustal layer seems to have an approximately constant thickness. The post-Zechstein, pre-stretching thickness of these two layers together was presumably, therefore, 5 km or less at the ends of the profile, but ~18 km in the centre. Whether or not erosion took place, it is clear that the crust was already highly anomalous by the mid-Permian so that the later, planar, 40-km deep Moho, depicted in Christie and Sclater's Fig. 4*a* as the initial (pre-stretching) crustal structure, is inconsistent with these implications from their own refraction results. (3) The major graben-boundary faults, probably active from the late Carboniferous (Stephanian) to the late Jurassic, are depicted (their Fig. 4*a*) as having had no effect on the Moho, whereas unobserved listric faults are postulated to have thinned the crust (their Fig. 4*b*) by a factor of ~2 shortly afterwards. Also not observed is the extreme rotation, of the order of 60°–80° (ref. 6), of the Jurassic and older sediments required to produce such extension—actual tilts are only a few degrees. Well developed listric faults can now be recognized elsewhere on seismic reflection sections (for example, ref. 7), but can only account for upper crustal extension of ~25%. (4) The effusion of a 3-km thick pile of mildly under-saturated alkali olivine basalts in the centre of the refraction profile[8] apparently pre-dates the initiation of the supposed stretching period by some 10 Myr, whereas rapid extension would probably result first in tholeiitic volcanism (particularly in the form of dyke swarms) before the more alkaline volcanism resulting from deeper partial melting. The only major pre-Tertiary tholeiitic dyke swarm in the region is considerably older, at ~290 Myr, preceding a major period of igneous activity in the Permian. In contrast, magmatism during the late Jurassic and early Cretaceous was trivial[8].

In view of these problems we conclude that rapid extension of the scale required never occurred. Other mechanisms such as loading of an elastic or visco-elastic lithosphere[2,9] can explain the last 120 Myr of North Sea subsidence just as readily as a thermal model, but without requiring such a catastrophic initiating mechanism.

M. J. Russell has suggested that the problem of the thin crust beneath the North Sea may be tackled by rejecting the assumption that the crust was originally of standard continental thickness and composition. The contiguity of the Scottish–Norwegian and North German–Polish Caledonides through the North Sea[10], and the implication, mainly from faunal provinciality, of three widely separated Lower Ordovician continental blocks[11], lead us to propose that the anomalous crust under the North Sea grabens may date back to the closing of a Lower Palaeozoic ocean. We therefore predict a small but significant difference in the seismic structure of the crust on either side of the grabens, as has been observed across the Iapetus suture[12] (Fig. 1). The later major tectonic and magmatic events of north-west Europe can all be ascribed, in principle, to the effects of nearby seafloor spreading in the early Permian[13], early Cretaceous[7] and the Tertiary, without resorting to an *ad hoc* stretching event.

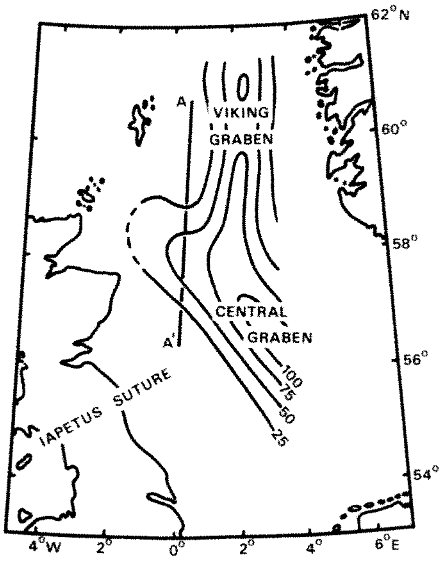

Fig. 1 Residual gravity anomaly (mGal) after removal of the effect of all Upper Palaeozoic and younger sediments (from ref. 2). AA' is refraction profile of ref. 1. Three-dimensional modelling predicts a Moho depth of 25 km below the centre of profile AA', on the lobe of overlap where the 200-km wide zone of thin crust below the Central Graben runs into the 130-km wide zone below the Viking Graben. Minimum Moho depth below the centre of each graben is 20 km, assuming a 'normal' Moho depth of 30 km and a density contrast 0.4 g cm^{-3} across the Moho.

CHRISTIE AND SCLATER REPLY—We thank Smythe *et al.* for providing the opportunity to elaborate on the extensional model for basin formation[1]. First, it cannot be denied that extension has taken place in the North Sea, and the strong temporal correlations between North Atlantic and North Sea activity[2,3] enable us to refute the suggestion that the model is *ad hoc*.

As noted by us, evidence for the required extension must be found in the North Sea geological record for the model to be acceptable. Concerning the amount and type of extension, we would make the following points.

(1) Although the refraction line is a linear profile, this does not constrain the extension to be parallel to it or even one-dimensional and indeed the model describes areal extension[4]. Clearly, the geometry of the basin requires two-dimensional extension to have taken place in the vicinity of well 3 (ref. 4).

0028–0836/80/400467—02$01.00

(2) Such extension, if azimuthally independent, would require linear extensions of 34 and 26% to produce the locally maximal values of *b* of 1.8 and 1.6 respectively[4].

The amount of extension accommodated by listric faults is debatable. Although Montadert *et al.*[5] suggest that listric-faulted blocks on the north Biscay margin, displaying tilts of 20° to 30°, allow some 15% extension, the same seismic reflection data have been interpreted by X. Le Pichon and J.-C. Sibuet (personal communication) to allow extension of 200% to 300%. Both Montadert *et al.* and Le Pichon and Sibuet cite extension as being the primary cause of crustal attenuation in this area, with post-rift subsidence the result of isostatic adjustment to cooling of the lithosphere.

We agree that magmatism during the Jurassic and early Cretaceous was trivial, justifying our assumption that crustal material was conserved. However, the apparent predating by basaltic effusions of the onset of extension by ~10 Myr seems more to support the placing of the stretching event in the Lower Jurassic than to refute the model.

The noted existence of a Permo–Triassic event in the North Sea may require an explanation of subsidence in terms of the superposition of two main stretching episodes. In this case, we would agree that the North Sea crustal thickness may already have been attenuated by the start of the Jurassic phase of activity, in which event, less Jurassic extension of even a one-dimensional type would be required to produce the seismic cross-section.

However, the good agreement between the seismic and gravity estimates of the depth to the Moho suggests that there is indeed crustal attenuation beneath the North Sea Basin, and 4 km of actual post mid-Cretaceous sedimentation is compelling evidence for something other than simple loading of an elastic lithosphere, which predicts a thickened crust[6]. A loading hypothesis would require the existence of a wide, 1,200-m deep depression at the time of the Aptian–Albian unconformity over a somehow previously thinned crust.

Counting integral numbers of amino acid residues

THE method of "counting integral numbers of amino acid residues per polypeptide chain" described by Creighton[1] is not new either in concept or in execution. The idea of using varying ratios of iodoacetamide and iodoacetate to alkylate proteins and then to determine the number of alkylated cysteine residues by gel electrophoresis was first introduced by Feinstein[2] in 1966. In that original paper starch gel electrophoresis was used. Subsequently, Feinstein and Stott[3] used isoelectric focusing to resolve the differently charged proteins. In both of those papers the 'charge-shift' technique was used to determine the number of free thiol groups on partially reduced proteins.

More recently Singer and I[4] have used 'charge-shift' analysis of fully reduced protein to determine the cysteine content. We have therefore used the method in exactly the same manner as that described by Creighton. Extension of the charge-shift method to other amino acid residues is an obvious possibility. However, the data presented by Creighton relate only to the determination of cysteine residues.

I am most surprised that the previous publications on the charge-shift method should have escaped the attention of both Creighton and the *Nature* referees.

A. R. WILLIAMSON

Institute of Biochemistry,

1. Creighton, T. E. *Nature* **284,** 487–489 (1980).
2. Feinstein, A. *Nature* **210,** 135 (1966).
3. Stott, D. I. & Feinstein, A. *Eur. J. Immun.* **3,** 229–235 (1973).
4. Singer, P. A. & Williamson, A. R. *Eur. J. Immun.* **9,** 224–231 (1979).

CREIGHTON REPLIES—The papers cited by Williamson[1–3] describing the 'charge-shift' method of determining cysteine residues, which has become the same in principle as the method I used[4], were unfortunately unknown to me, the referee of my paper, all the colleagues with whom I discussed this matter, and the authors of all review articles and monographs on the subject of amino acid analysis that I could find. A thorough search through the index of *Amino Acid, Peptide and Protein Abstracts* for papers on amino acid analysis also failed to uncover these papers. This ignorance of the development of Feinstein's original work[2] can be attributed to its publication only as a small part of papers dealing with the biosynthesis of immunoglobulins published in an immunological journal[2,3], with no mention of the method in either the titles or abstracts. This is an instructive example of how care must be taken if the attention of the appropriate audience is to be drawn to published work.

Having now studied these papers in detail, I note that the validity of the charge-shift method was not established at that stage, either by confirming the results with an independent, established method or by demonstrating that it gave the correct results with a well characterized protein. It was also used inappropriately with a protein that was electrophoretically heterogeneous so that the results were ambiguous[3]. Demonstrating the validity of this method is especially important because it depends critically on the completeness and the specificity of the reaction of cysteine thiol groups with iodoacetate and iodoacetamide. I demonstrated this by obtaining single electrophoretic bands of unfolded proteins treated with the limiting cases of just iodoacetamide and just iodoacetate[4]. There was then no uncertainty about where to start and where to stop counting the bands generated by reaction with mixtures of the two reagents. The number of bands generated gave the correct number of cysteine residues for six well characterized proteins. When this procedure is used with a new protein, a well characterized protein should always be included as a control, to ensure the specificity and completeness of the reactions.

It is clear that this general method of determining integral numbers of specific amino acid residues is simple, easy, and can give unambiguous results when properly applied. The general approach should be useful for some amino acid residues other than cysteine; the observations of Anderson and Hickman[5] using carbamylation and of M. Hollecker in this laboratory using succinic anhydride[6] demonstrate that it may readily be extended to lysine residues.

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature.* The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

BOOK REVIEWS

The genesis of experimental psychology

O. L. Zangwill

Wilhelm Wundt and the Making of a Scientific Psychology. Edited by R.W. Rieber. Pp.252. (Plenum: 1980.) £15.44, $24.50.

THIS book was compiled to mark the centenary last year of the establishment of the first laboratory in the world to be devoted exclusively to experimental psychology. Its founder was Wilhelm Wundt, a physiologist with a taste for philosophy, who had worked for many years at Heidelberg under the shadow of the great Helmholtz. After a somewhat undistinguished early career in physiology, Wundt was translated to Leipzig as a professor of philosophy, to which he was undoubtedly better suited, and at Leipzig he remained for the rest of his life.

In 1873, Wundt published the text on which his reputation has been principally based. In a later edition, this was translated into English by his devoted follower, E.B. Titchener, as *Principles of Physiological Psychology*. Of all Wundt's voluminous writings, this is, if not the best, certainly the best known. Wundt's own introductory statement to the original edition on "the task of physiological psychology" is one of the few extracts from his writings to appear in this volume which, however, also includes a fascinating review of the first German edition of the *Principles* by William James.

How did Wundt view experimental psychology? One may note first that whereas he saw physiological and experimental psychology as being virtually synonymous, he was in no doubt whatsoever that the latter warrants acceptance as a distinct and separate department of knowledge. This is well brought out in the second of the two excellent chapters by Kurt Danziger on Wundt's theoretical position. Arising from his exposition of Wundt's theory of human behaviour, Danziger directs special attention to the classical series of experiments on reaction times which were among the earliest fruits of his laboratory. Danziger treats the measurement of reaction times as in no sense a mere adjunct to physiology, as it had hitherto been viewed, but as a coherent manifestation of psychological research in its own right having direct relevance to the explanation of human behaviour.

As Wundt saw it, the most central of the issues underlying reaction time measurements was concerned with human volition. The distinction between "sensorial" and "muscular" reaction times, Wundt believed, had important theoretical implications for an understanding of volitional activity and its relationship to the evolution of higher-order choice and decision processes. Such issues, he considered, lie totally outside the province of physiology, which then even more than now was conceived to be limited to essentially reflex models of involuntary action. Indeed the prolonged neglect of Wundt's work in America was undoubtedly due, in part at least, to the protracted behaviourist hegemony and the reductionist philosophy which it embodied. Even in Germany, the belief that selective attention, so central to Wundtian thinking, lacked explanatory value, became a central tenet of Gestalt psychology and under its influence reaction times, too, ceased for many years to be of more than marginal interest.

Currently, behaviourism is clearly in decline, and cognitive and developmental preoccupations in psychology equally clearly in the ascendant. In consequence, the climate is once again more sympathetic to the Wundtian outlook and this book may itself result in a revival of interest in his work. True, concepts of information processing and control mechanisms have replaced the Wundtian concepts of volition, apperception and creative synthesis, the roots of which lie deep in the *Naturphilosophie* of mid-nineteenth-century Germany. As Danziger rightly points out, present-day psychology is concerned primarily with an understanding of human performance, governed by concepts of selective attention, information processing, and decision and choice. Such a psychology may, in some sense, widen rather than diminish the gap between psychology and the neurosciences, but it leaves unaffected Wundt's insistence on experimental psychology being conceived as an autonomous discipline which stands in symbiotic relationship with physiology. Further, although Wundt regarded social psychology as an historical and cultural rather than as an experimentally based discipline, his emphasis on its pre-eminent importance for psychology in general will find a sympathetic response in many quarters today.

One particularly valuable contribution made by this book is the challenge it provides to the received ideas about Wundt and his work which stem largely from the writings of Titchener and his pupil, E.G. Boring, the celebrated historian of experimental psychology. This challenge emerges particularly clearly in Blumenthal's chapter on Wundt and early American psychology, though it is unfortunate that it was not thought appropriate to reprint his enlightening reappraisal of Wilhelm Wundt which appeared five years ago. Danziger has also some highly relevant things to say about Titchener's many misapprehensions of Wundt's philosophical position. Solomon Diamond contributes a long essay on Wundt's early life and activities as a physiologist, though his somewhat uninhibited personal criticism may be thought to limit its biographical value.

Although inevitably a hodge-podge, this book will be welcomed by many people who are genuinely interested in the origins and development of experimental psychology, even though some of them may still continue to believe, with William James, that psychology is less a science than the hope of a science. ☐

O.L. Zangwill is Professor of Experimental Psychology in the University of Cambridge.

HBV *et al.*

William S. Robinson

Hepatitis Viruses of Man. By A.J. Zuckerman and C.R. Howard. Pp.269. (Academic: 1980.) £16.80, $39.

OCCASIONAL reviews of hepatitis viruses by experts are welcome because knowledge of these viruses has been advancing so rapidly over the past decade that it is sometimes difficult for those in the field, much less outsiders, to keep up and assimilate all of the new findings. Such reviews are most helpful when they are able to provide new insights, bring some order where chaos reigns among conflicting data, evaluate new findings in the context of other relevant and better studied biological systems, or provide a bibliography which makes a body of research literature readily available to readers. The authors of this book are active investigators in the field and have a broad knowledge of recent work. They intended this book to provide "an account of the more important published advances and exciting developments in this field". The book does provide a large amount of recent information about hepatitis viruses. It attempts to cover widely different aspects of such viruses, including their history, ultrastructure, antigenic structure, molecular structure, epidemiology, course of infection, pathology of associated diseases, immunology, laboratory testing, animal and cell culture infection, environmental control measures and management of infected patients, immunization and antiviral treatment. Most of the book by far is devoted to hepatitis B virus (HBV), less to hepatitis A virus and least to the newly recognized non A, non B hepatitis agents; coverage is thus in proportion to the amount of new information about each of the viruses.

Some aspects are more successfully covered than others. The first chapter, "The History of Viral Hepatitis", includes many important findings from the earliest recordings of hepatitis-like disease to recent breakthroughs that have propelled the field forward. This account is well documented with references. After this chapter the presentation changes. As each area is considered, recent findings are almost exclusively given, and older work is omitted or briefly summarized, often without referencing. Frequently statements are presented as fact without documentation. For example, a large part of the chapter "Pathology of the Liver in Acute Viral Hepatitis", is devoted to a near-textbook description of histological features of acute human viral hepatitis without documentation. By presenting only recent findings on epidemiology, only the surface of this subject is covered. Certain important and long-standing epidemiological concepts about these viruses are omitted such as the different epidemic and endemic patterns of infections, the different dynamics of the viruses in human populations and the different factors which are involved in maintenance of each in populations, to name a few. In some places experimental results are given without crediting the investigators, for example on p.26. An experiment in which HBsAg was detected "in 18 out of 24 saliva specimens and in 10 out of 10 samples of semen" is presented without a reference. Similar statements are found throughout the book. This failure to document the source of some recent findings that are given in detail in the book and the almost complete omission of older findings and reference to literature (that before 1975) greatly limit the value of this book as a reference source for investigators in the field, teachers and students. The authors suggest that the earlier literature is fully cited in a previous book by one of them. This, of course, is only partially satisfactory since it requires simultaneous reading of both books to obtain the whole picture and it leaves this book as only a partial account.

The information in the book is usually presented as a sequence of descriptions of the findings of individual studies. Little attention is given to comparison of findings of different investigators, offering explanations of differences in findings, suggesting new approaches which might resolve differences, or organizing and analysing complex subjects. For example, e antigen is such a complex subject and a number of apparently conflicting findings have been reported. Claims suggesting that e antigen is an immunoglobulin, related to lactic dehydrogenase, or that it may represent a virion component, have been published. These different findings are not critically analysed nor is a judgement as to the merit of each offered. No approaches are suggested for resolving the differences. Conflicting data concerning the relationship of e antigen to liver disease are similarly handled.

The chapter entitled "The Nature of Hepatitis B Virus" is similarly a descriptive account of experimental findings about the virion. The reader is given little feeling that HBV is a virus in the modern sense with specific genes whose functions are involved in viral structure, infection and replication. Although few details of virus replication at the molecular level are available for HBV, there is evidence for the identity of some viral gene products, such as HBsAg polypeptides, and evidence for locations of viral antigen synthesis and the structure of viral DNA forms in cells.

Finally it is disappointing that the structural, molecular and biological features of hepatitis B that distinguish it from viruses of other groups were not especially pointed out in order to provide a perspective of this interesting and unique virus. In this regard, the recent finding of a similar virus in woodchucks was not included. The woodchuck virus is important not only because it indicates that HBV may be only one member of a new group of viruses, but because its association with hepatoma in infected animals offers one of the most compelling arguments for an important relationship of viruses with properties like those of HBV to primary liver cancer, an issue with HBV in man.

Thus, although this book provides much recent and important information about several viruses which are of great biological and clinical interest, the choice of material and its presentation limit the book's value as an introduction to these viruses and as a reference work for those already familiar with the field. ☐

In memoriam: the English chalklands

Kenneth Mellanby

Ecology of the English Chalk. By C.J. Smith. Pp. 573. (Academic: 1980.) £23.80, $55.

As a schoolboy I thought of the chalklands of England as a crocodile. A geological map hung on the wall of one of my classrooms, and its most prominent feature appeared to me to resemble a light-blue reptile with the North and South Downs as the upper and lower jaws, the body turning round so that the tail ended up in Norfolk and Lincolnshire. Living in Scotland and the north of England, I never visited my crocodile until, as an undergraduate at Cambridge, I was taken by the botany department to study chalk grassland near Royston. I still remember my first visit, in spring, when the Pasque flower was at its best. This and many subsequent visits to Royston Heath, Salisbury Plain and other chalk grasslands continued to impress me with both the beauty and the scientific interest of these areas. Even when I dropped botany for entomology, the butterflies and other insects sustained my fascination.

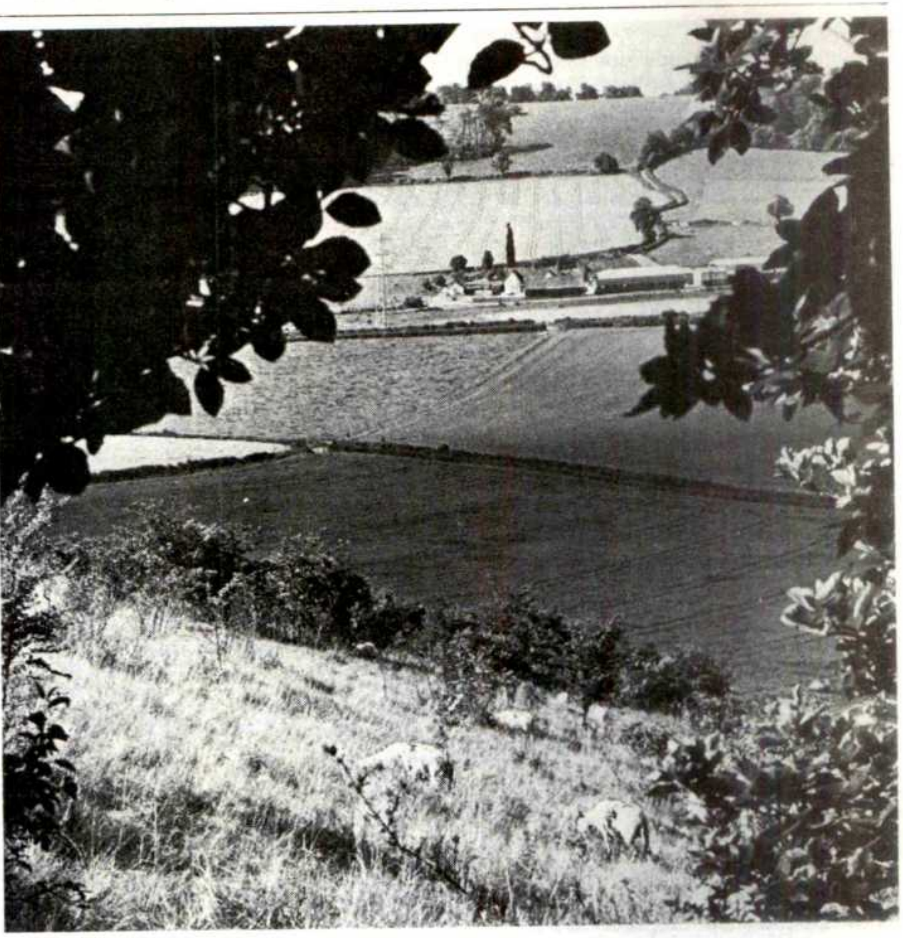
For over 100 years naturalists have shared my enthusiasm, for even a cursory glance through the literature shows that more work has been done on chalk grassland than on any other plant and animal habitat. Dr C.J. Smith has performed a notable service in bringing the results of this careful study into one book. He lists well over 700 references, and he is clearly familiar with the information contained in them all.

We are given a description of the chalk's geology and the history of the land use; there are details concerning the plants and animals and their interactions. The result cannot be called light reading: it is far too concentrated for that. But anyone interested in natural history who has visited the chalk will find something of interest, and something to stimulate him to further observation. Serious students will all acknowledge their indebtedness to Dr Smith's singleness of purpose, and this volume will be accepted for many years as the final authority on its subject.

The book makes it clear that the areas of chalk grassland which are of particular interest have all been profoundly affected by human activity. The land was first cleared of trees by our distant ancestors, mainly to grow arable crops. After a few years of declining fertility it was allowed to go down to grass, which was grazed by stock — cattle and sheep. The best turf has existed for centuries. This species-rich grass only persists when it is regularly grazed, otherwise rank growth crowds out the most prized plants, and shrubs develop in the first stage leading to the forest climax. The scrub and woodland have their own interest and beauty, but it is the grass with all its flowers which has the greatest appeal. The sad thing is that it is this old grass which is so rapidly disappearing from England. It remains on only about 3% of the area covered 200 years ago, mainly as small fragmented patches on slopes too steep to cultivate. It is being replaced by fertile arable fields and improved, productive but species-poor grass. The modern farmer obtains many times the yield of former days — in doing so he improves the soil in structure and fertility, but he totally and irreversibly destroys the area from the point of view of nature conservation.

I am less optimistic than Dr Smith about the future of the fauna and flora of the chalk. Some unimproved grass will no doubt remain in nature reserves but, with the rise in land prices, economic pressures will probably affect the rest. So I welcome this book as a memorial to those who have worked on the chalk, and a record of one of the glories which is so surely departing from the English countrvside. □

Kenneth Mellanby was director of Monks Wood Experimental Station, under the British Nature Conservancy, from 1961 to 1974.



Buttlers Hangings, a Naturalists' Trust Reserve, near West Wycombe in Buckinghamshire. The land here is too steep to cultivate, and represents the last remnant of chalk grassland and scrub between the woodlands of the plateau and arable land of the valley.

A milestone for the geologists of New Zealand

A. Ewart

The Geology of New Zealand. Chief editor R.P. Suggate. (Government Printing Office: Wellington, 1978/79.) Two-volume set NZ$92.50 + postage.

In 1950 the late R. W. Willett, then Director of the New Zealand Geological Survey, instigated an ambitious 1:250,000 mapping programme of New Zealand. Completed in 1968, the programme provided both stimulus and unity to geological research in New Zealand.

Only now, 15 years after the huge task of putting the results into print was started, have the efforts of geologists and editors culminated in the appearance of these two imposing volumes. Based on the contributions of 38 specialist authors, professionally produced and lavishly illustrated, the books represent the compilation and synthesis of a vast amount of data.

The organization of the text emphasizes the three distinctive tectonic phases through which New Zealand has evolved: the Tuhua Orogeny (mid to late Palaeozoic), the Rangitata Orogeny (mid to late Mesozoic) and the Kaikoura Orogeny (Miocene to the present day). The opening chapter provides the framework for the main text with sections on aspects of basic geology, and the following nine systematically treat, in great detail, the geology of New Zealand and its outlying islands, starting with the oldest sequences.

Six of the contributions lay down a descriptive basis. Each is concerned with a specific event and follows through the geological development of the region from the late Precambrian–Devonian to the Quaternary. Thoughtful editorial work is evident in that the format is consistent throughout: in each case an introduction leads on to consideration of the palaeontology, stratigraphy and petrology. Most notable is the profusion of illustrative material — maps, tables, correlation charts, photographs and line drawings litter the text. Interspersed between the descriptive chapters are three devoted to interpretation and synthesis of data on the three main orogenic phases.

The treatise concludes with a consideration of palaeogeographical and palaeoenvironmental evolution, from the early Palaeozoic to Recent, as deduced primarily from the fossil record. This last chapter emphasizes the affinities and palaeogeographical links of the faunas and floras, and attempts to identify the gross climatic patterns and changes through the fossil record and their timing.

Shortcomings of the work are predictable, indeed inevitable, given the extended period of production and the number of authors involved. The contributions vary somewhat in style, objectivity and depth of treatment. In certain chapters overlap of topics is evident, and the material is not always internally consistent (for example the discussions of metamorphism in Chapters 4 and 5). Because the main text was prepared in the early 1970s the interpretations are made largely within the context of the New Zealand region alone, with only sporadic attempts at synthesis in terms of modern concepts of plate tectonics. This problem was recognized by the editors, however, and at the end of Vol. 2 they have provided a supplement to each chapter which consists of a brief review of developments up to about 1976, together with relevant references.

The Geology of New Zealand does not provide an easy introduction to the region and it will undoubtedly be used mainly for reference. However, publication of the volumes is certainly a milestone for geological research in New Zealand. They will provide a firm foundation for future research and should also be of great value to all geologists concerned with the south-west Pacific, indeed to all those whose special interest is Mesozoic and Cenozoic geology. The chapters dealing with the history of these relatively younger rock sequences indicate how much New Zealand has to offer in such studies.

In all, this is an oustanding work. It is a tribute not only to the editors and authors, but also to the strength and enthusiasm of the New Zealand Geological Survey. ☐

A. Ewart is Reader in Geology at the University of Queensland.

Chemistry of steroids and peptides

J. S. Morley

Steroids and Peptides: Selected Chemical Aspects for Biology, Biochemistry, and Medicine. By J.B. Dence. Pp. 418. (Wiley-Interscience: 1980.) £20.85, $47.50.

THE commendable general purpose of the author is to present the background of steroid and peptide chemistry to research workers in biology, biochemistry and medicine. Of the various classes of naturally occurring compounds, steroids and peptides are arbitrarily chosen for discussion (future volumes may deal with carbohydrates, lipids and nucleotides). They are discussed separately in introductory chapters, and in chapters on synthesis and chemical properties.

The opening articles will be the most useful in that they deal with matters (occurrence, structure, nomenclature, physical properties and physiologically active species) of general interest to workers in other disciplines. The introduction to steroids is particularly well written. Even a modest background in chemistry should suffice to understand the clear accounts of seemingly complex topics — conformation, configuration, sequence rules, IR and UV spectroscopy, Woodward–Fieser rules and chirality, for example. Peptides are treated less well, and one is left with the impression that the author's experience of the field is drawn mainly from reading; perhaps this explains the often strange choice of examples. Nevertheless, basic information is well presented, and there is a useful summary of nomenclature rules (blatantly violated in later parts of the book!)

The chapter on steroid synthesis contains useful summaries of biosynthesis and steroid conjugates, but that on peptide synthesis may mislead rather than inform. There is, for example, no mention of protecting groups for C-terminal carboxy, and commonly used techniques are inadequately covered because of over-emphasis on newer, as yet unproven methodology. It is unfortunate that coupling methods are illustrated by reference to an unsatisfactory synthesis of the L,D,L-isomer of thyroliberin; the methods involved, in contrast to those used in a later synthesis, lead to a partly racemic product. If a reader ever "should find himself in a situation where he must synthesise a peptide" he would be well advised to refer to one of the many specialist reviews of peptide synthesis rather than to this chapter.

The discussion of chemical properties cover oxidation, reduction, substitution reactions, derivatization and microbial transformations (steroids), and modifications at the N- and C-terminus and side-chain groups (peptides).

Returning to the aim of the book, the author has, I believe, wrongly assessed the needs of non-chemical research workers. If he had devoted more space to the topics discussed in the introductory chapters, and omitted or curtailed coverage of chemical synthesis, his book could have been more strongly recommended. ☐

J. S. Morley is Head of Peptide Research at the Pharmaceuticals Division of ICI Limited, Alderley Park, Cheshire.

ANNOUNCING
A NEW JOURNAL

ARTERIOSCLEROSIS: A Journal of Vascular Biology and Disease

Published by the American Heart Association

This journal has been designed to provide a forum for the publication of high quality research from a variety of disciplines bearing on the biology, prevention, and impact of vascular diseases relating to arteriosclerosis. We invite papers on:

Vascular biology
Pathology of vascular lesions
Platelets and thrombogenesis
Lipid and lipoprotein metabolism
Connective tissue biochemistry and metabolism
Population and genetic studies
Interplay of risk factors
Arteriosclerosis in the young
Animal models
Evaluation of intervention
Detection and quantification of arterial lesions

Contact the Editorial Office for Guidelines to Authors: 1107 N.E. 45th Street, Room 316, Seattle, WA 98105, Phone: (206) 545-1609. Editor: Edwin L. Bierman, M.D. Associate Editors: Paul Bornstein, M.D., Laurence Harker, M.D., Arno J. Motulsky, M.D., Russell Ross, Ph.D.

Circle No. 25 on Reader Enquiry Card.

Pennant would be proud

C. M. Yonge

British Crabs. By R.W. Ingle. Pp.222 (British Museum (Natural History)/Oxford University Press: 1980.) £16.

WHEN the decapod crustaceans learnt to tuck an increasingly reduced abdomen under a laterally expanding cephalothorax, the crabs had arrived. The well-enclosed gills permitted exploitation of intertidal and, in warmer lands, of terrestrial environments. The lateral scuttling movement proved ideal for seeking widely dispersed food and for insinuation within protective shelter.

Thomas Pennant separated these "crustaceous animals" from the insects where Linnaeus had placed them, and the fourth volume of his *British Zoology* (1777) contains figures of our commoner species. These include the male and female of the Long-clawed Crab, *Corystes cassivelaunus* (Pennant), here reproduced to form a highly suitable frontispiece to a book representing the culmination of later studies initiated by William Elford Leach in his *Malacostraca Podophthalmata Britanniae* (1815–1820; completed by C. B. Sowerby in 1875).

Although less numerous here than in the tropics, there are 67 British crabs. Their long-needed modern description has now been admirably supplied in this authoritative book by Dr R. W. Ingle of the British Museum (Natural History). Initial accounts of early work on geographical and bathymetric distribution, and descriptions of external anatomy illustrated with accomplished line drawings, precede full systematic and descriptive information about all species. This is followed by 34 plates carrying double that number of extremely clear photographs. An exhaustive reference list completes a volume which will be welcomed by all marine biologists. It is a credit alike to author and to publisher, and a notable addition to works on carcinology. ☐

Sir Maurice Yonge is an Honorary Fellow in Zoology at the University of Edinburgh.

Will the DNA guidelines wither away?

On both sides of the Atlantic, the regulations for the control of recombinant DNA research are being substantially relaxed (see *Nature* 27 September and 2 October). At the present pace of about one major relaxation every two years, it will not be long before the regulations have virtually disappeared. Both in Britain and the United States, the regulatory authorities (the National Institutes of Health and the Genetic Manipulation Advisory Group) have decided that a substantial part of their work shall be in effect delegated to local safety committees, working within institutions (in the United States) or laboratories (in the United Kingdom). The categories of hypothetical hazard into which experiments of different kinds have been slotted in the past five years, have also been changed once again, with the result that a large proportion of the experiments still formally under the control of the regulatory bodies will now be exempt. Is it time that governments began to think of what should be done about recombinant DNA research say two years from now, when there is almost nothing left to regulate?

Some recrimination is unavoidable. Many impatient people, who have regarded the past period of regulation as an intolerable and unnecessary impediment to their work, will make fun of the way in which the guidelines were hardly complete before the process of dismantling them began. Some, alas, will take out their anger on hapless Professor Paul Berg, who is rightly or wrongly thought to have been the instigator of the movement to regulate recombinant DNA research — or to have provided governments with an excuse to do so. Then, no doubt, in other DNA laboratories, there will be some who will continue to complain that the genetic manipulators are being given an even wider licence to pervert the course of human evolution and so on. Both strands of complaint will be misjudged. Both camps should be grateful that the regulatory bodies have somehow kept the peace in the past five years.

The truth is that at the outset, five years ago, a great many serious people, many of them molecular biologists, were genuinely alarmed at the risks that recombinant DNA research might bring. The risks were always conjectural, but they could not be confidently equated with zero. But, in the past five years, solid evidence has accumulated that many of the conjectured risks are insubstantial. *Escherichia coli* K12 does not, after all, survive in the human gut, while the frequency of recombination of K12 with wild-type *E. coli* or other organisms has turned out to be too small to sustain the conjecture that altered genes might become permanent components of the gut flora. The recognition, since the guidelines were first drawn up, that introns are more the rule than the exception in eukaryotic genes has decreased the chance that a plasmid carrying a foreign piece of DNA will actually become a source of foreign and possibly damaging protein. Some of the more fanciful conjectures of the past — the possibility that engineered bacteria or viruses might disturb the immune system, for example — have not been much affected by discoveries in the past few years, but they were always conjectural conjectures, so to speak. In general, the discoveries in the past five years which bear on the safety of genetic manipulation support the argument that genetic manipulation is unlikely to create threats to people, other animals and plants that would not have arisen in the course of evolution. This does not imply that all risks can now be disregarded, but merely that most of the risks originally conjectured are less immediate than was thought.

The systems set up by most governments for regulating recombinant DNA research have served a useful purpose in the past five years. They have provided the general public with a sense that everything possible has been done to avoid or to diminish risk. Most of the committees responsible for administering the guidelines have functioned well. Some of them (the NIH committee, for example) have even functioned publicly. From the public point of view, they have also worked cautiously. Restrictions have been removed, and types of experiments recategorized, only after the wisdom of doing so had been fully substantiated. (The recategorization by NIH of certain animal virus experiments in the summer of 1978 may have been an exception.) One result may be that people have not been able to get ahead with research as quickly as they might. Another has been that there has never been a legitimate cause of complaint by the general public against the practice of genetic manipulation. Such warnings of impending catastrophe as there have been have cut very little ice.

The benefits of this climate of civility in the past five years far outweigh the inconvenience and the delay which some have suffered. The cost of the special laboratories which have been built to contain experiments no longer required to be carried out in such stringent circumstances is a small price to pay for the relative peace and quiet there has been. (The institutions saddled with them may take some comfort from knowing that if they become white elephants, they may also be taken as marks of their prestige in the late 1970s.) There is yet a chance that the case of recombinant DNA research may become a useful model of how new technologies might be introduced.

So what lessons can be learned from the experience of the past few years? And what does the future hold for recombinant DNA research?

The first thing to appreciate is that the time has not yet come to make a bonfire of the regulations. The main result of the most recent relaxation is, in effect, to license laboratories and their safety committees to carry out experiments in the lowest categories of supposed hazard. Categories, and prescribed containment, will remain for others, and it will be some time before further relaxation is possible. Looking ahead, some kinds of recombinant DNA experiments that people wish to carry out would in future (as now) fall within the scope of the guidelines which regulate experiments with dangerous pathogens even if the recombinant DNA guidelines were abolished. Problems of scaling-up from the laboratory to the manufacturing scale also remain, and the regulatory committees are rightly preoccupied with them. (One useful beginning would be to find a better distinction between the first and the second than the entirely arbitrary supposition that 10 litres of any culture constitutes "scaling-up".) Ultimately, however, procedures on an industrial scale will be regulated by the statutes which apply to occupational safety, so that that the withering away of the guidelines for recombinant DNA will not provide manufacturers with an entirely free hand.

Thus there is a prospect that the DNA guidelines may, at some time in the future, be subsumed in other and long-standing sets of guidelines. What about the experiments in the P2 and P3 categories (NIH terminology) that will continue to be regulated by DNA guidelines at least for the next few years. Even here, the regulatory authorities should move as quickly as they can towards some version of a licensing system — one in which laboratories (and their safety committees) take the first responsibility for deciding what degree of containment is appropriate for which experiment, and then provide the regulatory authorities with a

0028-0836/80/410473-02$01.00

report on what they have been doing at least once a year. Apart from the benefits that would follow for DNA researchers, questions of industrial secrecy would also by such a step be simplified enormously. In moving towards such a system, however, the committees should be much more concerned than in the past to coordinate their practice internationally. The unfortunate case of Dr Samuel Kennedy of the University of California (see *Nature* 18 September) may be a vivid illustration of the trouble caused when governments follow different standards. Nobody can know at this stage what part international competition played in the affair, but the German guidelines were at the time less stringent than the American — and Dr Kennedy's chief rivals in the study of the arbovirus genome are in West Germany. Is it not high time that the regulatory committees recognized that such ironies will persist as long as they decline (as they have almost studiously done) to talk to each other directly?

The question remains of how best to deal with problems like those occasioned by genetic manipulation which are certain to arise again. In retrospect, in countries as different as Britain and the United States, the committees set up to hold the ring between the public and the molecular biologists have served reasonably well. If anything, the molecular biologists have been more frustrated than the public, which is only right and proper. On balance, especially in the early days, it would have been helpful if the proceedings of the British group responsible for the guidelines had been carried on in public as, for most of its time, the corresponding American committee has been required to do by the Freedom of Information Act. Many incipient misunderstandings about the functioning of the Genetic Manipulation Advisory Group have been consequences of the secrecy imposed on it under the Official Secrets Act as well as by the conventions of Whitehall. People may rightly ask what kind of public assurance can stem from the proceedings of a secret committee. Even so, the committee has functioned better than many expected.

The most obvious deficiency of the past few years is that, faced with a problem of assessing the safety of a new and unexplored laboratory technique, the responsible committees (and the scientific community itself) did very little to provide the data on which objective assessments of safety might be based. It is true that people have fed each other quantities of *E. coli* from time to time, and there have been a few half-hearted attempts to see whether genes incorporated into bacteria can find their way into the somatics cells of laboratory animals. Few opportunities have been seized for looking into the ways in which bacteria carrying foreign genes might actually damage their adventitious hosts. The customary explanation, during most of the past five years, is that the people most competent to carry out such experiments have been too preoccupied with exploiting the new techniques whose safety was called in question. With a few conspicuous (and honourable) exceptions, those with the most vivid interest in demonstrating that their techniques are as safe as they now appear have been content with arm-waving. They, as well as the rest of us, are lucky that things have turned out as they have, and that the general perception of the risks of genetic manipulation has so quickly, and painlessly, moderated. It could have turned out quite differently.

McNamara's fond farewell to his bank

Who would think that the president of a large automobile manufacturer turned US Secretary of Defense at the height of the Vietnam War would turn out to be a superb president of the World Bank? The credentials, impressive enough, are on the face of things unfitting. Yet the governors of the bank plainly knew what they were doing when they appointed Mr Robert McNamara to his present post nearly fourteen years ago. During that period he has managed both to dramatize the cause of economic development in the poorest countries of the world and then to make the World Bank itself into a powerful instrument for prosecuting that cause. He has, in other words, justly earned the right to make the fierce complaints which marked his valedictory address to the members of the bank last week. And he is right, of course, to note that the cause of development has gone sour in the past few years, right to complain that many industrialized countries (Britain was singled out) are reducing their contributions to overseas aid, right to complain that the OPEC surplus states should carry a much greater burden and right to fear for those who carry the true burden of development:

> "We do not see their faces, we do not know their names, we cannot count their number. But they are there. And their lives have been touched by us, and ours by them."

In retrospect, Mr McNamara's most cheerful memories will no doubt be of the early 1970s, when he was stumping the world urging governments that they should not forget the "poorest of the poor" and at the same time persuading the members of his bank that their funds should be invested as often in social infrastructure as in mammoth capital projects. Even then, however, it was an uphill struggle. With a few rare exceptions (Sweden, for example), most industrialized countries never consistently came near the United Nations target for overseas aid of 0.7 per cent of GNP. Since the increase of the price of oil, performance has worsened — and the World Bank has become even more important as a source of multilateral aid. The explanation is, unfortunately, all too simple. Industrialized governments have become obsessed with domestic problems, many of them caused by the increased price of oil. But at a time when voters are being asked to pay more tax or to do without public services, governments are plainly unwilling to prosecute the cause of development. The Brandt Commission was upbraiding them for their neglect earlier in the year. Mr McNamara has now added his complaints.

The complaints are fair, but they will not be listened to with much care. One trouble is that governments are preoccupied with other things. A more serious difficulty, which both the Brandt Commission and Mr McNamara overlook, is that the cause of development has gone sour because relations between the industrialized states and the rest of the world have themselves gone sour. Although most oil consumers recognize by now that the crude oil prices of the 1950s and 1960s were unfair to the oil producers, they have not enjoyed the humiliations of the past few years, or the economic upheavals that have gone with them. And they will not forget them. In such circumstances however, it is natural enough, if wrong, that the Western oil consumers should be saying that if any group of states should take responsibility for helping with economic development of the poor countries, the OPEC states are the obvious candidates. So (as Mr McNamara says) they are. Unfortunately the OPEC states are even more preoccupied with their own problems than are the industrialized states of the West. Since there is no prospect that the members of the Warsaw Pact and its adherents will produce the kind of help that the developing countries need, it is no wonder that Mr McNamara's speech was so gloomy.

So is all hope lost? Not quite. Or perhaps not yet. There are a few clouds with silver linings. The OPEC states have somehow to manage their surpluses, usually by asking other people to do that on their behalf. There may be some pickings for development there. Better, even the past two sad decades have shown that some developing countries can actually develop, and make good. The example of India is not a joke. Better still, it appears now to have been understood in the West (but also in the developing world) that development assistance is not the provision of capital funds but help with the process of development, "infrastructure" as the saying goes. Sometimes this means teaching businessmen how to do accounts, politicians how to be ministers and children how to read. Building roads is by these standards capital-intensive. If only Mr McNamara had had another fourteen years, he might have been able to demonstrate what many suspect — that the most imaginative development is cheap.

Melanoma increase in radiation labs?

Livermore data may be significant

Washington

US Department of Energy officials remain baffled about the cause of an abnormally high incidence of malignant melanoma among employees of the University of California's Lawrence Livermore Laboratory, one of the nation's centres for nuclear weapons research.

An advisory board report released in Washington last week confirmed findings suspected since 1976, and substantiated earlier this year by California's Department of Health Services, that the incidence of skin cancer among laboratory employees was three to four times the national average.

The California study showed that between 1972 and 1977, 19 white workers at the laboratory had developed malignant melanoma, compared with between 4.6 and 6.4 cases expected using national statistics, a result which it said was "very unlikely to have occurred by chance".

At the request of the Department of Energy, the data were reviewed by an advisory board chaired by Dr Arthur Upton, then director of the National Cancer Institute. The board found no flaws in the Californian study and revealed that the increased incidence seems to have continued, with eight more cases of melanoma being reported up to June 1980.

However, the advisory board reports that preliminary efforts to explain the excess have not succeeded in implicating any specific cause. It says that the occupational safety, industrial hygiene and medical programmes of the laboratory appear to be well conceived and well conducted, and that additional protective health measures "appear to be unwarranted".

It also lists a range of possible environmental causes, from occupational exposure to chemicals to details of individual lifestyles, which it says should be studied in more detail to get to the root of the problem.

"Part of the difficulty is that there may be no problem at all. We still don't really know if this thing is real; it may be just a statistical fluke" stated one member of the board last week, pointing out that the continued high incidence could be the result of people looking for — and finding — melanomas many years earlier than they would otherwise be detected.

Although a relatively rare form of cancer, the incidence of malignant melanoma has been increasing faster than almost any other cancer in recent years. In San Francisco, for example, the number of cases rose from 5.8 to 11.2 per 100,000 between 1970 and 1975, and similar figures have been reported for other parts of the country.

One fashionable explanation is that, because the greatest increase has been found among fair-skinned professionals, whose work tends to keep them indoors, it may be caused by intermittent exposure to ultraviolet radiation, for example as a result of excessive sunbathing or other outdoor activity.

Preliminary examination of the occupational histories of those contracting skin cancer has failed to reveal any obvious common pattern of exposure to particular chemicals or forms of radiation, and the board's report points out that although malignant melanomas have been found in an irradiated person, epidemiological studies have failed to produce convincing evidence that tumours may be induced in the skin by ionizing radiation.

However, the possibility that occupational exposure to, for example, internal emitters and ultraviolet radiation may contribute to the aetiology of melanoma is one of several avenues that the laboratory intends to explore further. "It is just possible, because of changes in lifestyle such as improved nutrition, that we have managed to increase our risk of cutaneous melanoma to the point where, although radiation was not a cause in the past, it might have become one today", says Professor John A.H. Lee of the Department of Epidemiology at the University of Washington in Seattle.

In a memorandum submitting the board's report to Energy Secretary Charles Duncan, the Department of Energy's Assistant Secretary for the Environment, Dr Ruth Clusen, suggests that further studies by both the laboratory and the state Department of Health Services should be supported.

The latter has already proposed a major follow-up programme, which is being reviewed by the department that will take a detailed look at the particular social characteristics of the Lawrence Livermore workforce. A parallel study may also be carried out at another Department of Energy site.

The Lawrence Livermore Laboratory is operated by the University of California under contract from the Department of Energy. Its involvement in weapons research — and the resulting need to keep much of the research programme secret — has been the source of sharp controversy over whether its links with the university should be maintained.

Last year the university's board of regents rejected a call from California Governor Jerry Brown that all weapons-related research be moved to the Los Alamos Laboratory, and last month the regents agreed to start negotiations with the Department of Energy for a new management contract for the laboratory. The current contract expires in 1982.

David Dickson

EEC worries about veal and hormones

The massive veal market in Europe, consuming eight million calves a year, was on the verge of collapse this week following scares in France and Italy over the levels of an artificial growth hormone — diethylstilboestrol — in the meat. Diethylstilboestrol (DES) is a synthetic oestrogen which caused vaginal cancers in the daughters of mothers who were prescribed it (in large doses) as a protection against spontaneous abortion in the 1940s and 1950s. Its use is banned in the United States and in most countries of Europe, but a black market has sprung up because this chemical can add 5–15 kg to the weight of a calf and thus double a farmer's profits.

In Italy, the trouble began on 4 September, when the Ministry of Health placed a temporary ban on twenty-two brands of baby foods containing veal. A fairly crude bioassay had shown samples to contain an active oestrogen, probably DES. On 22 September a local magistrate in Latina, south of Rome, used the wide powers of Italian magistrates to impose a nationwide ban on the sale of veal. The Rome laboratory of the Istituto Superiore di Sanita, the technical arm of the Ministry of Health, is now making mass spectroscopic measurements of the hormones isolated from the baby foods to check for DES. In the view of a British scientist, the levels are probably "quite high" or they would be undetectable by the original method.

In France, pressure began independently from the left-wing trades union group, Paysans Travailleurs, whose members had accumulated evidence that French veal producers were using the synthetic hormone. Paysans Travailleurs then recruited help from the consumer group, the Union Fédérale des Consommateurs, which called for a boycott of veal in the September issue of its magazine, *Que Choisir*. Subsequently, in a rare enforcement of French law on the matter, a 29-year-old pharmacist and veal producer was jailed.

Pressure from farmers and other interests has forced the Italian magistrate to relax his ban somewhat, but sales of veal have still fallen by 50–60 per cent in both France and Italy, and the export of calves

0028-0836/80/410475-02$01.00

from Britain — where hormone use is controlled under the 1968 Medicines Act but not banned — has fallen to a trickle in a business normally worth £500,000 a week.

Last Tuesday agriculture ministers of the European Community tried to take a grip in the affair by promising that Commission officials would devise a scheme — within a couple of months — for uniform testing of hormone levels in meat throughout the EEC. Despite great pressure from Italy, however, the ministers drew back from imposing a total ban, but will not easily agree on the directive they have asked for.

EEC hormone law

Belgium, Denmark, France, Italy and the Netherlands already have a total ban on the use of natural or artificial hormones, but avoidance is thought to be commonplace. Belgium, France and West Germany take the view that a partial relaxation of the ban in favour of natural hormones — oestradiol and testosterone — would stop the abuse of the synthetic hormone which can be injected directly into the muscle as an oily, crystalline suspension, and is not easily detected by visual inspection of the meat after the animal is slaughtered; other hormone preparations, however, are administered as pellets implanted prominently in the ear. The ear is discarded at the slaughterhouse, but injected muscle will find its way straight to the table — or the baby food.

West German legislation, at present, distinguishes a list of hormones which may be administered — the positive list — and a list which may not — the negative list. On the latter are those which have an oral oestrogenic activity of more than one-fifth that of DES, so banning DES, the related hexoestrol, and two other artificial oestrogens. On the positive list at less than one-fifth the activity are the natural oestradiol and the artificial agent zeranol.

In Britain, the Medicines Act allows licensing of hormone preparations by the Veterinary Products Committee, under the Ministries of Agriculture and Health. Under these licences zeranol and hexoestrol are on free sale to farmers; and Hoecht's Finaplix (an androgen used in beef production) and Implixa (used for veal) administered by vets. The drugs may not be administered within at least 60 days of slaughter (although the drugs firms are pressing to reduce this period). The Pharmaceutical Society has the statutory authority to police the proper use of the drugs.

DES is no longer used in veal or beef production in Britain, although it is used occasionally in pig farming. One veal producer for the small — 70,000 head a year — British home market, Philip Paxman of Volac Ltd, said last week that he had stopped using hormones at all because of public pressure; and they are rarely used in the 300,000 head export market, he believes, because calves are shipped at 4–6 weeks old for fattening on the continent.

UK specialists in the use of sex hormones in farming argue that any proposed European legislation should distinguish between artificial agents and natural steroids (like oestradiol and testosterone); and that the use of natural steroids should be limited to tissue levels of around 1 in 10^9 — similar to those found in untreated farm animals. For the synthetic anabolic agents, and their frequently unknown residues, they should be shown to be non-toxic and non-carcinogenic before licensing.

European consumers unions, however, represented in Brussels by the Bureau Européen des Unions Consommateurs (BEUC) are pressing hard for all hormone use for meat production to be banned. It is too difficult for a policing authority to distinguish natural from unnatural hormones, says BEUC, so both should go. If agreed, this would have a big impact on beef production in the UK, which in the past few years has come to depend on hormone supplements for its profits, and would cause pressure to increase the use of antibiotics which have a similar effect on weight gain.

And perhaps Italy should worry more about olive oil than veal. According to one pharmaceutical company spokesman, vegetable oestrogens — of one-hundredth or so the bioeffectiveness of oestradiol, are present in olive oil at such a high level that the consumption of 50–100 g of olive oil a day would reverse an ageing woman's post-menopausal changes. But then if Italy can ban veal, it can probably ban olive oil too.

Robert Walgate

Polish farming

More meat to eat?

Agriculture is an extremely sensitive issue in Poland. After all, it was the announcement of increases in the price of meat products on 1 July that led to the recent wave of industrial unrest. Speaking last week at the Olsztyn Agricultural–Technical Academy, the Polish President, Henryk Jablomski, explained that what Polish agriculture needs is a robust, up to date and consistent farm policy, which will take into account the needs of development, technical equipment and the "fullest possible utilization" of scientific achievements. In particular, there is a pressing need for people of "considerable professional qualifications and social dedication" to implement research and guide agricultural development.

Under clause 6 of the Gdansk accords, the Polish government undertook to create "lasting prospects for developing peasant family farms which are the foundation of Polish agriculture". The greater openness of information stipulated by clause 3 of the same accords means that for the first time official figures comparing the performance of state and private agriculture are being made available to the general public. Some 75 per cent of Polish agricultural land is still in private hands — some 3 million family farms of which barely 400,000 exceed 10 hectares. A minimum of 15 –20 hectares is considered necessary for really efficient farming in Polish conditions, hence the large state farms would be expected to have the most advantages particularly because the state sector receives 64 per cent of all investment in agriculture. Yet, according to the official figures for 1979 (quoted by Leszek Chmielowski in *Zycie Warszawy*, 23 September), the state sector uses 2.5 times more chemical fertilizers and 2.6 times more concentrated feedstuffs to give the same amount of produce.

Chmielowski suggested that subsidies to state farms should be reduced, administrative costs minimized and unrealistic plans phased out. The land fund (largely made up of former private farms handed over to the state in return for a pension by elderly farmers without an heir eligible to succeed them) should not, said Chmielowski, simply be used to increase the area of (often unproductive) state farms, but should be made available to all private farmers who wish to expand.

Nevertheless, the members of the new "self-governing" farmers' union feel that Chmielowski's proposals do not go far enough. He stressed, for example, that the state sector, properly organized, still has "an important and growing role to play". But as Wieslaw Kecik, a young intellectual temporarily coopted as an "assistant" to the new union, explained, the greatest deterrent to the ambitious private farmer is his lack of security of tenure. Official policy, since the early 1970s, has aimed at "collectivisation without loss of production". If the state sector is to grow, the private farmers feel, it can only do so at their expense.

Moreover, said Mr Kecik, there are considerable price differentials in favour of the new sector. The private farmer must pay more for all essentials, and receives lower prices for his produce, except for a few "commercial" crops such as rape-seed and flax. Abolition of such inequalities, and the guarantee of land tenure, "must be", said Mr Kecik, "basic postulates of the new self-governing farmers' union".

The day after Chmielowski's article appeared, the Prime Minister, Josef Pinkowski, addressed a meeting of farmers and agricultural workers in terms of apparent reassurance. After calling on all those engaged in agriculture and its ancillaries, including research, to increase their efforts, Pinkowski indicated that the government would raise funds to create favourable conditions for "the whole of agriculture — all productive private farms". "We should like every farmer to feel that his work is secure", he added. "We want him to know that his intentions and production plans, his desire to

0028-0836/80/410476-02$01.00

modernize his farm and to increase its productivity, will meet with continuous support from the State."

Last Saturday, at the meeting of the Party Central Committee, First Secretary Stanislaw Kania was even more forthcoming. "Individual peasants carry the Society", he said. "We shall ensure that every peasant is certain of his ownership and his farming tenure."

The next few months should show how far practical policy implements these assurances. **Vera Rich**

Kopek interferon

Last week, the Soviet news agency TASS announced that interferon can be purchased in any Soviet drug store for 56 kopeks per ampoule. The Soviet Union, said TASS, was the first country to produce interferon commercially, and for more than a decade Soviet doctors have been using interferon to prevent influenza and other virus diseases of the respiratory tract. Soviet doctors, said TASS, also use interferon against leukaemia and viral skin diseases. A patent for interferon production has been purchased from the Soviet Union by Japan.

What the TASS announcement does not make clear, however, is the extremely low dosage in the 56 kopek ampoule. Samples analysed in Western laboratories contained dosages of the order of 1,000 units or less. The market price of Finnish interferon is US $25.00 per million units. At 64.4 kopeks to the dollar, Soviet interferon is therefore by no means competitive.

A careful reading of the TASS interview with Dr Valentin D. Solov'ev, moreover, reveals that studies on leukaemia, skin diseases, and also the veterinary use of bovine and porcine interferon, are still at the experimental stage. It is only the interferon nose-drops, which Dr Solov'ev himself pioneered in 1968, that are in regular use. However, Western experts find it difficult to understand the discrepancy between their results and those of Dr Solov'ev. In the West, interferon has been used successfully to prevent respiratory virus infections, but only at high doses and in patients with little or no natural resistance.

As far as mass prophylaxis is concerned, as the *British Medical Journal* observed recently, since interferon, like any intranasal liquid, has only a short half-life in the nasal cavity, but needs long-term contact with the nasal epithelial cells in order to make them more resistant to virus infection, "it is therefore difficult to understand how . . . nose drops containing a low titre of human leukocyte interferon could cause the degree of protection under epidemic conditions reported by Dr Solov'ev". **Vera Rich**

Gulf pollution

UN's other worry

War is the greatest immediate threat to the Middle East — but the destruction of its fragile water supply, the Gulf itself, must be next. At the end of this month local marine scientists meet in Kuwait, next door to the Iraq/Iran conflict, to pledge research spending of up to $5 million over two years to find out exactly what is happening to the waters of the Gulf.

The long-term development of the region, the Gulf States have recently recognized, depends on proper environmental management of the Gulf and its coastal regions; yet little is known of its ecology, oceanography or meteorology. The water of the Gulf is needed for agriculture, coastal industries, and for drinking, yet the highest density of tankers in any ocean discharges its ballast into it, and many industries such as desalination plants with their associated chloralkali works (using mercury catalysts), aluminium smelters (emitting hydrogen fluoride), fertilizer plants (emitting ammonia), and refineries (sulphur dioxide and hydrocarbons) belch out completely uncontrolled emissions. Already seafood is frequently tainted with oil, and city environments have deteriorated markedly in the past two or three years.

Kuwait Harbour, twentieth century skyline

There are also at least 20 major industrial development regions around the Gulf coast, enjoying the world's greatest rate of development, and populations are flooding to these areas from the interior. Often the legal or institutional mechanisms do not exist to control pollution. And all this is threatening a sea on average only 35 metres deep, which evaporates more water than it receives from river run-off. (The Indian Ocean contributes the balance, through the Straits of Hormuz.)

Sewage is coming under control more rapidly than other pollutants, because of the existence of international contracting companies which are selling systems to Gulf States. Sewerage networks and treatment plants will serve the whole of Kuwait by 1982, Qatar by 1985. But Bahrain's system is not planned to be complete until 2008, and Saudi Arabia's treatment plant on the Gulf is overloaded.

Hence the effort, catalysed by the Regional Seas Programme of the United Nations Environment Programme (UNEP) to undertake research into the sources and impact of pollutants. At present there are relatively few institutes in the region capable of doing the research, but the picture — UNEP estimates — will be "drastically changed" within a year. UNEP, with its experience in the Mediterranean pollution programme, will help with training, but the Gulf States will jealously guard their technical independence: they have no wish for "expert" teams descending from outside.

At Kuwait, seven research projects will be discussed. The most likely to be funded concerns oil: what are the principal sources of oil pollution in the Gulf, how is the oil distributed, and what are its effects on human health and the marine and coastal ecosystems? But to understand this question, the basic physical and chemical oceanography of the Gulf must be studied, and the biological balance of the sea understood.

Meteorology is also important. The "Shamal" winds blow dust which sediments much of the surface oil; Kuwait suffers frequent calms and temperature inversions which trap airborne emmission. Coastal mining is affecting wave erosion and sedimentation patterns, which could in turn affect access by the supertankers; Gulf currents at all depths must be measured. What is the residence time of water in the various regions of the Gulf? This question affects the concentrations that pollutants might be expected to reach.

Other studies would measure the levels of heavy metals in economically important marine organisms; and investigate the distribution and sensitivities of plankton, the lowest level of the food chain.

Robert Walgate

Nuclear equipment

Secrets lifted

Washington

US physicists concerned that their work may become subject to national security restrictions because of its potential military value to foreign powers will soon have a public list to turn to for guidance. The list should also be an invaluable guide to foreign governments wishing to find out what the United States considers sensitive in nuclear technology.

The main purpose of the list will be to provide officials in the Department of Commerce with guidance on what controls should be applied to technology exports in sensitive areas such as nuclear energy. The full list is being drawn up by the Department of Defense, as required by the Export Administration Act of 1979. Last week, as part of this exercise, the Department of Energy (DoE) published in draft form a table of what it calls "energy-related militarily critical technologies".

Details are given of the major components of all technologies related to the exploitation of nuclear energy, from nuclear fuel processing and fusion reactors to security techniques. For each "critical" technology, the department identifies "keynote hardware" necessary for its successful implementation. It describes not only the military and the civilian uses of the technology but also the foreign countries in which there is evidence that the technology is currently available.

The proposed classifications are only preliminary, and are open to public comment so that a more refined list can be produced. The department hopes that the list will be valuable in calling attention to areas of concern, but publication of the list may also prove to be controversial. Some countries, particularly in Europe, have previously argued strongly that as much information as possible about the components of nuclear technology — particularly those relevant to its military applications — should remain secret. They claim that publication could provide a shopping list for non-nuclear countries interested in obtaining nuclear weapons, making the job of limiting proliferation more difficult.

Department officials said last week that all the information in the list had been taken from the open literature. They claim that, although they have indicated where a country has the capability to develop a technology, this does not imply that it has done so, since much of the information was inferred from data reported in the scientific and technical literature.

The table accompanies a broader but less detailed list of militarily-sensitive technologies published in the Federal Register on 1 October by the Department of Defense. Its publication stems from recommendations made four years ago by the Defense Science Board that, if the United States wanted to restrict the export of technologies which might later be used against it, this might be achieved most effectively by shifting the focus of control from end products to the set of "critical technologies" on which the development of these products depended.

To those who might complain that the list is giving away information that could be useful to a potential nuclear power, the department points out that it has not listed many "black arts" or tricks of the trade which cannot be listed as keynote hardware, but may be just as essential to the proper operation or equipment.

The table was compiled in the framework of legislation aimed initially at increasing trade with the Soviet Union and other Eastern European nations: a revised approach was recommended as a way of doing this without sacrificing national security, by placing controls on know-how rather than directly on hardware.

Since then, however, federal policy has been pushed in two other directions. One has resulted from the decision to restrict high technology exports to the USSR following the Soviet occupation of Afghanistan. The other has been fall-out from the *Progressive* case, where a court agreed that once information has been made publicly available it can no longer be considered classified for legal purposes.

The result has been a schizophrenic desire to tighten restrictions in one direction and loosen them in another. The resulting ambiguity caused an overzealous State Department official earlier this year to prevent a postgraduate scientist studying in the United States from travelling to San Diego for a conference on fusion technology. **David Dickson**

Table Critical elements in nuclear fuel cycle technology — DoE

	Critical technology	Military use	Civilian use	Foreign availability
A.	Uranium enrichment	Nuclear weapons	Power reactors, research reactors	—
(i)	Gaseous diffusion	—	—	UK, France, USSR, FRG, Netherlands, China, Sweden, Switzerland
(ii)	Gas centrifuge	—	—	USSR, UK, Netherlands, FRG, Japan, France, Pakistan, Australia, Italy, Switzerland, Sweden, Brazil
(iii)	Laser isotope separation	Separation of fissile isotopes	Purifying materials	Canada, France, FRG, Japan, South Africa, UK, USSR
B.	Reprocessing technology	Nuclear material production	Power reactor fuel cycles	Belgium, France, FRG, India, Italy, Japan, Taiwan, UK, USSR
C.	Heavy water production	—	Power reactors	Canada, France, USSR?, Norway?, India, Argentina
D.	Fuel fabrication	Nuclear propulsion, nuclear materials production	Power reactor fuel	France, USSR, Canada, FRG
E.	UF_6 production	Feed for enrichment plant	Feed for enrichment plant	USSR, France, FRG, Belgium, UK, Japan, China, South Africa, Italy, Canada

European rockets

Range reprieved

The European Space Agency's rocket launching ranges have been reprieved, at least for a further five years. But they will now have to operate on a reduced scale. This was the chief outcome of the meeting last week of the agency's Scientific Programme Committee, at which the representatives of France, West Germany, Norway and Sweden undertook to provide 80 per cent of the cost of operating the two rocket ranges in Sweden and Norway.

The meeting was marked by a further attempt by the United Kingdom to reduce its commitment to the two ranges, at Kiruna (Sweden) and Andoya (Norway), at present estimated to be £1.8 million a year. Although originally a principal partner (with West Germany) to the tune of 40 per cent of the cost, Britain has been reducing its contributions since 1977, largely on the grounds that its need has been reduced since the ending of the Skylark programme.

Last week, the British representatives appear to have startled their partners by suggesting that, from the end of 1980, the British contribution to the total budget of the ranges should be reduced from 20 per cent to roughly three per cent, with a time limit of only three years.

The proposal was not formally accepted at last week's meeting, but will now be put to the Council of the Space Agency for a final determination. Switzerland and the Netherlands also offered last week to continue their contributions at about two per cent of the total, but declined to sign the protocol that would have ensured full operation of the two ranges.

The Science Research Council (SRC)'s position appears to be that its need in the past three or four years has been to launch about six or seven Petrel rockets each year, and that rocket launching facilities in Canada and Alaska can be used on a one-off basis more cheaply than the average cost of the European subscription. Contributing members of the European organization, known as ESRANGE, are required to pay a fee for each rocket launched in addition to their subscription, and neither of these costs includes that of the rocket or of the equipment which it carries. **Judy Redfearn**

0028-0836/80/410478-01$01.00

British PWR

One year back

The announcement last week by Britain's Central Electricity Generating Board (CEGB) that it will be applying for permission to build its first pressurized water reactor (PWR) at Sizewell in Suffolk was not unexpected. That it may also choose to build another reactor, possibly another PWR, on the same site two to four years later, was more of a surprise. The CEGB says, however, that two 1,200-MW reactors on the site would be roughly in line with permission granted in 1974 to build one 2,000-MW advanced gas-cooled reactor alongside the existing 420-MW Magnox station.

The CEGB will be putting in a formal planning application for the first plant, Sizewell B, early next year. That will include a basic reference design drawn up by the National Nuclear Corporation. By the end of next year, the main stage of the design will be put to the Nuclear Installations Inspectorate for fault analysis, well before the public inquiry expected to take place in the summer of 1982.

The form of the inquiry is not yet settled. Past experience, especially that of the Windscale inquiry in 1978, suggests that, if the board is given the go-ahead, it will be mid-1983 at the earliest before construction can begin, putting back the British government's plans for the next generations of nuclear power stations by one year.

The basic design of the British PWR is that of the Westinghouse Corporation, but its adaptation to local conditions, and especially to British safety standards, is a considerable task. According to the industry, the British standards are among the most stringent anywhere, chiefly because of the multiplicity of stand-by systems required. Designing the buildings to house the Westinghouse system for the soft sands of Sizewell will also add time.

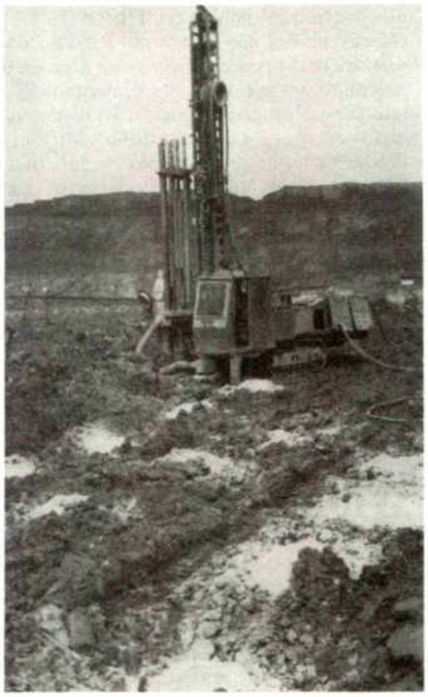
About a dozen of the 200 or so engineers now working on the design have come from Westinghouse and the US Bechtel Corporation, an arrangement that has prompted some opposition from those outside the industry who feel that Britain has the expertise to go it alone. The Bechtel Corporation, which has helped to design PWRs throughout the world, has claimed that the cost of building a PWR in the United States is about $850 per kW compared with the estimate of £1,000 per kW in Britain. Apart from differences in the accounting basis of these calculations, much of this difference is said to stem from the present strength of sterling, additional safety requirements, construction problems specific to the Sizewell site and the low productivity of the British construction industry. In any case, according to the generating board, the figures now being talked of are estimates, not contract prices. **Judy Redfearn**

Mining Polish sulphur

Trying harder

Sulphur production in Poland's Tarnobrzeg basin is to be doubled as part of the country's economic recovery plan. The present output of the area is 5 million tonnes per year, one-third of world production, of which 80 per cent is exported, so that this increase could play a major part in paying off Poland's soaring international debts.

Sulphur production is both one of the oldest and one of the newest industries in Poland. In 1415, King Wladyslaw Jagiello granted the miners of Krakow the right to prospect for "sulphurous minerals" in the vicinity. Four hundred years later, in his classic treatise "*On the Resources of the Carpathians and Other Polish Mountains and Plains*" (Warsaw, 1815), the Polish mineralogist Stanislaw Staszic remarked that "Poland stands on sulphur". By the end of the nineteenth century, however, existing mines had been worked out, and in 1921, the last of the old mines, at Posadza, closed down.



Between the Wars, several geologists suggested that sulphur beds might be located in the Miocene sediments of the Sub-Carpathian foreland, but it was not until 1953 that substantial deposits were located at Tarnobrzeg. Open-cast mining began the following year. Towards the end of the 1960s the Gryzbow and Jeziorko mines were opened; these use a borehole method of underground melting, and some 80 per cent of Polish sulphur is produced by this technique.

The Polish sulphur industry is now backed by a considerable research and development structure. Environmental problems of the industry and the regeneration of worked-out pits were elaborated in the early 1970s by a special team at the Krakow Academy of Mining and Metallurgy, and as the officials of the Tarnobrzeg mine point out, land reclamation begins as soon as a particular sector of the pit is exhausted. Plans are in hand to use closed-cycle water in all borehole mines.

Although Poland is the world's largest sulphur producer, there are, however, occasionally odd shortages on the home market. Earlier this year, Gdansk radio noted that the local epidemiological station, which is responsible for environmental monitoring, had been unable to obtain necessary supplies of sulphuric acid. In 1979, it received only 8 litres, instead of the 200 ordered.

The increased production from Tarnobrzeg, which should remedy such defects as well as boosting exports, should not, in the short term, make serious inroads into Poland's sulphur reserves. According to one expert at Tarnobrzeg, at the current rate of production, Polish mines already in operation hold enough reserves for at least another 75 years, and a similar amount of sulphur is estimated to lie in other natural deposits not yet even broached.

In the Soviet Union the outlook for sulphur production seems less optimistic. Although the Soviet Union has some indigenous sulphur, the deposits are deep and difficult to exploit, and some 10–12 per cent of Poland's sulphur exports go to the Soviet Union. A joint Soviet–US survey also indicates that there will be a world shortage in sulphur by the year 2020, because of soaring demands from the Third World. The promotion of research into cost-effective method of recycling sulphur would help the situation — at present, reclaimed sulphur costs four times mined sulphur.

For the moment, however, the main problem faced by the Polish sulphur industry is how to extract the sulphur fast enough. At the Tarnobrzeg open-cast pit, for example, the stockpile between the mine and the processing plant is virtually zero, and a breakdown in the conveyor belt lasting more than a few hours could bring the processing plant to a halt. The transport/export process is also operating full-tilt. Sulphur is exported either by rail or through the liquid-sulphur terminal at Gdansk (the home port of Poland's three liquid-sulphur tankers). So when, early in September as a kind of postscript to the recent industrial unrest in Poland, the Tarnobrzeg sulphur-workers finally went out on strike — seeking pay and social security parity with miners rather than factory workers — the authorities were quick to ask for the election of a strike committee to keep the disruption as brief as possible. **Vera Rich**

CORRESPONDENCE

Hurricane damage

SIR — Not only did hurricane Allen select many small island countries, it did so while affecting their capitals the least. Of the nine island countries directly affected by the hurricane before it struck the Central and North American mainland, seven were most seriously affected in areas which did not include the capital city; Barbados, St Vincent, St Lucia, Dominican Republic, Cuba, Jamaica and the Cayman Islands. In nearly all cases, statements of the hurricane's effects issued from the capitals were qualified by references to isolated areas or "the interior" from which reports had not yet been received, but with the expectation that when they were, figures of dead and damage would rise significantly.

When serious hurricanes occur in provincial and rural areas which are normally remote and inaccessible, the degree of local self-reliance and local self-government may determine the capacity for recovery. Dependence on central national government, usually the case, will only function effectively through country-wide communications systems. It is systems of communication, however, which often suffer most significant hurricane damage, quickly isolating provincial and rural areas from the capital, and from each other. Trees fall, blocking roads and causing telephone and electric power cables to be severed, cable poles and radio antennas to collapse and power supplies to fail. Telephone, radio and telex systems become inoperable, and airports close. Roads are destroyed by sea erosion and landslide, and travel by boat is impossible or extremely dangerous until gales have subsided.

The development of international and regional precautions is principally based on improved international communications systems, but effective precautions have to be implemented and undertaken within and by each country. Effective readiness will depend on political will, personal commitment, local understanding and infrastructural resources. Certainly, improvements to inter-island and international communications are needed, but until more efficient national assessments of disaster impact, and consequential needs, are developed through improved national communication of all kinds, there will be little effective use, in disaster, of the improvements to international communications that are being scheduled. More importantly, the present incoming warnings of hurricanes, whilst receivable by governments in the capitals, may not be available to local communities. Ultimately, effective communication facilitates further decision, action or undertaking, which will be the quicker only if administrative and infrastructural resources are upgraded to enable appropriate responses.

Field research from the University of Bath, supported by the Leverhulme Trust, undertaken in two countries (one of them in the Caribbean) has shown the smallest countries to suffer the greatest national scale, as distinct from magnitude, of disaster damage, and hurricane Allen has seemingly selected many Caribbean small countries for reiteration. Provincial districts are more vulnerable to hurricane damage in terms of damage distribution, than the urban centres. Hurricane Allen has not only selected many of the smallest and poorest countries of the Caribbean, on which to inflict itself, but also the most rural and poorest of those countries. In their experience of hurricane Allen these areas have made manifest a double vulnerabilit which identifies a need for improved preparedness against such eventualities and greater self-reliance before many more hurricanes have passed.

AChE uses

SIR — We would like to comment on an advertisement from the US Army in the September 11th edition of *Nature* (p.xxxiii) calling for scientists in the genetic engineering field to submit proposals to "clone" the gene for the human enzyme acetylcholinesterase. Isolating the gene for the enzyme and cloning it in bacteria using genetic engineering techniques will allow large quantities of pure acetylcholinesterase to be prepared for the first time. The US Army may have a number of uses for the enzyme in mind: as an antidote to nerve gases for soldiers in battle, as a test for other antidotes and as a test for the effectiveness of new nerve gas weapons. Many workers in the genetic engineering area see the potential for developing this biotechnology into the basis for an ecologically sound and highly energy efficient industry of the future producing useful products. We deplore the signs that the military/industrial powers are moving into the field to distort the technology into the manufacture of commodities of war.

Willberforce no ape

SIR—Wrangham's publication (*Nature* 18 September)[1] of the hitherto unknown verses of Wilberforce is interesting and valuable. Unfortunately he repeats the story that Wilberforce played into Huxley's hands, and Huxley scored a great victory. Neither of the two journalists present thought he had. Nor did Joseph Hooker, writing to Darwin the following evening; he thought that Huxley had done well but that it was he, Hooker, who had made the case for darwinism[2]. Lyell thought so too[3].

Wilberforce was not an obscurantist. In his review of the *Origins of Species* he was at pains to emphasize that Darwin's theory should be judged only on scientific grounds[4]. Wilberforce allows that Darwin's theory could be true, and "if Mr Darwin can . . demonstrate to us our fungular descent, we shall dismiss our pride, and avow, with the characteristic humility of philosophy, our unsuspected cousinship with the mushrooms" (ref.4, p.231). Wilberforce objected that Darwin had not, in 1860, made out his case, and that there were serious difficulties, in view of the known stability of species, in supposing that one species could be transmuted into another.

These were serious scientific arguments, worthy of a vice-president of the British Association. Darwin acknowledged their cogency[5]. It was not really until the 1940s that they were adequately answered. Although now we can say with confidence that Darwin was right and Wilberforce wrong, Wilberforce was not being wrong-headed. On the evidence available at the time, his was a perfectly reasonable position to take, and the one taken by most scientists[6].

It is doubtful that Wilberforce asked Huxley whether he was descended from an ape. It makes a good story, but Wilberforce had used the *first* person plural in his review, and the use of the first person is borne out by Wilberforce's biography and one — admittedly late — account[7]. What Wilberforce may have asked Huxley in the second person is where he drew the line between human descendants and ape-like ancestors, if, as was generally admitted, the offspring was of the same species as the parents[8]. It is an instance of the Sorites fallacy, of which biologists are impatient, but which has been much discussed by logicians in recent years. Huxley, however, was ready to answer the question he had not been asked. Three months earlier, in the April issue of the *Westminster Review*, he had accused the critics of Darwin of making him out to be no better than an ape himself, and since Wilberforce was now criticizing him for being a darwinian, he must be calling him an ape too.

Wilberforce was, as Wrangham says, both honest enough to see the force of the arguments in favour of evolution and sensitive to some of its implications — not so much theological as human. In 1860 genetic arguments were being adduced in the United States in defence of slavery, and Wilberforce had in his review a witty passage about the colour prejudices of ants, who always have black ants as their slaves (ref. 4, p.253-254). Evolutionary arguments could be used — in our century have been used — to justify the degradation of man. Wilberforce realized, as these verses show, that a theory's being uncomfortable does not preclude its being true, but that its being true does not prevent its being uncomfortable.

One other moral may be drawn. Science cannot flourish without scientific controversy, and in every scientific controversy most of the views canvassed will ultimately be shown to be wrong. Nobody holds it against Einstein that he confessed himself unable to believe in a dice-playing God. Why is not equal charity extended to Wilberforce's contribution to the British Association?

NEWS AND VIEWS

Whatever happened to neutrino mass?

Earlier this year, the high-energy physicists and the rest of us were much excited by preliminary reports that neutrinos may not, after all, be devoid of mass. For a few weeks in the spring, people in several disciplines were more than ready to embark on yet another substantial modification of accepted ideas. Cosmologists and astrophysicists as well as the theoretical particle physicists were involved. If neutrinos have mass, that might suffice to hold the universe together, the cosmologists were saying. Astrophysicists were looking for an explanation of the puzzling discrepancy between the measured and predicted fluxes of neutrinos from the sun. But now, the wave of excitement has died down almost as quickly as it blew up. Observers of the scene may be forgiven for suspecting that the whole affair was a consequence of the notoriously fertile imagination of the particle physicists. What is happening? And what lies ahead?

The events of the past few months are easily narrated. From three independent sources there were reports that neutrinos might be more interesting than the massless (and chargeless) particles that Pauli first postulated (in 1932) to explain why electrons from the beta decay of identified isotopes do not carry away all the energy released in the decay. Most attention centred on reports of conference presentations by Dr F.W. Reines, of the University of California at Irvine, that a reactor experiment had provided evidence of the phenomenon called neutrino oscillation (see Rujula and Glashow, *Nature*, 21 August). In this process, one type of neutrino will spontaneously be converted into a mixture of all types.

When the process was first suggested on theoretical grounds by B. Pontecorvo in 1968, there were of course only two types of neutrinos, corresponding to the electron and the mu-meson. (Strictly speaking, just as there is an anti-electron corresponding to the electron, so there is an anti-neutrino corresponding to the ordinary electron neutrino). Now, with the discovery of the tau-lepton, and the supposition that there must be a corresponding tau-neutrino, there is more scope for oscillation.

Reines' experiment (carried out at the power reactor at Savannah River) is acknowledged to be a difficult one. A reactor on power is a prolific source of neutrinos, but the background of neutrinos generated by nuclear processes elsewhere in the universe is also substantial. The trouble is that the experiment is bedevilled with potential uncertainties and errors — too little is known of the energy spectrum of neutrinos from a power reactor and the frequency of nuclear reactions is small (because neutrinos are what they are). It seems to be necessary to look for a 20 per cent effect (the change in the frequency of the reactions stimulated by the neutrinos) with a piece of equipment of poor precision. Only the accumulation of data over time will provide a clear answer.

This, no doubt, is why Reines's experiment has provoked controversy among the particle physicists, most of it well-mannered. Some complain at the statistical treatment of the data, others at the physical interpretation of the observations. All, even Reines, appear to agree that more data (and therefore time) is needed before anybody can be certain. This is why many people see more hope in experiments which are quite different. Some of the difficulties may be overcome by working with energetic beams of neutrinos produced artificially by particle accelerators.

Others, however, think there may be more future in experiments designed to measure directly the mass of the electron neutrino (if, indeed, it should differ from zero). Oscillation and mass are connected by the theories now being designed to unify three of the four natural forces of nature (gravity excluded). If neutrino oscillation, or interconversion of neutrinos takes place, then neutrinos should also have mass — and each of the three types of neutrino should have a different mass. The demonstration of either non-zero mass or of neutrino oscillation would most probably bring comfort to the theorists.

Attempts at the direct measurement of neutrino mass are by no means novel — if, in the old days, the theorists went around saying that neutrinos have no mass, what more natural than that experimentalists should set out to check the assertion. Moreover, there seems very little doubt that the best route to a direct measurement of the neutrino mass is by observation of the electrons emitted by radioactive tritium, one of the least energetic of beta decays and thus one in which the energy-spectrum of the decay electrons will be most sensitive to the mass of the neutrino.

In the late 1960s, measurements like these had set an upper limit to the neutrino mass of 60 electron-volts, itself something like one part in 100,000 of the mass of the electron. More recently, however, a group from the Institute of Theoretical and Experimental Physics in Moscow has announced that measurements of the energy spectrum of decay electrons from tritium gives a mass for the electron-neutrino which is different from zero and somewhere between 14 and 40 electron-volts.

So far, the chief effect of this has been to stimulate others to embark on similar investigations and several tritium experiments are under way. (For example, in Stockholm and in Chalk River, Canada — and no doubt in many other laboratories.) The experimental difficulties are almost bizarre.

The objective is to measure the energy of decay electrons accurately when the energy is a fraction of an electron-volt — and the accuracy that matters most is that when the energy is least and where, in the nature of beta-decay, the number of decay electrons is also least. Tritium must be mounted in such a way that decay does not itself disturb the measurements — in the Moscow experiment, for example, tritium was incorporated into sugar molecules whose disruption after a decay was even in itself a source of experimental confusion. Evidently, the smaller the neutrino mass, the more difficult these experiments will be.

If the upper limit on the neutrino mass gets too small, the cosmologists will of course lose interest. They require a mass of some 30 electron-volts to close the universe. Nothing less will interest them. For accounting for the unexpectedly small neutrino flux from the sun, the mere phenomenon of oscillation will suffice. The mass is comparatively unimportant.

The particle physicists are the most downcast by the cloud now hanging over the non-zero neutrino mass. Their problem is simple. If the unified theories of particles are to work as simpler but apparently successful theories have worked in the past, neutrino oscillations should happen, and the neutrino mass should differ from zero, if only by a very small amount. In other words, there is a now familiar dilemma. A favoured theory predicts some phenomenon whose measurement is inherently difficult. Gravitational waves predicted by the general theory of relativity are an obvious illustration. But these are precisely the circumstances in which, with the best will in the world, people are tempted to make more of their data than is fair.

Nations and numbers, 1980

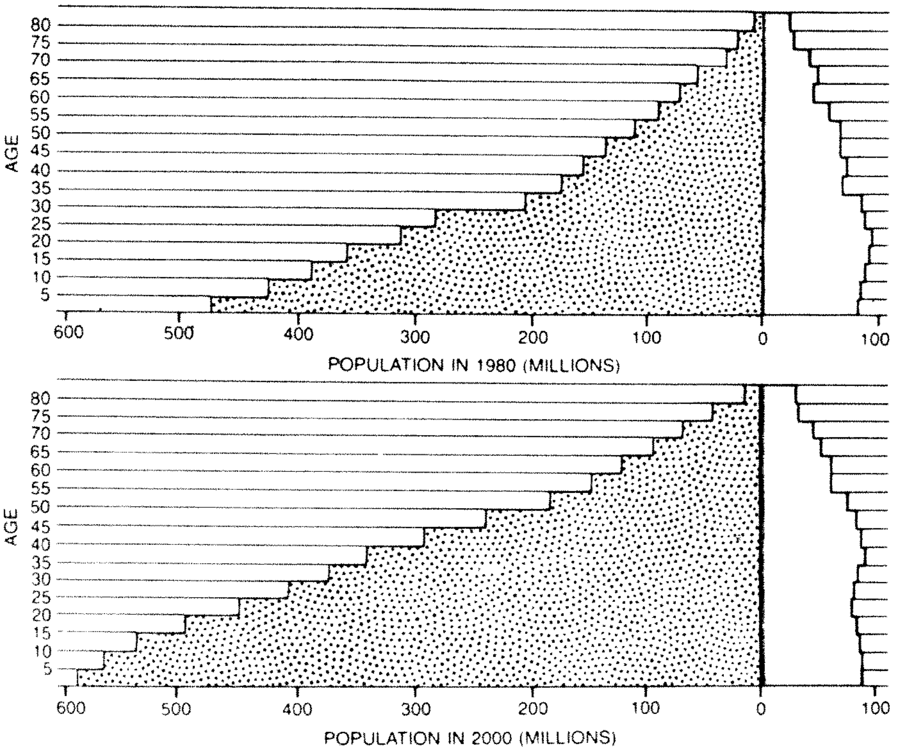
from Robert M. May

THE continuing increase in the global population is such that most of us have difficulty keeping track of the current figure — for 1980 it is 4.4 billion. As noted in previous News and Views articles[2-5], this global number conceals much variation among individual nation states and among regional groupings. Any analysis of population trends and prospects must deal with these variations; a particularly good recent analysis is by Mauldin[6] (in the special 'Centennial Issue' of Science). Over the 30-year span 1950-1980, the population of the world has grown by 70%, from 2.5 billion to 4.4 billion. In this period, Europe underwent a relatively small increase of 23%, the USA and the USSR both had increases of just under 50%, while the developing countries almot doubled their population (from 1.7 billion to 3.3 billion, with increases of 125% in Latin America, 114% in Africa and 85% in Asia).

Looking ahead, Mauldin[6] suggests "the prospects until the year 2000 are for a slowing of growth rates for all areas except Africa, but the numbers to be added will be enormous". The United Nations projections foresee continued decline in the rate of population growth in developed countries; the estimates are for an increase of less then 8% over the next 20 years in Europe, and about 17% in the USA and the USSR, to give an average figure around 12-13% for all developed countires. The so-called developing countries seem likely to increase their population by about 50%, broken down as 76% in Africa, 65% in Latin America, 55% in South Asia and about 24% in East Asia.

All this adds up to a remarkable change in global demographic patterns over the second half of the twentieth century; over this 50-year span the developed countries are likely to have increased their populations by about one-half (from 830 million to 1270 million), while the developing countries are likely to have seen a threefold increase in population (from around 1.7 billion to around 4.9 billion).

These facts and projections are summarized in Figure 1, which shows the age distribution of the total populations of developed and of developing countries in 1980, and the corresponding UN projections for the year 2000. The high proportion of young age classes in developing countries is characteristic of relatively rapidly growing populations. Even though growth rates are likely to slow down over the next 20 years, the large number of people yet to move into their reproductive years in developing countries means that populations will continue to grow. This phenomenon — the "momentum of population growth" — can be expressed most dramatically by noting that even if zero population growth (ZPG — birth rates equal to death rates) could be attained overnight in a developing countries, they would still be committed to a rough doubling of total population before coming to equilibrium; the triangular age profiles on the left in Figure 1 will eventually settle to the more rectangular pattern of the age profiles on the right (characteristic of ZPG populations), but these 'rectangles' must be erected on the large base of the infant cohort.



The magnitude and age composition of the total population in developing countries (shaded, on the right) and in developed countries (unshaded, on the left) are shown; the top figure is for 1980, and the bottom represents the UN projection of the year 2,000. The figure is adapted from Mahler[7], who observes "Comparison of the 1980 and 2000 shapes shows how the underdeveloped countries' large population now under 15 will move into laborforce years, exacerbating unemployment, and how baby-boom cohorts of developed countries will have aged."

Observations about the size and growth of the world's population are notoriously subject to many uncertainties[6]. As discussed previously[3], the current population of China, which represents about one-quarter of the global total, is unknown to within 5% or arguably even 10%. The Chinese census planned for 1981 may produce a firmer figure. The most populous African country, Nigeria, is estimated as somewhere in the range 70 to 85 million, but it could be more. The current fuss about the 'undercount' of city populations in the 1980 USA census, and its consequences for Federal aid distributed according to population-based formulae, emphasizes that even the US population is uncertain to within about 2%. As we look to the future, we peer through a glass ever more darkly.

With these caveats, the projections summarized above are based on country-by-country extrapolations of present trends[6-8]. These vary greatly among the developing countries, as can be seen from Table 1. The Table shows the crude birth rates (expressed as births per 1,000 of population) in 1965 and in 1975, for the less developed countries with populations in excess of 35 million (Vietnam is excluded because the information about vital rates is thought to be unreliable. The Table also shows the percentage change manifested in the crude birth rate between 1965 and 1975 (with an asterisk denoting no significant change), along with a qualitative assessment of the strength of family planning programs in the country.

Table 2 represents a more encompassing, but less detailed, version of Table 1. This Table shows the average percentage decline in crude birth rates between 1965 and 1975 in 94 developing countries, grouped according to social setting and the intensity of family planning efforts. Social setting is a variable which combines rankings on 7 socioeconomic scales: adult literacy; school enrollment; life expectancy at birth; infant mortality rate; per capita gross

national product; percentage of males employed outside agriculture; and percentage of population living in cities of 100,000 or more[6-9]. Although there continues to be much dispute and uncertainty about the cause of recent fertility declines in developing countries, Table 2 shows that both 'social setting' or degree of development and family planning programs have significant correlation with patterns of declining fertility[9].

Most population estimates for the year 2000 cluster around 6 billion (the 'high, medium and low' UN estimates[8] are 5.9, 6.2 and 6.5 billion), mainly set by the 'momentum' effects discussed above. Any estimate of the eventual steady state global population is necessarily much more uncertain. The momentum of population growth means that populations in developing countries will continue to undergo significant increases until well into the twenty-first century, and there is no consensus as to when, and at what rate, fertility will begin to decline in Black Africa, Bangladesh and Pakistan. Mauldin's[6] assessment is that "if the leaders of the major developing countries view rapid population growth as an impediment to economic development and act accordingly, and if the donor community also continues and perhaps increases assistance to such countries, the population of the world might plateau around 10 billion. But larger numbers are all too possible." And none of the estimates take any explicit account of the problems of feeding these multitudes. □

Table 1: Decline in crude birth rates, 1965-1975, in countries with populations of 35 million or more (after Mauldin[6]).

Country	1980 population (millions)	crude birth rate (per thousand)		percentage decline in crude birth rate, 1965-1975	family planning program

Towards the conquest of hepatitis B

from Arie J. Zuckerman

THE current issue of the *New England Journal of Medicine* (9 October) reports the remarkable success of a carefully controlled trial of hepatitis B vaccine in a high risk population in the United States. This achievement by Wolf Szmuness and his colleagues must be regarded as a milestone in the annals of preventive medicine because hepatitis B virus has not yet been propagated and serially passaged in cell culture. The credit for the development of this unusual vaccine lies with the series of studies conducted between 1970 and 1973 with the MS-2 strain of hepatitis B by Krugman and his colleagues. (*J. Infect Dis.* **122**, 432; 1970; *New Engl. J. Med.* **288**, 755; 1973).

Their studies demonstrated that diluted serum containing hepatitis B virus heated to 98°C for one minute prevented or modified infection in 69 percent of susceptible individuals. These observations provided the stimulus for the preparation of a vaccine using the 22nm small spherical hepatitis B surface antigen particles purified from the plasma of healthy carriers and inactivated with formaldehyde, with our without treatment by heat.

Hepatitis B is of tremendous importance in every field of medical practice; with progression of the infection some patients experience chronic liver disease including cirrhosis, and there is also an association with primary liver cancer. Infection with hepatitis B virus, particularly in early life, may be followed by the persistent carrier state. The world reservoir of carriers at present is estimated to number about 200 million, and they too may suffer liver damage.

The wide range of parenteral and inapparent parenteral routes of transmission of hepatitis B includes the transfusion of blood and certain plasma derivatives, the use of inadequately sterilised syringes, needles and instruments, sexual contact, particularly among promiscuous homosexual men, and possibly transmission by blood-sucking arthropods. In some regions of the world, transmission of hepatitis B to infants may be as high as 50 percent from carrier mothers, or from mothers with acute infection in pregnancy or shortly after delivery.

A vaccine against hepatitis B is urgently required for groups at high risk of infection. These groups include patients requiring multiple transfusions, patients with natural or acquired immune deficiency and patients with malignant diseases; patients and staff of haemodialysis, transplant and oncology units and residents and staff of institutions for the mentally-handicapped. Viral hepatitis is an occupational hazard amongst health care and laboratory personnel. High rates of infection occur in homosexual men, drug addicts and prostitutes. The high rates of perinatal transmission of hepatitis B in some regions may make protective immunisation of susceptible women of child-bearing age and of infants the only practical way of interrupting transmission of the infection. Immunisation must also be considered for

Arie Zuckerman is Professor of Microbiology and Director of the WHO Collaborating Centre for Reference and Research on Viral Hepatitis at the London School of Hygiene and Tropical Medicine.

0028-0836/80/410483-02$01.00

persons living in areas where the prevalence of infection is high.

Szmuness *et al.* chose for the trial a young, healthy population of male homosexuals who are known to be at an unusually high risk of infection (*Ann. intern. Med* **83**, 489; 1975). The cooperation of the participants in this meticulously organised, placebo-controlled, randomised, double-blind clinical trial of the hepatitis B vaccine was excellent: the loss was 15.4 percent of those entered, a rate much lower than the projected 40 percent annual rate of loss. Of the 1,083 susceptible individuals who received the first injection, 96.5 percent received the second injection six months after the primary inoculation. The follow-up was excellent and of the 6,332 scheduled visits and bleedings, 91.2 percent were actually carried out.

Hepatitis B surface antibody developed within one month of the injection in 31.4 percent of recipients of the vaccine; this increased to 77 percent one month after the second injection, to 87 percent within three months and to 90 percent within six months. The booster injection at six months produced a further increase to 96 percent and high titres of antibody persisted, essentially unchanged, for 18 months of follow-up in 65–70 percent of the subjects. There is the possibility, of course, that the vigorous antibody response found in some of the subjects was boosted naturally by repeated exposure to the virus. Nonetheless, the antibody response resulted in a dramatic reduction in the incidence of infection in the vaccinated group. This high protective efficacy was observed in all sub-groups of participants, including those with a large number of different sexual partners who are most at risk.

Much has been written about the possible undesirable side-effects of a vaccine prepared from plasma of persons who are persistent carriers of hepatitis B surface antigen (Zuckerman, *Nature,* **255,** 104; 1975) and guidelines have been proposed by the World Health Organisation for the preparation of such hepatitis B vaccines (WHO *Techn. Rep. Series,* **602;** 1977). Rigorous purification of the 22nm spherical hepatitis B surface antigen particles was undertaken during the preparation of the vaccines used in the trial by Szmuness *et al.* Digestion with pepsin ensured freedom from contaminating host substances, and the purified particles were treated with formaldehyde to inactivate any residual live virus(es). The vaccine was tested for live hepatitis A virus in susceptible marmosets and for live hepatitis B virus in susceptible chimpanzees and it was also tested extensively to ensure the absence of extraneous viruses. There was no evidence that residual hepatitis B virus was present in the preparation and no seroconversion in the vacinees could be attributed to the intact virus. It is gratifying that most of the adverse reactions were relatively minor, rarely more than a sore arm, although rashes, nausea, vomiting, joint pain and fatigue were also reported. Fever occurred in 2.6 percent of those vaccinated and in 2.2 percent of the those receiving the placebo and, indeed, the incidence of all side-effects was similar in the two groups.

Finally, a most important finding was that the development of hepatitis B surface antibody is synonymous with protection against hepatitis B. Therefore, as the authors point out, once immunogenicity has been demonstrated in a particular population which might not respond as well as young, healthy adults, there should be no need to prove efficacy again; indeed such a procedure might be ethically questionable and delay the availability of the vaccine to those who need protection.

Variable stars and galaxies

from Julian Osborne and Richard Cole

The night sky may appear almost unchanging but a closer look reveals that there are many astronomical objects showing some form of variability. The extent and form of this variability was the topic of a recent conference* and, at its close, one might have been forgiven for thinking that there could be no safe standard stars left!

Variability seen in the whole Sun was reviewed by Stenflo (Institut fur Astronomie, Zurich). Of the short timescale variations, only the 5 minute oscillations are well established. Diameter variations with periods between 5 minutes and 1 hour are still controversial and theoretical understanding difficult because of the large number of eigenmodes with periods in this range. Exciting news came with the confirmation of the 160.01 minute period by Fossat and Grec (University of Nice). The period has been seen as a Doppler pulsation since 1974, and although observed by groups in Crimea, Birmingham and Stanford, has remained doubtful because 160.01 minutes is close to one-ninth of 24 hours. The University of Nice group went to the South Pole and obtained an uninterrupted run of data from the full disk lasting 120 hours.

Observations from the South Pole both suppress Earth rotation effects, and make use of the very good sky transparency. All groups report the same period, amplitude and phase but a theoretical explanation awaits identification of the order and mode of the oscillation. Kotov (Crimea Astrophysical Observatory) reported that the amplitude changes at the rotation period of the Sun and that there are small accompanying variations in brightness and cm radio emission.

Very long period variations were reported by Hughes (Queen's University, Ontario; Sterrewacht, Leiden) who was analysing 32 years worth of 10 cm radio data. He noted periodicities at 1,150 days and about 700 days, neither of which were present throughout the data. A 750 day periodicity was seen during 1970-75, as claimed by Sakurai (*Nature* **278,** 146; 1979) for the neutrino flux, and as seen by Shapiro *et al.* (*J. atmos. Sci.* **19,** 506; 1962) in the relative sunspot number. Of course, a relationship between the solar core and the overall activity of the sun would be very interesting. Other periodicities have been seen, all of which are consistent with a 260 day variation.

Ciatti (University of Padua) reviewed our knowledge of the 135 classified supernovae, showing the clear distinction between type I (64%, 3 — 4 $M_\odot$, M-S progenitors from old disk population) and type II supernovae (28%, progenitors greater than 10 $M_\odot$, stars in spiral arms). Hughes reported the discovery of a new SNR (G109.2-1.0) with the Westerbork telescope. The remnant has a good circular shell of 24 arcmin diameter, and is at a distance of 4.7 kpc. It has been seen as an X-ray source by the Einstein satellite.

The 1979 Type II Supernova in M100 was exceptionally well observed, there being data in the radio, IR, optical, UV and X-ray ranges. Evans (University of Keele) showed that only pre-existing circumstellar graphite grains explained the infrared excess seen 260 days after maximum light.

Palumbo (Instito TESRE del CNR, Bologna) reported UV observations which show the existence of an additional slow moving shell (10^3 km s^{-1}) exterior to the expanding photosphere (10^4 km s^{-1}). The shell, which had twice the radius of the photosphere at one week, is thought to be due to the progenitor's stellar wind, which is required to be $10^{-4} M_\odot$ yr^{-1} to provide the 0.2 $M_\odot$ of the shell. Whilst not seen at radio wavelengths 10 days after maximum, it was observed one year later ($S_{6cm} = 5mjy$). So far there is only an upper limit to the X-ray emission. Double structure has also been observed in the Crab Nebula by Danziger (ESO), in that there appears to be two expansion velocities for each spectral line ($\Delta V \sim$ 265 km s^{-1}).

In a review on pulsars, Lyne (Jodrell Bank) said that the recent Molongo survey had increased the number of radio pulsars to over 320, including 3 binary pulsars (of which only 1913 + 16, shows energy loss attributable to gravitational radiation). There are thought to be at least 5 × 10^5 pulsars in the Galaxy. (Taylor, *8th Texas Symp.* 1977 and Davies *et al.* *MNRAS* **179,**

Julian Osborne and Richard Cole are in the Mullard Space Science Laboratory, University College, London.

*Fifth European Regional Meeting of the IAU — "Variability in stars and galaxies" was held at the University of Liege, Belgium, on 28 July 1980.

0028-0836/80/410484-02$01.00

635, 1977). These have an average lifetime of 4 × 10^6 years, derived from their characteristic age and migration velocity. Together, these give a pulsar creation rate of about 1 every 8 years, greater than the supernova rate of 1 every 20 to 100 years. Thus, there appears to be more pulsars created than supernovae, although no other birth mechanism for pulsars is known which would provide the high migration velocity (150 km s^{-1}) and scale height (400pc). The problem would be relieved if the Galactic electron density was 0.02 cm^3 instead of 0.03 cm^3, or if pulsars could be created in supernovae that did not create optically visible remnants. However, Hefland's work with the Einstein satellite (*IAU Symp.* **95**, Bonn Aug. 1980) shows that many young supernova remnants do not contain pulsars, thus making the problem worse.

Van Paradijs (University of Amsterdam, MIT) provided a lucid review of X-ray bursters. Dividing the binary galactic X-ray sources according to the ratio of their X-ray and optical luminosities gives two distinct types of X-ray emitters:-
(1) L_x/L_{opt} less than 10; primaries are O,B stars $M_v \sim -5$, hard X-ray spectra, X-ray pulsars, X-ray eclipses common. (2) L_x/L_{opt} greater than 10, primaries are 'Sco type', $M_v \sim +3$, soft X-ray spectra, busters.

A typical burst will have a rise time of 1 second and a decay time of 10 – 60 seconds. There are, however, two types of burst activity. Type I bursts are seen from all bursters, they occur every couple of hours and their spectra soften during decay. Type II bursts are only seen from the 'Rapid Burster' (MXB 1730-335), which also exhibits type I burst activity. The type II bursts occur about every 10 seconds and have spectra which do not soften. The energy of a type II burst is proportional to the time from the previous burst, implying accretion build up and overflow.

The estimate of 1 - 5 $M_\odot$ for the mass of the X-ray emitter and the estimated radius of the emission region (10 km) have given rise to a successful model for type I bursts. In this, the X-ray emission is due to thermo-nuclear flashes in the helium rich material on the surface of a neutron star, this being accreted from a binary companion.

This model describes the bursts well, with the bursts ceasing if the accretion rate is so great as to cause continuous nuclear burning. Until recently there was no evidence for the binary nature of the bursters but, recent spectral observations of the optical counterparts suggest a companion to CenX-4 (*IAU* circ. 3487), and an accretion disk in AO620-00 (Murdin *at al. MNRAS* **192**, 709; 1980). The optical counterparts of these stars, and of A1742-28, are K type stars.

Correlated optical bursts have been seen in three sources so far. (1735-44, 1837 + 05, 1636-53; Van Paradijs). The energy of the optical bursts is 5 orders of magnitude lower than that of the X-ray bursts and are thought to be due to reprocessing of the X-ray flux. There is a 2 second delay between the X-ray and the optical bursts, reprocessing might cause a delay of 0.5s so the implied distance to the reprocessing site is 1.5 light seconds. It is expected that the reprocessing occurs around the edge of an accretion disk, the size of which implies a neutron star companion of 0.4$M_\odot$ consistent with K-type stars.

Pederson (ESO) reported optical and X-ray coverage, noting one slow burst (rise time 3-4 sec) in optical and X-ray from MXB 1636-53, and one fast optical burst (rise time less than 200 msec) from MXB 1735-44, for which there was no X-ray coverage. Infra-red bursts from the 'Rapid Burster' were described by Jones (Imperial College). This group has discovered very bright bursts ($m_k \sim m_h \sim 6$) of $\sim$10 sec duration with fast flashes (some less than 0.3 sec) superimposed. These bursts are only an order of magnitude less intense than the X-ray bursts, but do not follow the known type I or type II behaviour.

Walker (RGO) has been studying the blue light curve of the black hole candidate Cyg X-1 over the past 8 years. He has found that the light curve and period have varied. A periodic change is suggested, such as a third object (period > 18 years) or precession of either of the known components.

His most recent data showed a dramatic change in the light curve. The primary maximum had decreased and the secondary maximum had increased and attained a double structure. This behaviour had been seen once previously, just before an X-ray transition. Evidently, an X-ray transition did take place between mid May and early June of this year (*IAU* Circ. 3491).

Shklovsky (Space Research Institute, Moscow) described his model of the peculiar object SS433, as an O,B super giant with an extreme stellar wind (10^{-4}m yr^{-1}) in a binary system with a neutron star of low magnetic field at the centre of an accretion disk. These are surrounded by an expanding cloud, optically thick to infrared radiation. The moving lines are reproduced by blobs which become optically thin to Hα as they are blown from the accretion disk onto the circum-system cloud. These blobs become shocked and heated to $10^{7\text{-}8}$ K to produce X-rays.

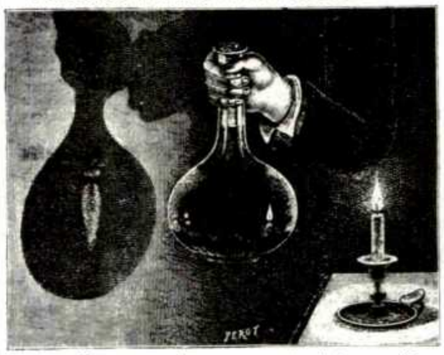
King (University of Leicester) confirmed a previous X-ray iron line detection, and suggested a change of the X-ray continuum; no periods were found in the range 1-200 days, despite considerable X-ray variability. The infra-red flux is also variable ($\Delta M = 1.6$), the IR colours however, remain constant. There is a suggestion of an 11.8 day IR period, but no period was seen at 13 days.

Observations of SS433 reported by Schilizzi (Dwingeloo Radio Observatory, Holland) showed milli arcsec variation within 6 months. At a larger scale, Spencer (Jodrell Bank) described the radio structures as consisting of an unresolved central core (less than 0.3") with a flat spectrum and a 3" halo with a spectral index of —1.1, elongated in the direction of the SNR W50. He noted a 1 week flare in the core which was not seen in the halo.

Ciatti has undertaken a study of moving lines, observing that they vary irregularly in intensity and wavelength, sometimes forming multiple systems. He notes that the velocity and angle of the jets varies night by night whilst following the general precession. His best fit period is 165.5 days, using 200 nights observations over 3 cycles. The intrinsic colours of SS433 lead Firmani (Instituto de Astronomica, Mexico) to conclude that the primary is an early type star intermediate between Of and WN8. These stars are of 15 $M_\odot$ burning helium in

100 years ago

PHYSICS WITHOUT APPARATUS



To illustrate the geometrical laws of refraction through lenses, a good reading-glass of large size is a desirable acquisition. Spectacle-lenses, though of smaller size, and therefore admitting less light, are also of service. In the absence of any of these articles, it is generally possible to fall back upon a water-decanter, provided one can be found of a good globular form, and not spoiled for optical purposes by having ornamental work cut upoin the sides of the globe. The figure shows how this decanter, filled with water, is to be employed. It is held a few inches away from a white wall, and a candle is placed at the opposite side, so that its light falls through the decanter on to the wall. The candle is moved towards or away from the decanter until the position is found in which its rays focus themselves upon the wall giving a clear inverted image of the candle flame upon the wall. The experiment may be varied by setting down the candle on the table and then moving the decanter to and fro until a definite image is obtained. If a large hand reading-glass be available, the image will be much clearer than with the improvised water-lens; and a further improvement in the manner of experimenting may be made by using a screen of white paper or card instead of a whitened wall on which to receive the image.

0028-0836/80/410485-02$01.00

their core, with $2 M_\odot$ H envelopes. The time to loose this envelope gives a 20,000 years life time for the SS433 phenomenon. He expects there to be 10 SS433 type systems in the galaxy.

Pauliny-Toth (Max-Plank-Institut) presented interesting pictures of the variations in the milliarcsec structure of active galactic nucleii. He mentioned 3C84, in which 3 bright regions are expanding but not moving apart, the rate of expansion implies that the source 'began' 20 years ago; all regions having the same spectrum. He discussed 4 sources showing apparent super-luminal velocities: 3C273, in which 3 central compact components are separating in the direction of the main jet; 3C345, in which a double component has changed to a core-jet structure; 3C120, in which there were strong outbursts in 1971-74 when the source was double (the central source is now a core-jet and there are no outbursts); and 3C279, which is showing 21c separation of a double source, and 40c separation of a new third component. By contrast, NGC 1275 shows only a slow expansion (0.1c) and no separation of the components. □

On the Tibetan plateau

from Peter Jackson

THE Tibetan Plateau has long fascinated not only romantics and mystics, but also geoscientists. It has been recognised as one of the most interesting areas of the globe particularly in relation to continental drift and tectonics, since it was here that the Indian plate, which broke away from Gondwanaland, crashed into the Eurasian plate about 38 million years ago. The suture line lies along the valley of the Tsangpo river, about 100 kilometres north of the main Himalayan axis.

The area remained generally closed to science although, after the Peoples Republic of China asserted itself in the area in the 1950s, reports filtered through of some activity by Chinese scientists. It was thus with some excitement that geologists and natural scientists received invitations from Academia Sinica to participate in a symposium on the geology and natural history of the Qinghai-Xizang (Tibetan) Plateau. Over 60 scientists from 17 countries gathered in Peking in May for a week of meetings at which the Chinese reported in detail on the results of 20 years of research in Tibet.

Liu Tung-shen, Vice-Chairman of Academia Sinica, told the meeting that the rich fossil beds on the plateau had yielded 3,800 species of over 30 families in recent years, compared with only 300 before 1950. In the Himalaya, fossils of *Glossopteris* and cold water biota were found in late Palaeozoic beds, while north of the Tsangpo fossils of *Gigantonoclea* and warm water biota were uncovered in the Permian formation, indicating the importance of the valley as a palaeontological boundary.

Palaeogeomagnetic study confirmed that areas to the north and south of the river valley belonged to different plates — to the north the crust is about 70 kilometres thick, and to the south about 50 kilometres thick. Isostatic anomaly in the Everest area is + 120mg, and uplift is continuing as the Indian plate still pushes north. For the last 100,000 years since the Pleistocene a rise of 10 mm per yr has been estimated by Chinese scientists.

It is believed that the Himalayan system may have been completed between Miocene and Pliocene, but even in late Tertiary the plateau may not have been more than 1,000 metres in elevation, judging from fossils of the three-toed horses *Hipparion* found during the recent explorations. The Himalayas are considered to have reached great heights in the late Pleistocene, bringing about a climatic change to present conditions when they blocked the warm wet monsoon and made Tibet a cold, arid area.

The week in Peking was an absorbing and active one but was just a preliminary to the real object of interest — a two-week field excursion to Tibet, from Llasa westwards and finally passing through the Himalayas to Kathmandu.

The high altitude physiologists found that the Tibetans,although their capital Llasa is at a height of 3,660m, had the same blood haemoglobin values as lowlanders in, for example, Shanghai, but lowlanders up on the plateau showed a significant increase in haematological values, which became normal only after 10 to 15 years. The surprising revelation was that when lowlanders, whose haematological values had become normal, returned to the lowlands they suffered a period of one to three months of re-adjustment. A high percentage of the lowlanders have to leave the plateau because, after a year or two, they develop chronic mountain sickness with a tremendous increase in red blood cells.

Many of the visiting scientists had taken with them NASA earth satellite imagery of the area through which we passed. Glaciologists noted that studies of the imagery in the United States tied in well with what was actually observed. The surprise in paraglacial geology was that typical phenomena such as the sorting of stones by freezing and thawing on slopes was not as widespread as expected at such high altitudes. It became evident that this was because of the extreme dryness of the air so frost action was almost absent. Characteristic phenomena were found only in moist areas.

Glaciation in Tibet appears to have been little more during the Pleistocene than it is today, and E. Reiter of Colorado State University suggested that this was because the Indian summer monsoon, which brings in moisture and snow, was either very short during the Pleistocene or sometimes even absent. He suggested, on seeing heat shimmer in temperatures of about 9°C on a 5,220 metre pass, that heat from the plateau generates an anti-cyclone and draws in the monsoon from India. During global cold periods, however, such as during the Pleistocene, when the gradient between the equator and the poles is strong and the sub-tropical high pressure belt is drawn towards the equator, the northward pull of the Tibetan plateau may be insufficient to bring in the monsoon.

Most of the valleys had sand dunes, which, in some cases, such as around Lhasa, were shapeless conglomerations resulting from complicated wind patterns. But along the Tsangpo near Xigatse, and further west near Tingri, sickle-shaped dunes were seen, which were the result of a steady up-valley wind. T. Pewe, of the University of Arizona, remarked that silt particles from among the sand had blown up the hills and walked back down forming areas of retransported loess favourable to agriculture. He said that according to Professor Liu, this was the first report of loess in the area.

Scientists of several disciplines commented on signs of over-exploitation and damage to the physical environment, which indicated the need for considerable care in the future economic development of Tibet. Almost every other cart met on the roads carried fuel. Men and women were seen trudging homeward with heavy loads of shrubs, such as *Sophora moorcroftiana*, which had been dragged out by the roots.

Jack Ives, of the University of Colorado, pointed out the conspicuous and recent gulleying and dissection of fans resulting from deforestation and over-grazing, probably combined with the development of a colder and more arid climate in the last 3,000 years. Ives had presented a paper at the symposium on mapping natural hazards, which stressed the dangers of placing settlements on alluvial fans because of floods and rock and mud flows. In Tibet many villages were placed just there, presumably because of the availability of water. It was agreed by both foreign and Chinese scientists that there was a need for collaborative research to pinpoint dangerous trends, to help decision makers improve the welfare of the people of Tibet and to achieve a better ecological balance and effective management of natural resources. It was considered especially important to use new techniques developed in the US for areas where the data base is short — as it is in Tibet — to predict floods and other dangers to settlements on alluvial

0028-0836/80/410486-02$01.00

fans.

While Chinese experts pointed to some remarkable results in agricultural production and spoke of the potential of Tibet, the visitors stressed the need for caution in view of the short growing season, which could be seriously affected by variability in annual rains, possibly resulting in bad harvests and famine.

Perhaps the least satisfied of the visitors were the zoologists, despite the thrill of collecting lizards, fish, butterflies and small fauna at record altitudes. Brought up on old records of remarkably tame wildlife in Tibet — wild yak, wild ass, blue sheep, antelope, gazelle, geese and duck — they were disappointed to see no large mammals, and birds were generally sparse in numbers. There were only two or three sightings of shy bar-headed geese (*Anser indicus*), which used to be numerous and confiding on the plateau. This seemed to indicate strong hunting pressure in contrast to the former reverence for wildlife. However, Chinese zoologists reported that there were still populations of most Tibetan species on the sparsely inhabitated central plateau, which whetted appetites for further studies.

Collaboration between Chinese and foreign scientists has already begun, and, as a result of the symposium, there is now likely to be a burst of activity aimed at unravelling the secrets of Tibet and applying the knowledge there and elsewhere. □

SCIENCE COLLEGE

Mycorrhiza and crop production

from D.S. Hayman

VESICULAR-ARBUSCULAR mycorrhiza, a symbiotic fungus-root association, can greatly increase the utilization of phosphate present in soil. Recent research suggests that the symbiotic association can be harnessed to achieve more economical use of costly superphosphate fertilizers and better exploitation of cheaper, less soluble rock phosphate.

The vesicular-arbuscular (VA) mycorrhizal fungi infect more plants than any other fungi and are necessary for many plants to grow well, but until recently, they had escaped widespread attention. This is for two reasons: first, the association is so well balanced that young feeder roots show no sign of damage even when densely infected, and second, the fungi themselves cannot as yet be cultured in the absence of a living root and so do not appear on agar plates used to isolate other soil and root-inhabiting micro-organisms.

VA mycorrhizal infections are seen as vesicles and arbuscules borne on the mainly aseptate hyphae occupying the root cortex. Similar structures have been reported in fossil roots some 300 million years old and are present in their modern relatives (ferns, psilopsids and clubmosses), as well as in some gymnosperms and angiosperms colonizing most habitats around the world.

VA mycorrhiza is found in most agronomic species except the brassicas and sugar beet and is widespread in the two major crop families, Leguminosae and Gramineae. Important crops where benefits from mycorrhiza have been shown include pasture and forage legumes (but not lupins), maize, wheat and barley, potatoes, many vegetables, herbaceous and tree fruits, and many tropical plantation crops. Temperate zone plants with thick fleshy roots and few, short root hairs generally benefit considerably from VA mycorrhiza; for example, onions, citrus, grapevine, sweetgum and *Coprosma*. In the tropics, pineapple, *Stylosanthes*, *Centrosema*, coffee, tea, cocoa, oil palm, papaya and rubber all have dense VA infections. Cassava appears to be obligately mycorrhizal which probably explains why it is able to grow in impoverished phosphate-deficient soils (Van der Zaag *et al.*, *Field Crops Res.*, **2**, 253; 1979) while needing high phosphate concentrations in solution culture.

The extent to which particular plants depend on mycorrhiza is largely governed by their root morphology. Generally those with the most limited root-soil contact (coarse, hairless roots) benefit most from the network of mycorrhizal hyphae extending from the mycelium inside the root to the surrounding soil. Ions such as phosphate are fairly immobile and a phosphate-depletion zone often develops around roots in phosphate deficient soils. The hyphae are able to reach beyond this zone and directly translocate nutrients from the soil to the root cortex where transfer to the plant occurs. There is often a dramatic response to mycorrhiza in such soils while, in contrast, there is little effect on the uptake of readily mobile ions such as nitrate. Experiments with ^{32}P-labelled phosphate indicate that VA mycorrhizal hyphae obtain their extra phosphate from the labile pool rather than by dissolving insoluble phosphates. This may account for plant growth responses reported in silos amended with some phosphate fertiliser. The better utilization of sparingly soluble rock phosphates is explained by the hyphae making closer physical contact than roots with the ions dissociating at the particle surface.

Mycorrhizal benefits are not limited to improved phosphorus uptake. Absorption of other elements including zinc and copper can be enhanced. Recent work (see Allen *et al. Can.J.Bot.* **58**, 371; 1980) suggests that growth hormones such as IAA and cytokinins may be present at higher concentrations in plants that are mycorrhizal than in those that are not. There is also some evidence that plants with mycorrhiza may be better equipped to withstand stress conditions such as occur during transplanting or periods of drought, in soils containing toxic levels of aluminium, manganese or salt, or in unstable soils where the hyphae may bring about soil aggregation. In legumes, nodulation and nitrogen fixation have been greatly increased by mycorrhizal innoculation, sometimes beyond that achieved by adding phosphate fertilizer alone. Certain host-fungus combinations may also increase a plant's resistance to some root pathogenic fungi and nematodes. Whether this occurs by direct physical exclusion through competition for sites, or by metabolic changes involving antibiotic production or increased vigour has not yet been clarified. There are situations, however, where the VA fungal drain on host carbohydrate or possible disruption of host metabolism may outweigh the benefits to the plant. This swing from mutalistic symbiosis to parasitism has been shown in some grasses and cereals grown at above optimum phosphate levels.

As the effects of VA mycorrhiza on plant growth are generally positive much research is directed towards harnessing its advantages. This requires an understanding of the physiology and ecology of the association, a knowledge of which crop species or cultivars are most likely to benefit from mycorrhiza, screening and selection of the most efficient fungal endophytes, development of suitable procedures for large-scale innoculum production and innoculation techniques, and an assessment of field situations where mycorrhizal innoculation would be most valuable. Factors that decrease mycorrhiza in the field, for example, pesticides, high fertilizer levels and poor aeration, should also be considered.

Experiments carried out using plants in pots have helped our understanding of mycorrhizal function but they are not always a good guide to responses in the field. Field experiments, however, pose two major problems: how to produce high quality (pathogen-free, high viability) innoculum in quantity (see Menge *et al.*, *Proc.Int.Soc.Citriculture* **1**, 129; 1977) and how to innoculate crops on a field scale (see Mosse & Hayman in *Tropical Mycorrhiza Research* ed. Mikola, Oxford University Press, 1980). Innoculum can consist of infested soil (usually from stock plants and containing spores, mycelium and infected root fragments), clean infected roots (as grown in nutrient-flow culture, see *Rothamsted Report* (1) 188; 1980) or pure fungal cultures (not yet achieved). For

D.S. Hayman is on the Soil Microbiology Department, Rothamsted Experimental Station, Harpenden, UK.

0028-0836/80/410487-02$01.00

annual crops sown over large areas inoculum can be pelleted with the seed or placed in the seed furrow either dry or in a slurry. Such material is bulky, yet enough must be applied to ensure substantial early infection when the crop's demand for phosphate, and hence mycorrhiza, is at a peak. Perennial crops are more easily handled since they can be innoculated in containers to produce vigorous mycorrhizal colonization of the root system by appropriate endophytes before transplantation.

Field situations must be selected where mycorrhizal benefits look most probable; crops already known to be responsive to mycorrhiza should be tested in nutrient-stressed soil at sites where the indigenous population of mycorrhizal endophytes is small or inefficient. Current examples are marginal sites in temperate regions (for example, white clover in hill pastures), ferrolateritic soils which are deficient in and/or 'fix' phosphate as found in huge expanses of the tropics (for example, the Brazilian cerrado), eroded, degraded or unstable sites (for example, coal tips, quarries and sand dunes), and soils fumigated to remove plant pathogens (for example peach and citrus nurseries in California.)

Results so far have shown that growth responses to field innoculation with selected mycorrhizal endophytes can vary from nothing to around threefold. Test crops have included white clover in Britain and New Zealand, lucerne in Spain and Britain, maize and cowpea in Nigeria and cereals in Pakistan. Similar responses have been reported in citrus and up to 84 fold increases in sweetgum in fumigated nurseries in the US. Less dramatic, but nevertheless important responses, are also possible in more standard agricultural soils and techniques to measure these should be refined. In many other situations, however, mycorrhiza may have no discernable effect on crop yield.

At this stage, despite the enormous recent upsurge in mycorrhizal studies, undue faith in mycorrhiza as an agricultural elixir should be tempered by a realistic appraisal of which aspects might best be exploited on a practical scale. □

Tales of two accelerators

from P.I.P. Kalmus

At 17.00 on 6 June 1978, Nimrod accelerated its last particles. The users, a Queen Mary College — Rutherford Laboratory collaboration, recorded their final events in a kaon-nucleon polarization experiment and ended a fifteen year era during which several hundred scientists from the UK and overseas had used the 7 GeV proton synchrotron at the Rutherford Laboratory. Three weeks later a meeting took place where the events surrounding the conception, construction and life of this machine were recalled by a small number of distinguished speakers.

In September of the following year the 12.5 GeV Zero Gradient Synchrotron of the Argonne National Laboratory in Illinois was closed down, and a two-day symposium was held to recall its history and achievements. The proceedings of both these meetings have recently appeared in print. *Nimrod: The 7 GeV Proton Synchrotron,* edited by John Litt, is available from the Rutherford Laboratory and *History of the ZGS,* edited by Joanne Day, Alan Krisch and Larry Ratner, is published by the American Institute of Physics as No. 60 in its conference proceedings.

It is tempting to contrast the two machines, to compare their performance and to look for different styles of conducting high energy physics in the two countries, but I will leave that to some future historian of science. Some sociologist might even read national characteristics into the fact that in Britain we waited three weeks before holding the wake whereas our American colleagues held theirs two weeks before the death of the ZGS! However, to me, the similarities between the stories of the two machines and their user communities are much more striking than their differences.

Nimrod was built to enable UK universities to carry out research in the exciting new field of high energy physics. The concept of a national laboratory with central facilities was, however, a novel one in Britain and was viewed with considerable suspicion and apprehension by some prominent university scientists. Similarly, the main purpose of the ZGS was to provide the universities of the American Mid-West with facilities which would rival those on the East and West Coasts, and the idea of basing academic research at a Government laboratory was viewed with hostility by some universities and, in particular, by the Mid-West Universities Research Association.

However, both machines were authorised in the late 1950s. Both made use of the well-established weak focusing principle. Particles make slow oscillations in the horizontal and vertical planes about the idealised orbit. The oscillations have large amplitudes and require a guiding magnet of large aperture. It was felt that the design was safer for achieving high intensity beams than the newly invented strong focusing principle which was being used in the CERN and Brookhaven machines. These were then under construction and were designed for higher energy but much lower intensity. In fact, the strong focusing machines performed extremely well and their intensities were raised gradually over the years to rival those of the wide aperture machines.

Already during the construction periods the directors of both projects went to considerable efforts to involve members of the university community both in policy making and in the actual design and construction of bubble chambers, beamlines and other facilities. In this both laboratories were highly successful. The fears of university scientists that they would be taken over by Big Brother proved groundless, and in fact Rutherford and Argonne became shining examples of how technologically complex central facilities can serve large user communities. This expertise lives on: the Users Organisation at Fermilab is modelled on that at Argonne and the Rutherford Laboratory (now combined with Appleton) is serving the needs of university scientists and engineers in a variety of fields.

Both accelerators began operation in 1963. Although not the highest energy machines in Europe or America, the range covered by their particles was a particularly fruitful one, the available energy being comparable to the rest mass energy of the stable hadrons and the lower lying unstable particles.

The achievements of the users of Nimrod were primarily in strong interaction physics, in particular, nucleon-nucleon and meson-nucleon interactions. Starting with total and elastic differential cross sections successive generations of experiments measured gradually more complex spin parameters using polarized targets. Much of our present knowledge of hadron spectroscopy stems from this machine. The ZGS, partly because of its higher energy, supported a rather wider variety of experiments including, for example, neutrino interactions in the 12 foot hydrogen bubble chamber. In its final years there was a vigorous programme of physics using an accelerated and extracted beam of polarized protons. The ZGS was the obvious machine for this technique as its uniform magnetic field was likely to cause less beam depolarization than might be the case in other machines.

Well over 200 experiments were conducted at the ZGS and each was a significant research project occupying the effort of perhaps ten physicists for three years. The Nimrod booklet gives a list of 120 PhD theses written on work done with this accelerator.

Both machines were closed prematurely, and both for the same reason — to release funds and support for the new generation of more powerful accelerators at CERN and at Fermilab. The kaon-nucleon experiment that concluded the Nimrod

programme is now analysed and published. The postgraduate student who worked on it has written his thesis and is embarking on the next stage of his career at CERN. A whole generation of high energy physicists, some of whom are now at the forefront of particle research, received their training at Nimrod or the ZGS. I personally feel privileged to have participated in a small way in both these adventures. ☐

Diseases of the motor unit

from a Correspondent

IT has been estimated that more than one third of neurological hospital admissions can be attributed to neuromuscular disorders. This large group of diseases was the subject of a recent conference* and, perhaps the major message to emerge was that many basic techniques are now being adapted to serve as specific probes in studying both normal and disordered structure, function and interactions of nerves and muscles. Where such probes have been applied, for example in the case of α-bungarotoxin and myasthenia gravis, rapid progress has been made. The newer techniques offer similar promise for understanding of the muscular dystrophies and other neuromuscular disorders.

The Duchenne form of muscular dystrophy (DMD) is the commonest of the muscular dystrophies and is inherited as a sex-linked recessive trait. It produces progressive muscular weakness in boys and culminates in total disability before the teens. Circumstantial evidence suggests a disorder of the plasma membrane manifested by leakage of muscle-specific enzymes into the circulation, minute breaks in the plasma membrane early in the course of the disease, and a large number of biochemical defects in muscle and other cells. Much evidence was added at the meeting for a membrane or membrane-associated abnormality, although the underlying defect was not defined. Using freeze-fracture techniques Bonilla and Schotland (University of Pennsylvania) found decreased intramembranous particles in sarcolemmal membranes of DMD and facioscapulohumeral dystrophy muscles. These changes suggest defects in the sarcolemma but their significance is not understood. Red blood cells of patients with DMD show increased phosphorylation of a specific membrane protein fraction in band II of spectrin (Roses, Duke University). Although he has identified the sub-fraction responsible for this effect there is little enthusiasm for the idea that the spectrin abnormality could reflect the basic biochemical defect in DMD. Other cell types, such as lymphocytes, may also show membrane abnormalities. Gruemer (Medical College of Virginia) reported that there is decreased capping of DMD lymphocytes upon exposure to anti-human immunoglobulin. Despite the inability of several research groups to confirm these results, Gruemer carried out a double-blind study in collaboration with the Johns Hopkins group that correctly identified DMD lymphocytes in over 90 percent of samples. In another leukocyte study, Shay (University of Texas) demonstrated a defect of microtubules in mononuclear cells from DMD patients and carriers, using immunofluorescent techniques. A variety of biochemical abnormalities were reported in DMD tissues, including a decrease in adenyl cyclase in sarcolemmal membranes of cultured muscle (Wilner, Columbia University) and an increase in calcium transport by DMD erythrocytes (Pleasure & Mollman, University of Pennsylvania) These disparate findings continue to provide tantalizing evidence for a cell membrane defect in DMD, but are still far from identifying the nature of the defect, or indeed proving that it bears any important relationship to the disease process.

The mechanisms by which abnormal muscle tissue self-destructs may provide more immediate practical applications. There are two proteolytic enzyme systems in muscle fibers (Goldberg, Harvard University), the lysosomal enzymes which degrade normal proteins before their disposal, and an ATP-dependent enzyme system which degrades defective proteins. By blocking the lysosomal enzyme system with leupeptin and other antagonists, muscle breakdown and the degradation of specific proteins can be prevented. Stracher (State University of New York) has applied this interesting approach by using leupeptin in animals with 'dystrophies', or with denervated muscles, and has found a significant retardation of muscle wasting and histological changes.

The changes that occur in muscle cells after breaching the sarcolemmal membrane (as probably occurs in DMD), can be studied by making multiple micropunctures in skeletal muscles *in vivo* (Karpati, Montreal Neurological Institute). The retraction of myofibrils and dilatation of sarcoplasmic reticulum are similar to the changes seen in early lesions of DMD. Perfusion of the limb with EDTA reduces the severity of the lesions, suggesting that calcium may be involved in the destructive process. W. K. Engel (NIH) visualized calcium in human muscle biopsies by a histochemical method. He reported that both damaged and regenerating fibers appear to have elevated calcium concentrations; thus, calcium may contribute to degenerative and regenerative processes in muscle cells. A. Engel (Mayo Clinic) stained muscle biopsies from a wide variety of disease conditions for activated complement complexes (the 'membrane attack complex'). All muscle fibers undergoing necrosis contained activated complement components regardless of the underlying disease.

These studies all suggest that there are several definable steps between the initial lesion in muscle disorders and the ultimate destruction of the muscle fiber. Therapeutic measures aimed at interfering with these intermediate steps may be able to offer effective treatment.

Developments in the field of myasthenia gravis (MG) have outstripped those in other areas of neuromuscular disease. The availability of α-BuTx (α-bungarotoxin) as a specific probe made possible the indentification of the ACh receptor defect nearly 7 years ago. Since that time, much progress has been made in understanding the pathogenesis and devising treatments for this disease. Drachman (Johns Hopkins University) described the mechanisms by which anti-ACh receptor antibodies produce a reduction of available receptors. They include: (1) accelerated endocytosis and degradation of the ACh receptors, (2) blockade of the receptors' active sites, and (3) antibody-mediated, possibly complement-dependent, damage to the receptors and postsynaptic membranes. The mechanism of endocytosis was further elaborated by Pumplin (University of Maryland) and Drachman, who showed by freeze-fracture techniques that cross-linking of ACh receptors by the antibody causes them to clump and aggregate, before their endocytosis *via* coated pits that form in the muscle membrane. Fuchs (Weizmann Institute) reported that immunization of rabbits with denatured ACh receptor can diminish the severity of experimental autoimmune myasthenia gravis (EAMG), presumably by stimulating the production of antibodies that block the binding of more pathogenic antibodies against the native ACh receptor. Another strategy involved the use of anti-idiotype anti-bodies that appear to protect against EAMG. Such therapeutic approaches may eventually be used in human MG. Lindstrom (Salk Institute) has prepared an extensive collection of monoclonal antibodies against ACh receptor from the electric organs of rays and eels, for the purpose of mapping the structure of the ACh receptors.

Major progress has been made in understanding the 'trophic' interactions between nerves and target cells. ACh transmission may account for the motor nerve's role in regulating the resting membrane potential (RMP) and the extrajunctional ACh receptors of skeletal muscle (Drachman, Pestronk & Stanley, Johns Hopkins University). Post-synaptic blockade of ACh transmission completely reproduces the effects of surgical denervation on the RMP and the extrajunctional ACh receptors, while disuse results in a partial denervation-like effect on these two muscle parameters. The formation of junctions

between nerves and muscles induces the accumulation of ACh receptors (Fischbach, Harvard University) and a low molecular weight substance from chick spinal cord and brain that produces an increase in ACh receptors of cultured muscle has been extracted. The implication of this and other similar studies is that such substances may play a role in the subsynaptic accumulation of ACh receptors at neuromuscular junctions.

Reverse trophic influences of the innervated target cells on neurons within the chick ciliary ganglion were described by Landmesser (Yale University) & Pilar, (University of Connecticut). During development, an excessive number of nerve cells compete to innervate a limited number of target cells; those neurons that form connections are able to survive and mature, while those that fail to connect undergo cell death. The proportion of cells that die can be greatly increased by ablating the target and conversely, the proportion of survivors can be increased by pruning out some of the ciliary neurons. The same effect is also seen in tissue culture; the maturation and survival of ciliary neurons is enhanced by co-culture with an appropriate target tissue, skeletal muscle.

The regulation of nerve sprouting was analyzed by Pestronk and Drachman. Pharmacological denervation (using blockers of nerve conduction of ACh release) induces sprouting of nerve terminals which branch and enlarge over the surface of each muscle fiber. Extrajunctional ACh receptors appear to play a role in this type of sprouting, since blockade by α-BuTx prevents the formation of terminal sprouts. However, in collateral sprouting occurring when neighboring muscle fibers are denervated little effect is produced by blockade of ACh receptors. Finally, intrinsic factors such as age may greatly effect the nerve's ability to sprout — both terminal sprouting and regeneration after injury are progressively impaired with increasing age.

The basement membrane of the motor endplate may be particularly important in neuromuscular junction formation (McMahan, Harvard University) Even after destruction of skeletal muscle cells, the basement membrane retains its organization, and is capable of serving as a target for regenerating motor nerves. Moreover, the basement membrane appears to act as a scaffold for the reorganization of regenerating muscle. If a muscle is damaged and then allowed to regenerate, new endplates form at their previous sites, as directed by the remaining basement membrane.

Extracellular matrix may also play a role in interactions between Schwann cells and axons. The 'dystrophic' mouse shows a defect in myelination of nerve roots, with some Schwann cells apparently refusing to ensheath the naked axons. Aguayo (Montreal General Hospital) showed that grafting segments of unmyelinated nerve roots from 'dystrophic' mice to normal or even 'dystrophic' mice resulted in correction of the myelination defect. Bunge (Washington University) was able to reproduce the myelination defect in tissue culture of 'dystrophic' mouse dorsal root ganglia, and to correct the abnormality by the addition of fibroblasts or of serum. This suggests that the lack of an extracellular substance normally secreted by Schwann cells results in impaired myelination.

Perhaps the greatest promise for future research in neuromuscular disease lies in the application of a variety of powerful new biological techniques to the eminently workable nerve-muscle system. Among the new techniques described at the conference were monoclonal antibodies to serve as probes of surface membrane components of chick skeletal muscle (Fambrough, Carnegie Institute of Washington) and tissue culture of pathological muscle. Successful culture of skeletal muscle from patients with myotonic dystrophy was demonstrated by Appel (Baylor College of Medicine) and abnormalities in cultured Schwann cells from patients with adrenal leukodystrophy and Issac's syndrome by Askanas (NIH). Finally, the techniques of modern biochemical genetics are just beginning to be applied to skeletal muscle. Recombinant techniques have been used to clone genes for contractile proteins by Yaffe (Weizmann Institute) and Schwartz (Baylor College of Medicine). H. Epstein (Baylor College of Medicine) pointed out the encouraging prospects for identifying the genetic abnormalities in the muscular dystrophies by such methods. □

Crystallizing membrane proteins

from Richard Henderson

After many years of disappointing failures the first succesful attempts to crystallize membrane proteins have recently been reported. Large three-dimensional crystals suitable for X-ray analysis are needed for the resolution of the protein structure in atomic and chemical detail, a level of analysis essential for the understanding of phenomena such as channel selectivity and the mechanism of action of membrane bound pumps and receptors.

In the first paper, Ozawa *et al.* (*Proc. natn. Acad. Sci. U.S.A.* **77**, 928; 1980) describe crystals of the cytochrome c oxidase-cytochrome c complex. These crystals were made from detergent (cholate)-solubilised oxidase almost completely depleted of lipid (<1%). Cytochrome c was added to make a 1:1 complex and crystals obtained by removal of detergent by dialysis. The crystals contained both oxidase and cytochrome c in a 1:1 ratio, but both detergent and lipid were absent. They are thus well-characterised chemically but the extent of crystalline order remains to be determined by X-ray diffraction. At the moment, they are needles rather too small for analysis.

The most successful and promising reports used the detergent, octylglucoside, recently made commercially available. In two exciting reports, crystals were made by precipitation of membrane proteins solubilised in octyl glucoside without removal of the detergent. The crystals thus contained a substantial amount of detergent in addition to aqueous regions, the protein and perhaps also some lipid.

Michel and Oesterhelt (*Proc. natn. Acad. Sci. U.S.A.* **77**, 1283; 1980) used 2.5 — 2.8 M salt to precipitate octyl glucoside-solubilised bacteriorhodopsin, obtaining two crystal forms, one needle-shaped and the other cube-shaped. These crystals are truly three-dimensional and one form (the needle) is ordered to at least 8 Å resolution. The needles have the interesting property of being strongly dichroic and the purple chromophore is oriented almost exactly along the needle axis. Further structural work should therefore be useful to determine the chromophore orientation and if better diffraction patterns can be obtained, the crystals may well be suitable for higher resolution analysis.

Garavito and Rosenbusch (*J. Cell Biol.* **86**, 327; 1980), used polyethylene glycol to precipitate the pore-forming protein, porin that comes from *E. coli.* outer membranes, after solubilising with octyl glucoside. They obtained birefringent rhombic plates and prisms using β-octyl glucoside and non-birefringent but larger, bipyramids using α-octyl glucoside which they had to synthesize themselves. The large bipyramids gave X-ray diffraction spots out to 3.8 Å resolution making them ordered at least to a resolution close to that required to reveal atomic detail.

This recent flurry of successful crystallizations may now mean that membrane proteins are sufficiently purified and characterised, and that detergent development is sufficiently well-advanced, that a substantial effort to crystallize many more membrane proteins should be started. Perhaps these results, exciting in themselves, will provide the impetus for these efforts. It seems that it would now be worthwhile both to try to crystallize other membrane proteins and to develop other detergents like octyl-glucoside, which itself remains in solution while the protein-detergent complex is precipitated. □

REVIEW ARTICLE

Transcription and RNA processing by the DNA tumour viruses

Edward B. Ziff
The Rockefeller University, New York, New York 10021

Messenger RNA synthesis by the DNA tumour viruses proceeds by a complex but versatile series of transcription and RNA processing steps. The major mechanistic features of this pathway are probably very similar to those used by the animal cell host itself. The viruses have, however, evolved intricate arrangements of protein coding sequences and sites for RNA initiation, polyadenylation and splicing which allow them to use their genetic information to maximum advantage.

THE DNA viruses which infect animal cells and transcribe their messenger RNA in the host nucleus provide an attractive and easily manipulated system for studying eukaryotic gene expression. The phenomenon of messenger RNA splicing, now recognized as occurring throughout the eukaryotic kingdom, was first discovered in the human adenovirus. This virus, together with the simian virus 40 (SV40) and the mouse virus, polyoma, which will also be considered in this article, realises the full potential of RNA splicing to assemble a range of different messages from a limited amount of primary genetic information. To maximize the efficiency of their relatively small genomes, they have evolved complex transcription units in which the primary transcripts can be processed in different ways to yield different end products (for a review of transcription unit design see ref. 1). Adenovirus-2 (Ad-2, and the very similar Ad-5) is a member of the group C human adenoviruses, and transcribes its RNA from a 35,000-nucleotide linear DNA genome. SV40 and polyoma are both papovaviruses, with covalently closed circular supercoiled genomes ~5,200 nucleotides long, and closely related genetic organization and mRNA maps. (The closely related human papovavirus BK[2] will not be discussed here.) This review summarizes the arrangement of genes and messenger RNAs within the three viruses, and compares mRNA synthesis pathways to illustrate common mechanistic features. In addition to productive infections, all these viruses can cause neoplastic transformation in certain cell types, but this will not be considered here.

Transcription of adenovirus-2

Ad-2 productive infection of HeLa cells proceeds through a ~36-h infectious cycle which is conventionally divided into early and late stages, separated by the onset of viral DNA replication approximately 8 h after infection (for a review see ref. 3). Ad-2 transcription is by the host RNA polymerase II[4,5] and both DNA strands encode mRNA[6,7].

Transcription during the early stage follows a complex programme. There are at least five early transcription units (shown in Fig. 1) to which mRNA species and proteins have been mapped[8–16]. Each of these, including EIA and EIB, the two tandem transcription units at the left end, has a separate promoter, demonstrated by nascent chain analysis[17], UV transcription mapping[18,19] or 5,6-dichloro-1-β-D-ribofuranosylbenzimidazole (DRB) inhibition of transcription[20]. Structurally distinct capped mRNA 5′ termini[21] are encoded by each of the early regions and have been mapped within sequenced DNA templates[22]. Although unique caps were found for region EIA and EIB[22], the caps for EII[23], EIII, EIV and the protein IX mRNA are heterogeneous, and result from staggered 5′ termini encoded within a 2–6-base region (C. C. Baker and E.B.Z., unpublished results). The staggering is non-random and favours the use of purines rather than neighbouring (or intervening) pyrimidines, reminiscent of the prokaryotic initiation preference for purines (for a review, see ref. 24). The two left-end transcription units EIA and EIB encode functions capable of cell transformation[25–28], and have been partially sequenced in Ad-5 (refs 29, 30). Region EIA products are also implicated in the efficient production of mRNAs from the other early regions (see below)[31]. Mutants in region EIB are complemented by human embryonic kidney cell functions, and this region may encode the Ad-2-specific tumour antigen[32]. Region EII encodes a 72,000 molecular weight DNA binding protein (DBP) which participates in DNA replication[33,34] and may regulate early transcription during the late stage (see below). Region EIII is distinguished by its location wholly within the major late transcription unit and encodes a glycoprotein which appears on the cell surface[35,36]. EIII and EIV yield mRNAs with complex splicing patterns[12,14]; notably, two 3′ termini have been detected for mRNAs with the region EIII 5′ end. Two additional leftward regions which are tentatively allocated to the early class are known. One encodes the IVa2 protein, a minor component of the virion; the second, which maps between map coordinates 19.8 and 23.5, encodes low abundance mRNAs and is the locus of the ts36 DNA minus mutation[37].

Modulation of early mRNA synthesis

Ad-2 early transcription units are not activated simultaneously, EIA being expressed within 1 h of infection, EIB, EIII and EIV somewhat later, and region EII within 2–3 h of infection[38].

The expression of transcription units at the left end of the genome is of particular interest. These encode multiple mRNA species which have common 5′ and 3′ termini but differ in the internal arrangement of their splices[8,12,14–16]. During the early stage of infection, region EIA encodes two 13S species, EIA-a and EIA-b shown in Fig. 1*B*. The donor splice points for these species differ by approximately 200 residues and their DNA sequences have been mapped[39]. The alternative splices change the internal peptides of region EIA proteins without altering the amino or carboxy termini. These EIA transcripts are very rapidly transported to the cytoplasm, and have a short half life[40]. Region EIB encodes two species, EIB-a, a 22S mRNA, and EIB-b, a 13S species[12,14,41]. During the late stage of infection, the proportions of the different left-end mRNAs change to favour the splicing pattern of the shorter species. A new 9S mRNA, EIA-c, appears from EIA, and the amount of EIB-b

0028–0836/80/410491—09$01 00

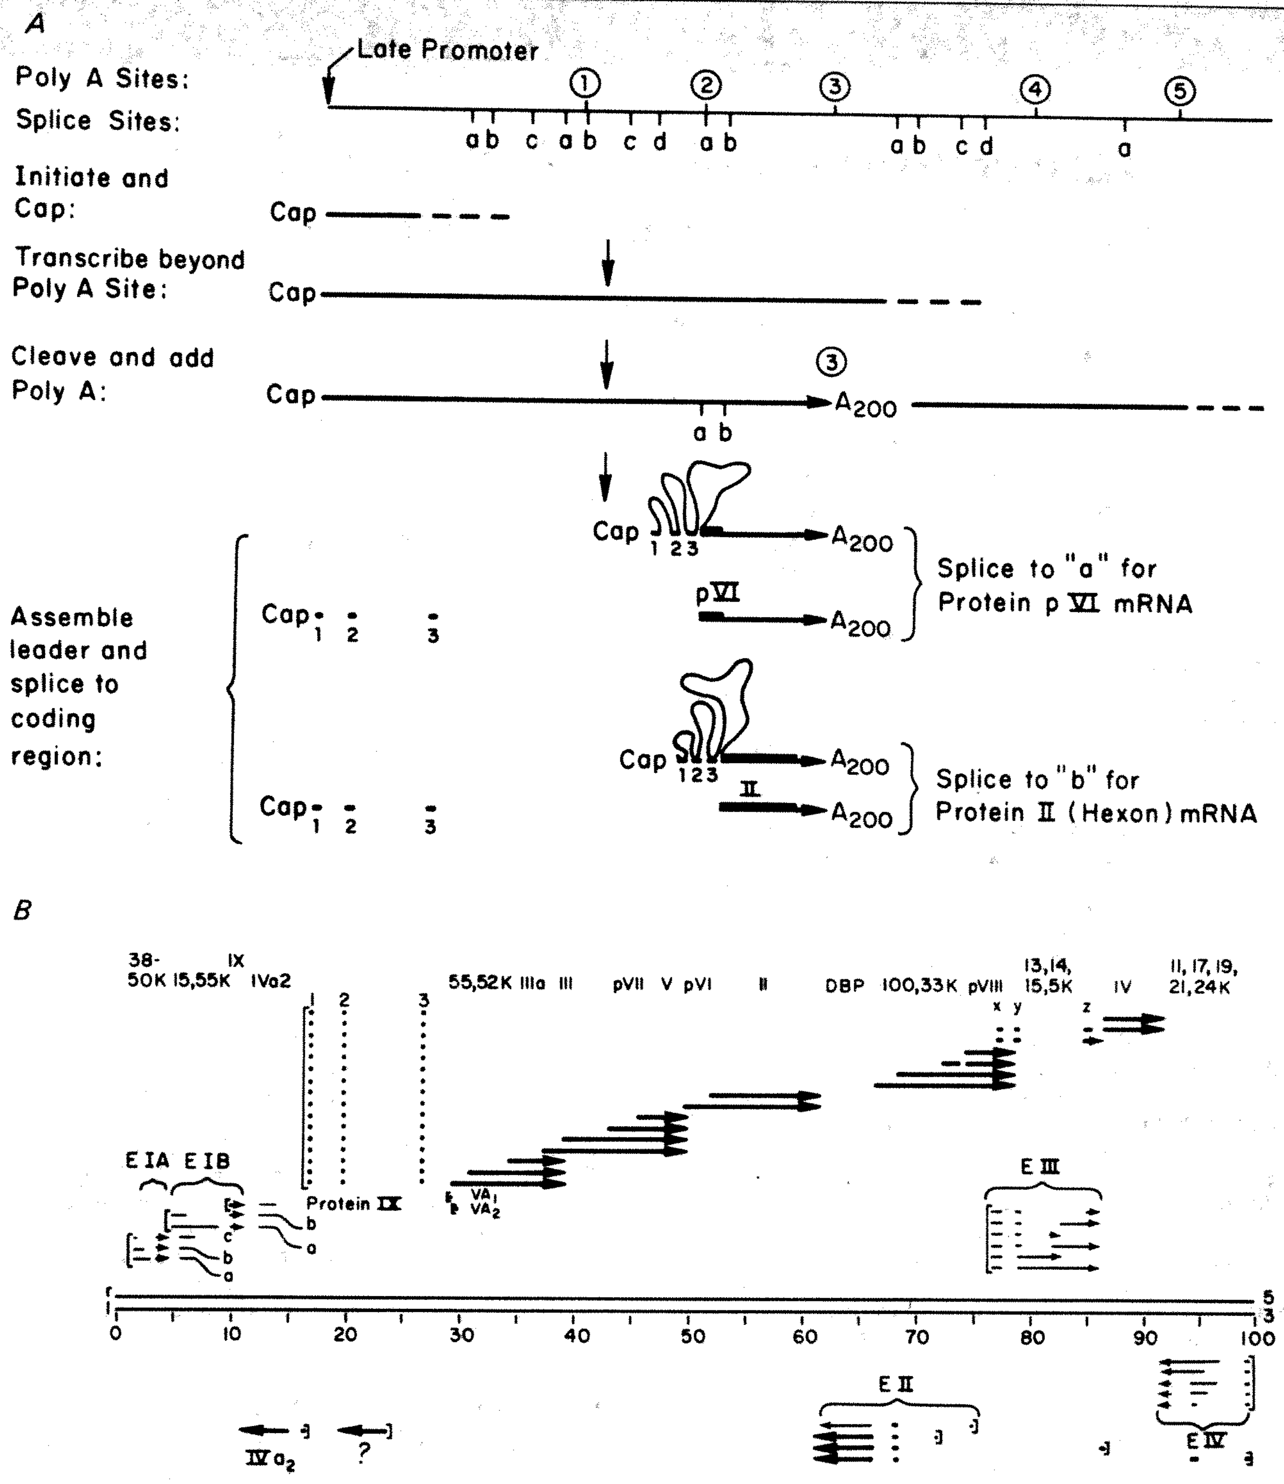

Fig. 1 Synthesis of messenger RNA by adenovirus-2. The physical map of Ad-2 is divided into 100 units, each consisting of ~350 nucleotides. RNAs synthesized from left to right utilize the DNA r-strand as template and are 'rightward' transcripts. Those transcribed in the opposite direction are 'leftward'. *A*, Transcription and processing of late messenger RNA. Precursors to late messenger RNA are rightward molecules initiated at the major late promoter and are capped while nascent RNA, Five sites, ① to ⑤, exist for the polyadenylation of these transcripts. However, only one poly(A) site is used for any given transcript, although on average the five sites are used with approximately equal frequency. RNA polymerase transcribes beyond the functional poly(A) site, ③ in this example, and continues until it reaches the far end of the genome at coordinate 100. Soon after the polymerase passes ③, while the RNA is still a nascent molecule, the transcript is cleaved to expose the poly(A) acceptor. RNA sequences encoded at coordinates 16, 19 and 27 are spliced together to form a non-coding tripartite 5′ leader. This leader is subsequently spliced adjacent to a coding sequence. Several alternatives are possible for this final splicing step when any particular poly(A) site has been utilized, for example joining the leader to *a* or to *b*. In the example shown, splicing to *a* juxtaposes the leader to the coding sequences for the pVI protein, while splicing to *b* splices the leader adjacent to the hexon coding sequence. The mRNA produced by splicing to *a* contains the coding sequences for both pVI and hexon. However, eukaryotic ribosomes do not re-initiate translation at internal positions, and translation of this multicistronic mRNA is confined to the first cistron, pVI. Hexon is translated from mRNA with leader spliced to *b*. Two 'choices', selection of the poly (A)site and the leader splicing site, therefore govern the mRNA species which is produced from the primary transcript. This processing pathway allows 14 or more different proteins to be encoded within a single transcription unit, and places their expression under the control of one promoter. *B*, Adenovirus-2 messenger RNA maps. Early messenger RNAs fall within five separate transcription units, EIA–EIV. Each early transcription unit encodes multiple species which differ in the positions of their internal splices. The mRNAs encoding the proteins IX and IVa2 are expressed at an intermediate stage of infection. Species from the major late transcription unit fall into five 3′ co-terminal families with all members of a given family sharing a common poly(A) site. The mRNAs from this transcription unit also share a common 5′-capped tripartite leader. For mRNAs within a 3′-co-terminal family, this leader is spliced adjacent to different coding sequences. Other leader sequences, *x*, *y* and *z*, appear in some fibre (protein IV) mRNA molecules. The protein translation products of various mRNAs are aligned with their genes. The VA RNAs are RNA polymerase III products described in the text. See text for refs. *B* is redrawn from ref. 16.

accumulating in the cytoplasm increases dramatically by 50–100-fold[12,40,41].

Further evidence for the temporal complexity of transcription comes from the Ad-2 protein IX[42,43]. Its mRNA is synthesized later than the early mRNAs but synthesis still occurs in the presence of cycloheximide or cytosine arabinoside (Ara C), which block late mRNA[44]. The protein IX mRNA is therefore assigned to an 'intermediate' stage of transcription. It is unspliced and has a 3′ terminus that coincides with that of the EIB mRNAs, but its 5′ end is encoded at coordinate 9.7, about 1,800 residues downstream from the EIB cap site[42,43]. Nascent transcripts initiated at 9.7 are not found in the early state nor is the protein IX mRNA detected in the cytoplasm at this time. Both are detected during the late stage[19]. These experiments strongly indicate that these are separate promoters for the protein IX mRNA and the EIB mRNAs, and that the 5′ end of the protein IX mRNA is not formed by cleavage of a larger EIB transcript, thus suggesting transcriptional control.

Ad-2 early proteins may participate in the control of Ad-2 early gene expression. Region EIA mutants yield diminished quantities of early mRNAs from the EIB and EII–IV transcription units[31,45,46], suggesting that a product encoded by EIA may be required for efficient expression of the other early regions. It is noteworthy that transcription from each early region occurs in the presence of a variety of protein synthesis inhibitors[38,47], suggesting that synthesis of an EIA protein is not an absolute requirement for expression of the other early regions.

Early transcription units are also subject to negative regulation. When early RNA synthesis is monitored in the presence of Ara C, a drug which blocks both DNA synthesis and most late mRNA, early viral transcription is shut down approximately 6 h post-infection[48–50]. However, if protein synthesis is blocked by cycloheximide, early mRNA is overproduced (or stabilized) relative to the wild type, suggesting that negative control of early transcription (or mRNA stability) depends on protein synthesis[51].

The pertinent viral regulatory protein blocked by cycloheximide may be the DBP, the translation product of early region EII[52]. The DBP has a single-stranded DNA binding function in viral DNA replication, but also has the capacity to bind to DNA termini or double strands[53]. Several facts suggest a complex role for the DBP in adenovirus gene expression. With ts125, a mutant of Ad-5 that produces a temperature-sensitive DBP, early transcription does not undergo its normal shut-off[48–50]. A detailed analysis of early transcription with cells infected with ts125 shows that the major negative effect of the protein is on region EIV, and that control of the rate of synthesis of region EII is normal in ts125 infection at the non-permissive temperature[54]. The apparent negative regulatory action of the DBP on early region EIV could parallel the proposed SV40 large T antigen autoregulation (see below), which is thought to act at the RNA initiation step. In this connection, it is of interest that the DBP and SV40 T antigen are related by their capacity to change Ad-2 host range. Although Ad-2 expresses both early functions and certain late functions, including replication of its DNA in monkey cells[55–57], a greatly decreased yield of infectious particles is obtained[58]. The cause of the block imposed by monkey cells is unknown, but certain late proteins are synthesized in decreased yield[59], possibly as a result of reduced levels of synthesis of functional mRNAs[60,61]. Simultaneous infection with SV40 overcomes the host range block. Expression of the sequences coding for the proline-rich carboxy-terminal segment of the SV40 T antigen (see below) is implicated as the relevant SV40 function because Ad–SV40 hybrid recombinant viruses which encode this segment of T are also non-defective in monkey cells[62–64]. Also, SV40 mutants with deletions at the 3′ end of the early region that remove C-terminal peptides (Fig. 3*B*) are defective in adenovirus helper function[65]. Microinjection of a related Ad–2–SV40 hybrid protein which contains the C-terminal peptide also overcomes the block[66]. Mutants of Ad-2 which overcome the block have been selected, and marker rescue experiments have mapped the locus of the mutation within the DBP gene[67]. The mutant DBP thus seems to fulfill a function required during monkey cell infection that can also be provided by SV40 T antigen.

The full story of Ad-2 early regulation is likely to be even more complex. During the early stage of infection, the 5′ end of region EII mRNA is encoded near coordinate 75 (ref. 23). However, during the late stage a considerable fraction of the mRNA from region EII has a 5′ leader encoded at either coordinates 72 or at 86 (refs 12, 16). Thus, there is an activation of 'late specific' 5′ ends for transcripts of 'early' region EII DNA. In agreement, synthesis of this early protein continues into the late phase[68].

The early to late switch

The major shift in Ad-2 gene expression is the early to late switch, which is closely coupled to the onset of DNA replication and dramatically increases the abundance of late transcription unit mRNAs. These messengers contain a common tripartite 5′ leader (whose detection marked the discovery of splicing) which is encoded at coordinates 16, 19 and 27 on the genome as shown in Fig. 1*B*[69–74]. The 5′ terminus of this leader is released by T1 RNase as an undecanucleotide[75] which is encoded at coordinate 16.45 (ref. 73). With the onset of the late stage, transport of cell mRNA to the cytoplasm ceases, although synthesis of polyadenylated cellular nuclear RNA continues[68].

Although the mechanism of this shift is not known, it has been established that blockage of DNA replication by chemical inhibitors of DNA synthesis such as Ara C[12] or by DNA minus conditional lethal mutations[76,77] prevents the formation of most late mRNA. Thus, ts125 fails to synthesize late mRNA if placed at the non-permissive temperature during the early stage of infection[77]. It also fails to replicate its DNA[33]. As found for ts mutants of SV40 T antigen at the non-permissive temperature[78], the onset of DNA replication (rather than the maintenance of synthesis) seems to be the critical factor for late mRNA synthesis. If ts125 is shifted to the non-permissive temperature during the late phase, late RNA synthesis continues although DNA replication ceases[77]. Late mRNA synthesis is also dependent (at least indirectly) on protein synthesis, and late mRNA (as well as DNA replication) is blocked if cycloheximide is added early in infection. The block to late mRNA caused by these drugs may not be absolute because the coordinate 16.4 'late' capped 5′ terminus is found in cycloheximide-treated cells early in infection (E.B.Z. and A. Shaw, unpublished results). In the presence of Ara C, late mRNA species with their 3′ end at coordinate 38 are found[12].

Virus promoters and primary transcripts

The precursors to mRNAs from the major late transcription unit are large rightward-transcribed nuclear molecules up to 25 kilobases long[79–81]. The initiation site for late RNA (5′ terminus of the primary transcript) was mapped at coordinates 16.3–16.5 by the nascent chain method applied to isolated nuclei[82] and *in vivo*[73]. The RNA initiation site was mapped more precisely by showing that late nuclear RNA contains marker oligonucleotides encoded just downstream from the late cap site but lacks sequences predicted by the DNA structure immediately upstream[73]. This was confirmed for transcripts synthesized *in vivo* and in isolated nuclei[22,82,83]. Coincidence of the promoter and the cap site implies that the initiating residues of the primary transcript are incorporated into the capped 5′ terminus of late mRNA.

RNA initiation site structures

Many eukaryotic structural genes contain a region of homology[84] which precedes the mRNA cap site by 30 or 31 residues and has the canonical structure TATAAA (the Hogness box). The presence of the Hogness box in the Ad-2 late promoter[73] and at a constant location with respect to cell cap sites, suggests that it is involved in transcription initiation. Other regions of homology are shared between the late promoter and the globin[73,85] and conalbumin genes[86]. The majority of the Ad-2 early cap site sequences also share a Hogness box[22], suggesting that each early cap site is also an RNA polymerase II initiation site. Region EII seems to lack a Hogness box[23], as do the late SV40 and polyoma cap sites (see below), but the significance of this difference is not known.

Regulation of the late primary transcript

Initiation of a capped transcript at the late promoter has been obtained *in vitro* with a soluble system using Ad-2 late promoter DNA, RNA polymerase II from HeLa cells as well as polymerase from various heterologous sources including *Xenopus*, and an S-100 fraction from uninfected cells[87]. 'Fingerprint' analysis of these *in vitro* transcripts gave the pattern of RNase T1 oligonucleotides found *in vivo*, indicating selective and accurate initiation at the cap site *in vitro*. Extracts of whole uninfected HeLa cells also initiate capped late promoter transcripts up to 5,000 nucleotides long, without polymerase supplementation[88]. Moreover, the latter system also initiates at the cap sites for the early promoters EIA and EIB, and the intermediate promoter protein IX.

The fact that for correct initiation *in vitro*, the Ad-2 late promoter (as well as early and intermediate ones) requires no viral component other than the cloned 5′ segment of the transcription unit suggests that no virus-encoded factor is required to activate this promoter, at least when it is present as naked DNA. Late transcription could be negatively controlled at the initiation step by a 'repressor', or the late promoter could be active at all times, with the primary transcript changing from non-productive to productive transcripts. Indeed, late transcripts proximal to the coordinate 16.5 promoter are hypermolar in comparison with downstream (coordinates 30–100) sequences[82]. Thus, a proportion of late transcripts are terminated before they reach the major blocks of late genes. A similar (although not necessarily related) observation has been made for RNA synthesized in the presence of DRB[20,89]. This drug acts at a site downstream from the promoter, and limits transcripts to promoter-proximal (potentially the attenuated) sequences[90].

Processing of late transcripts

The pathway for processing late mRNA is given in Fig. 1*A*. The 3′ ends of mRNAs from the late transcription unit are encoded at five poly(A) sites, each to the right of coordinate 16 (ref. 91). These have been mapped precisely at coordinates 38, 50, 62, 78 and 92 (refs 16, 92–94). Radiolabelling studies indicate that RNA sequences in polyadenylated nuclear molecules adjacent to each of these five poly(A) sites are labelled with equal kinetics in time periods less than required to complete the transcript, implying that nascent RNA is the poly(A) acceptor[95]. The size of the newly polyadenylated RNAs implies that they retain essentially all their intervening sequences, and received their poly(A) before splicing occurred[95]. Unspliced polyadenylated molecules are also observed by electron microscopy[96] and RNase T1 oligonucleotides from the late Ad-2 first intervening sequence are found in nuclear molecules with 3′ poly(A)[73]. However, with such large RNAs it is difficult to exclude the possibility of the excision of short stretches before poly(A) addition occurs. Isolated nuclei also synthesize polyadenylated transcripts with 3′ ends at coordinates 38, 50, 62 and 78, coincident with the *in vivo* poly(A) sites[97]. The nonpolyadenylated fraction of this RNA, however, also includes species with 3′ termini at coordinates 38 and 50, as well as a proportion of large molecules with partially spliced 5′ leaders. Although some splices may occur on nonpolyadenylated RNA, the final splice of the leader to the mRNA main body seems to be confined exclusively to the polyadenylated RNA class.

With early regions EII and EIV, polyadenylated nuclear RNAs are also readily detected with the size and map position expected for unspliced but capped precursors[98–100]. Studies on the production of mRNA from early regions EII and EIV have determined the size of the molecule to which labelled poly(A) becomes attached after brief exposure to ^{3}H-adenosine. Over 90% of the new poly(A) was on unspliced molecules[101]. If the unspliced, polyadenylated precursor to region EII mRNA is labelled *in vivo*, and nuclei are isolated and incubated with cell extracts, this RNA is spliced *in vitro*[102]. The general rule seems to be that poly(A) addition precedes splicing, but it is not known whether this effect is a consequence of rapid poly(A) addition and slow splicing, or whether poly(A) addition is a prerequisite for splicing.

Late in infection, Ad-2 transcription occurs in equimolar amounts along the entire late transcription unit (with the exception of hypermolar transcription near the promoter discussed above)[80,95]. The primary transcripts initiated at coordinate 16 extend beyond the five poly(A) sites, and proceed virtually to the

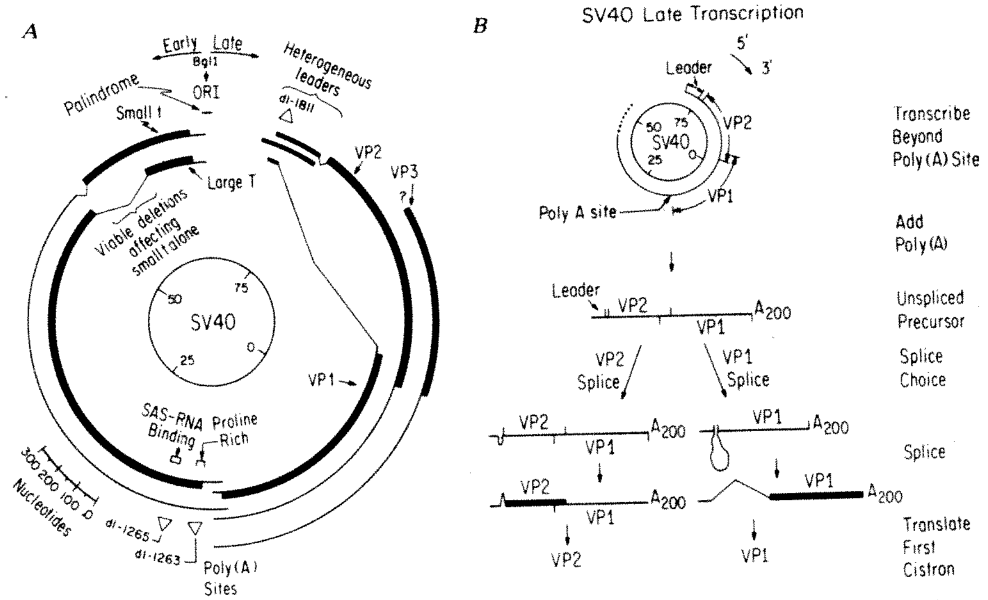

Fig. 2 SV40 messenger RNAs. *A*, Messenger RNA map. The 5′ termini of SV40 mRNAs map near the origin of DNA replication (ORI). ORI contains an inverted repeat palindrome centred on the *BglI* restriction endonuclease cleavage site. The ORI region is shown in detail in Fig. 4. Early mRNA species are transcribed anticlockwise on this map, and late clockwise. The polyadenylated 3′ ends of early and late mRNAs overlap. Two early mRNAs, which differ in the positions of their internal splices, encode, respectively, the SV40 tumour antigens small t and large T, which are amino co-terminal. The T mRNA lacks the translational terminator sequence for the t protein and T translation continues essentially to the 3′ end of the mRNA. Late mRNA species encode the structural proteins VP1, VP2 and VP3. VP2 and VP3 are carboxy co-terminal, and both differ from VP1. A single DNA sequence, however, encodes the amino terminus of VP1 and the carboxy terminus of VP2 and VP3, but two different reading frames are used. The leaders spliced to the coding regions of the late mRNAs are heterogeneous, with multiple 5′ termini. The VP3 splicing pattern is not well established. The effects of DNA deletions, the presence of a SV40 associated small RNA (SAS RNA) and possible functions of the proline-rich carboxy terminus of T are discussed in the text. *B*, Pathway of synthesis of SV40 late mRNAs. Newly formed late nuclear transcripts are molecules which extend from the cap site(s) beyond the poly(A) site, but are shorter than the full length of the genome. These primary transcripts are apparently cleaved and polyadenylated at the poly(A) site to yield unspliced molecules with the 5′ and 3′ ends of mature mRNA. As with Ad-2 late mRNAs (Fig. 1), multiple pathways exist for splicing this precursor to allow synthesis of a family of 3′-co-terminal mRNAs. In the example given here, the alternatives of splicing the leader adjacent to either the VP2 or the VP1 coding sequences are shown. The cistron closest to the cap is translated. See text for refs.

end of the genome at coordinate 100 (ref. 103). At this stage of infection, mRNA 3′ ends are apparently generated by cleavage. Products from both the 5′ and 3′ sides of the cleavage have been detected in isolated nuclei[97]. Although only approximately one-fifth of the RNA mass reaches the cytoplasm[95,104], polyadenylated sequences are transported almost quantitatively[95]. This implies that there are no non-productive polyadenylation events, and that only one poly(A) tract is added per late transcript although all five potential acceptors are transcribed. Thus, polymerases can evidently traverse one poly(A) site non-productively, utilize a second downstream site and avoid non-productive polyadenylation at the remaining positions, although they are transcribed and the acceptor is a nascent RNA. This suggests that the transcription complex actively prevents non-productive poly(A) addition, possibly through a regulated commitment of the polyadenylation machinery to one of the poly(A) receptors to the exclusion of the other four, at the time of initiation[95]. Alternatively, the virus may have evolved a gradient of poly(A) site efficiencies which counterbalances map positions and ensures that each poly(A) site is used with approximately equal efficiency. The Ad-2 late 3′ acceptors contain the AAUAAA homology found near the poly(A) of cell mRNAs even for termini encoded within the transcription unit, for example, at coordinate 50 (ref. 91).

The number of translatable Ad-2 mRNA species from the late transcription unit[105] is greater than the number of 3′ termini. This excess is explained by the existence of messengers which are staggered in sequence at the 5′ end (adjacent to the 5′ leader), overlap at internal positions, and share common 3′-terminal structures[92]. The late mRNAs are organized into five banks of overlapping messengers (see Fig. 1*B*)[91,93,94]. Present evidence suggests that the larger of the 3′ co-terminal species (from a given family) contain coding sequences for more than one protein, but that only the 5′-terminal coding sequence is translatable[92,93,106]. Adjacent sequences, silent in the large mRNAs, are translated from shorter mRNA species belonging to the same 3′-co-terminal message family[92,93,105–107]. This model is supported by the fact that the 5′ leader, sequenced for both the fibre[72] and the hexon[108,109] mRNAs, lacks an AUG, but that translation initiation sites are found within the mRNA main body. These late 3′-co-terminal families parallel the papovavirus late 3′-co-terminal mRNAs described below. The late leader also contains a sequence complementary to the 3′ end of 18S ribosomal RNA which may facilitate ribosome binding[73,108].

If we consider the 3′-co-terminal messengers (and their translation products), the five poly(A) sites divide Ad-2 late protein coding sequences into discrete blocks capable of expressing more than one protein through the formation of 3′-co-terminal mRNAs. With the Ad-2 late transcription unit, two post-transcriptional 'choices' (outlined in Fig. 1*A*) presumably govern which segment of nuclear RNA will be transported to the cytoplasm as mRNA: selection of the poly(A) site from one of five positions within the late transcription unit followed by selection of the site to which the leader is spliced. All these events are nuclear[110]. The actual mechanism for removing the intervening sequences may be quite complex. Late nuclear RNA contains species which have the leader assembled as far as 19.3, 21.6, 24.8, 25.6, 26.0, 26.2, 26.4 and 26.9 coordinate map units and which are colinear downstream[96]. These results suggest that the primary pathway for processing late nuclear RNAs has a sequential polarity for splicing from 5′ to 3′. In some cases incompletely spliced mRNAs are transported to the cytoplasm. With the fibre mRNA, and a related mRNA synthesized by an Ad-2–SV40 hybrid virus, a proportion of the molecules contain up to three extra leader segments, *x*, *y* and *z* of Fig. 1*B*; however, these do not affect translation[111,112]. With infections in monkey cells, a proportion of the fibre mRNAs retain even larger abnormal RNA sequences which are derived from coordinates 66–78 and are normally present only in mRNAs from the fourth co-terminal block[61]. Thus, the monkey cell block (see above) may result from defective splicing or premature transport. Sequences used for both early and late splicing show extensive homology with equivalent cell sequences, implying common sequence recognition for the cell and at least some splices of both early and late viral transcripts[23,73,113].

Although the mechanism of splicing is not established, most models postulate an intramolecular mechanism (see Fig. 1*A*), perhaps with small RNAs bridging the splice junctions and holding the exon sequences in close proximity to allow accurate cleavage and religation[114]. With Ad-2, attractive candidates for this role are the RNA polymerase III-encoded virus-associated (VA) RNAs. Two prominent species, 5.5S and 5.2S (about 156 nucleotides long), are encoded by genes which lie just in front of the late gene block, close to coordinates 29–30 on the Ad-2 map (Fig. 1*B*) and separated by a short spacer[115–118]. Both species of VA RNA appear during early infection, but the 5.2S species levels off and the 5.5S species increases during the late stage[116]. Splicing models have been proposed in which VA RNA base-pairs with splice junctions of late transcripts[119].

In addition to polyadenylation and splicing, late mRNAs are modified by methylation of internal A residues at the N^6 position[120]. These are added in the nucleus before splicing and (in contrast to the bulk of the RNA transcripts) are highly conserved on transport to the cytoplasm, suggesting that they may play a part in designating which sequences from the large transcript are to appear as mRNA.

mRNA arrangement for SV40 and polyoma

As with adenovirus, productive infections of SV40 and polyoma involve the temporal regulation of gene expression, with the synthesis of 'early' and 'late' mRNAs at different stages in infection. The early and late mRNAs of SV40 and polyoma are transcribed with opposite polarity with respect to the DNA physical map, and use opposing DNA strands as templates. Their 5′ termini are, however, clustered within a region of the genome that includes the origin of DNA replication[121–124]. Because the complete DNA sequences of SV40[125,126] and polyoma[127–132] have been determined, precise gene and mRNA mapping is possible.

The arrangement of SV40 genes and transcripts is shown in Fig. 2. During the first 8–10 h of SV40 infection, mRNAs are synthesized for two early proteins, the 90–100 kilodalton large T antigen[133] required for viral DNA replication, and the 15 kilodalton small t antigen[134–137] implicated in cell transformation (for a review see ref. 38). The mRNAs for SV40 T and t have closely mapping or identical 5′ and 3′ termini, but differ in their splicing[139,140]. The RNA encoding t is colinear with the DNA sequence from an AUG at coordinate 66 to a terminator at 55 (refs 140–142), but is followed by a downstream splice which falls completely within the untranslated region. In the T mRNA, the 5′ side of this splice shifts to remove the terminator and allow T translation to continue essentially to the 3′ end at coordinate 17 (ref. 140). The T and t proteins thus share amino-terminal sequences, but differ at their carboxy termini, and the smaller protein is encoded by the larger mRNA[143–145]. As a consequence of the early splicing patterns, deletions in DNA exclusive to t shown in Fig. 2*A* do not affect T synthesis[146]. Recently, a SV40-associated small RNA (SAS RNA) of unknown function, induced late in infection, has been identified that can associate with early viral mRNA near the 3′ end of the coding region (Fig. 3*A*) (ref. 147 and P. Berg, personal communication). If small RNAs indeed mediate splicing, a third splicing arrangement for SV40 'early' messengers may exist.

The messenger RNA map of polyoma is shown in Fig. 3*A*. Initiation of early transcription probably occurs near the beginning of the early region, because a defective genome that contains only tandemly repeated copies of the replication origin is an efficient template for early RNA synthesis[148]. With polyoma, evidence for organization of early genes is provided by alignment of open reading frames in early DNA with known early proteins encoded by the wild type and by deletion mutants. This analysis identifies early coding regions with splices analogous to those for SV40 T and t (refs 138, 149–151) and predicts proteins with highly homologous amino acid sequences^{127,132,152}. As with SV40, deletions in the t gene between coordinates 80 and 85 (hr-t deletions shown in Fig. 3*A*) do not change the apparent size of T^{153}. Downstream from the t gene, two reading frames are open for translation, suggesting that the T gene is overlapped by a second, out of phase, coding sequence. Polyoma encodes a third major early protein, the 55 kilodalton middle T, which shares amino-terminal peptides with T and t but differs at the carboxy terminus$^{154-159}$. Messenger RNA for T is synthesized according to a third early splicing pattern which also removes the t terminator, but joins the coding sequences for the amino terminus to the second large open reading frame, which is shifted with respect to the T frame. The frame-shifted overlap of polyoma middle T and T mRNAs results in differing carboxy termini for the two antigens, encoded by the same DNA segment, and is reminiscent of the cistron *D–E* and *A–B* overlaps in ΦX174 (ref. 158).

Both polyoma and SV40 encode three late proteins, VP1, VP2 and VP3, which are structural components of the virion^{131,159}. Mapping of nascent late transcripts places the start site for the late SV40 transcription a short distance upstream from coordinate 0.735, very near the region of the DNA which encodes the late mRNA 5′ termini, as shown in Fig. 2*B*, and suggests transcription initiation at the cap sites^{160}. The SV40 late messengers have heterogeneous capped 5′ termini encoded in a ~400-residue region adjacent to the replication origin (Fig. 4)$^{161-163}$. As with Ad-2, capped purine 5′ ends predominate greatly over pyrimidines. Two 5′ termini starting with AUU account for the majority of the species^{164,165}. A deletion mutant of SV40, d1-1811, mapped in Fig. 3*B*, which lacks the major cap site is, however, viable and transcribes mRNAs which have 5′ termini that are minor components in a wild-type infection^{166}. Polyoma late mRNAs also have heterogeneous 5′ termini. Three of these have been mapped in the genomes by sequencing and arise from a cluster, again with purines favoured over pyrimidines^{167}.

T antigen function

SV40 T antigen, as well as a protein encoded by the adenovirus–SV40 hybrid D2 which contains the carboxy-terminal sequence of T antigen, binds to the SV40 DNA replication origin, protecting the region shown in Fig. 4^{168,169}. The 5′ end of the early (T antigen) messenger RNA is encoded within the binding site for this antigen^{140}. Thus, T antigen may regulate its own synthesis, possibly through binding to the initiation site for its mRNA. This idea is supported by the overproduction of early mRNA by ts A mutants of SV40 at the non-permissive temperature$^{169-174}$. Post-transcriptional steps may also regulate early mRNA synthesis. In undifferentiated embryonal carcinoma cells, early mRNA is transcribed but it is neither spliced nor transported to the cytoplasm^{176}. However, when these cells are stimulated by retinoic acid to differentiate, early transcripts are processed into early mRNA^{175}.

The replication origin

In binding to the SV40 origin, successive T antigen molecules are added in the direction of the late cap site(s)^{169}. Functional T antigen is required for the initiation of each round of DNA replication^{177,178}, and DNA replication is in turn required for the onset of the late stage of transcription. However, if replication has already commenced, a temperature shift of a ts T antigen mutant which halts DNA replication permits continued transcription of late RNA^{179}. Late RNA sequences are also detected in the nucleus at low levels at early times before DNA replication$^{180-182}$, or when DNA replication has been blocked with ts T antigen mutants^{183}. Similarly, polyoma 'late' sequences may be detected at early times, before DNA replication, at a stage when late mRNA is not yet being synthesized^{184}. These observations imply that late RNA synthesis is not strictly dependent upon DNA replication. SV40 DNA may be isolated as a 'minichromosome' complex which contains histones in a beaded nucleosomal structure^{185}. A short region of this complex which extends from the origin of DNA replication to the late cap sites (coordinates 0.67 to 0.73, Fig. 4) is preferentially cleaved by a variety of nucleases, suggesting that these residues are exposed to the solvent, rather than being masked by the histones of nucleosomal beads$^{186-188}$. This same region contains the proposed SV40 RNA initiation sites, and if this structure is maintained *in vivo*, exposure of the putative promoters to the

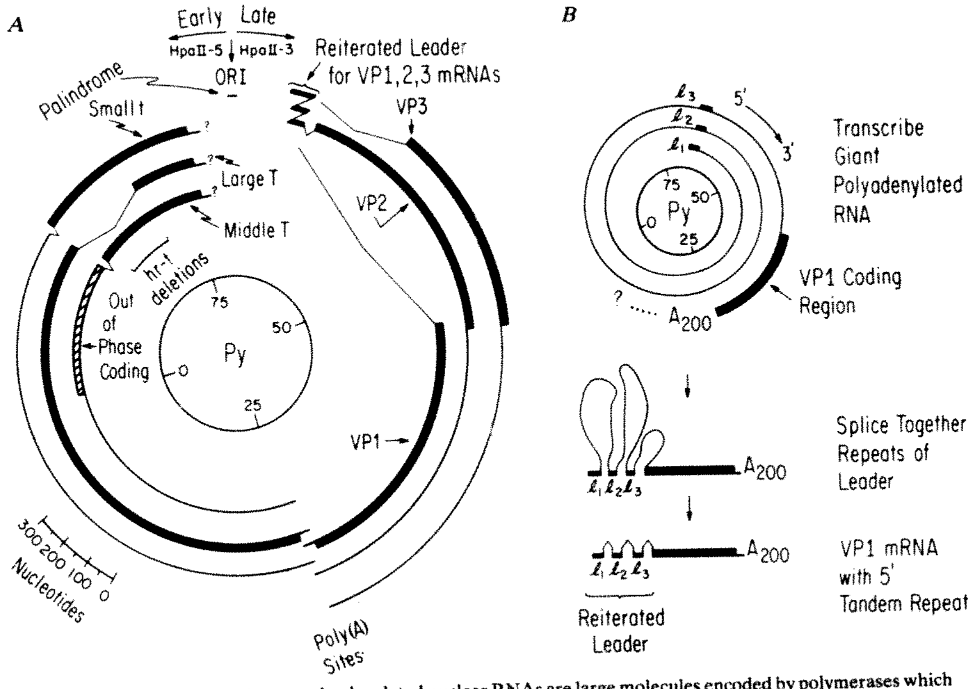

Fig. 3 Polyoma messenger RNAs. *A*, Messenger RNA map. As with SV40 (Fig. 2), the 5′ termini of polyoma mRNAs map near the origin of DNA replication (ORI). The sequence of the ORI contains an inverted repeat palindrome which overlaps the junction of fragments 3 and 5 from *Hpa*II restriction endonuclease digests of polyoma DNA. Early mRNAs are from anticlockwise transcripts, and late from clockwise transcripts. Polyoma synthesizes three early mRNA species which encode the tumour antigens small t, large T, and middle T. Although the exact splice points for the early mRNAs have not been determined, the t and T messengers have splicing patterns comparable to those of the equivalent SV40 mRNAs. With the mRNA for T, splicing allows translation to continue beyond the t gene. Translation enters the region encoding T, however, in a second out of phase reading frame generating a novel carboxy-terminal sequence for T. The arrangement of coding sequences in the polyoma late messengers is analogous to those of SV40 (see Fig. 2) and the polyoma mRNAs also have heterogeneous capped 5′ termini (not shown). The 5′ leader, however, contains a novel tandemly reiterated sequence (see below). The hr-t deletions are discussed in the text. *B*, Polyoma VP1 mRNA synthesis. At the late stage of infection, polyoma polyadenylated nuclear RNAs are large molecules encoded by polymerases which make several transits of the circular genome. These polymerases can transcribe the late poly(A) acceptor sequence without addition of poly(A), on one transit, but use the poly(A) acceptor sequence on a subsequent pass (compare with late Ad-2 in Fig. 1). It is not established whether this 3′ end is formed by RNA cleavage. The mature mRNA contains a 5′ leader with tandem repeats (1_1, 1_2, 1_3) of a sequence that exists only once in the genome. The reiteration results from the splicing together of each occurrence of this sequence within the giant polyadenylated RNA and joining the repeated structure to the VP1 (shown here), VP2 or VP3 coding sequences. See text for refs.

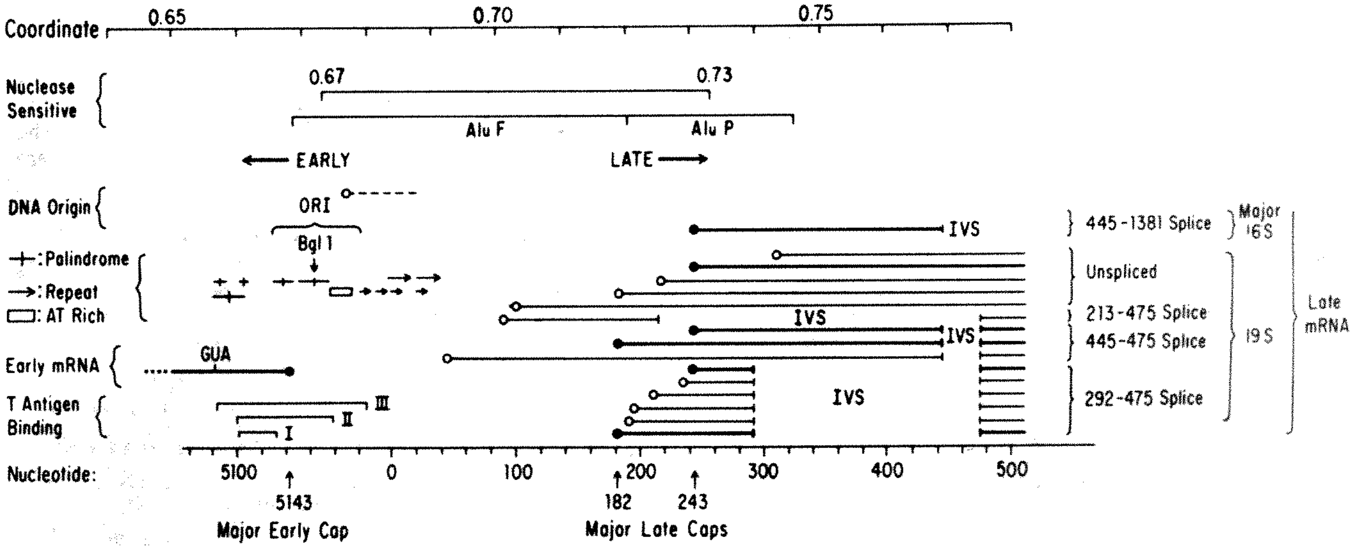

Fig. 4 Organization of transcripts and DNA sequences within the ORI region of SV40. A detailed map of the DNA replication origin (ORI) region of SV40 between coordinates 0.64 and 0.78 is shown (compare with Fig. 2). This region encodes the cap structure (●—, major species; ○—, minor species) of SV40 early (transcribed 5′ to 3′ leftward here) and late (transcribed right) mRNAs. The AUG of early mRNA which encodes the amino terminus of T and t tumour antigens is shown. The limits of ORI defined by deletion mutants are indicated. ORI contains a 27-base inverted repeat sequence centred on the *Bgl*I restriction endonuclease cleavage site, and is flanked by various direct and palindromic inverted repeat sequences and an A+T-rich region. The sequence of one arm of the central palindrome is also highly repeated in several animal cell DNAs. The SV40 T tumour antigen, and related proteins, bind as mono-, di- or trimers to the ORI DNA and protect, respectively, sequences I–III from DNase digestion. Because the cap site for early mRNA lies within this binding site, T antigen may autogenously regulate its synthesis by repressing transcription of its mRNA. The capped 5′ termini of late mRNAs are heterogeneous and encoded within a ~400-nucleotide region adjacent to the ORI. SV40 minichromosomes are sensitive to nuclease in this region. DNase 1 preferentially cleaves between coordinates 0.67 and 0.75 and restriction enzymes such as *Alu*I release the restriction fragments *Alu* F and *Alu* P more rapidly than other fragments. Intervening sequences (IVS) and splice sites for late 19S and 16S mRNAs are shown. See text for refs.

nucleoplasm could facilitate RNA polymerase binding to the DNA.

During bi-directional SV40 DNA replication, if new histone synthesis is blocked by cycloheximide, parental histones distribute themselves asymmetrically, with 80–90% segregating with the 'leading' side of the two DNA replication forks[189]. With SV40, the parental DNA which is the template for the leading side of DNA replication (at both forks) is also the template for mRNA. In the cell, nucleosomes also preferentially associate with DNA template strands which code for stable cell nuclear RNA. Thus, replication origins and RNA initiation sites may have similar arrangements in the cell and the virus[189].

It has recently been shown that a major class of DNA repeat sequences found in animal cells contains a 15-nucleotide sequence which is homologous with a sequence at the SV40 DNA replication origin[190]. The 15-nucleotide sequence forms one half of a palindrome which is centred about the *Bgl*I cut site of the virus at coordinate 67 (Fig. 4). In the cell, these sequences are interspersed between many genes[191], including those of the mouse β-globin gene cluster[190] where, in an *in vitro* transcription system, they are transcribed by RNA polymerase III[192]. The homologous sequence is also found at the DNA replication origins of polyoma, BK virus and hepatitis B virus, and within a small RNA which hydrogen bonds to mRNA[190]. Although it is possible that these repeats in the cell are DNA replication origins interspersed between transcription units, and are cellular targets of T antigen, their function has not been established.

Formation of the polyadenylated 3′ end

The polyadenylated 3′ ends of SV40 early and late mRNA converge at coordinate 17 and overlap[126]. As indicated in Fig. 3*B*, SV40 late transcription continues in an equimolar fashion at least 1,000 residues beyond the poly(A) site of late mRNA, implying that a cleavage event forms the 3′ end[160,193]. With polyoma, polyadenylated late nuclear transcripts are giant RNA molecules (see Fig. 3*B*), two or three times larger than genome length[194,195]. These probably result from multiple transits of the polymerase around the circular genome. Just as polymerases transcribing Ad-2 late RNA can pass five poly(A) sites but use only one, so polymerases may make several passes across the late polyoma poly(A) site before a functional poly(A) receptor is synthesized. For both papovaviruses, the AAUAAA hexanucleotide homology is found adjacent to early and late poly(A) sites[126,131].

Splicing papovavirus late mRNA

The predominant late RNA sequences in the nucleus are unspliced and extend from the cap site(s) to the poly(A) site. This suggests that capping and polyadenylation precede splicing[193]. Splicing of SV40 yields, with approximately equal efficiency[196], two major size classes of mRNA: 18S–19S, which encodes VP2 and VP3, and 16S, which encodes VP1[126,197,198]. At least two alternative forms of 19S mRNA are found which differ in the splicing of the 5′ leader (Fig. 4)[162]. For both forms, the 5′ leader is non-coding, and the same AUG which lies within the main body of the mRNA is utilized for initiation of VP2 translation[162]. To form the VP1 mRNA, a much larger intervening sequence is removed, and the leader is juxtaposed to a second downstream AUG which initiates VP1 translation[199]. In fact, this AUG lies within the VP2 gene, but the VP1 and VP2 gene sequences which overlap are read in different frames. The mRNA for VP3 is not well characterized, but the gene for this third late SV40 protein forms a 3′-co-terminal overlap with the VP2 mRNA, and utilizes an internal AUG codon of VP2 for the start of translation[200]. The choices of splice available for forming SV40 late 3′-co-terminal mRNA shown in Fig. 2*B* directly parallels the Ad-2 splice choice of Fig. 1.

Late mRNA species from SV40 can survive the deletion of large segments of their leaders without loss of function[201,210,211]. Integrity of the splicing sites themselves, however, is a prerequisite for stable mRNA synthesis. If the splice junction on one or both sides of an intervening sequence is deleted, the transcript is destabilized and is degraded in the nucleus[202–205]. The short sequence homologies at splice sites, GU at the donor (5′) side and AG at the acceptor (3′) side, found in cellular genes[206], are also found for SV40 (ref. 162).

Although the arrangement of late genes and mRNAs in polyoma[207,208] is very similar to that in SV40, the existence of the giant polyadenylated polyoma nuclear species apparently permits splicing mechanisms to form mature mRNA leaders with a novel structure. The polyoma late mRNAs contain a sequence which is reiterated in the 5′ leader, but which occurs only once in the DNA[209]. In the processing model which explains this paradox (Fig. 3*B*), giant polyoma transcripts are spliced to join together each occurrence of the repeat sequence in giant RNA to form a reiterated leader structure[209]. SV40 late mRNA also has reiterated leaders, but with a lower frequency, consistent with the shorter average size of nuclear transcripts[212].

Conclusions

Studies of DNA virus transcription suggest a common pathway for the synthesis of many viral mRNAs that includes initiation at the cap site, transcription of the mRNA precursor beyond the functional poly(A) site, cleavage and polyadenylation to form the 3′ end, followed by splicing and transport. Many features of this pathway are likely to be shared with the cell. The viruses have, however, evolved complex arrangements of coding sequences and sites for initiation, splicing and polyadenylation of RNA which use the pathway to maximum advantage. The next task is to identify the steps in these pathways that are regulated, and to identify the viral and cellular components which exert control.

Rapid polymer transport in concentrated solutions through the formation of ordered structures

B. N. Preston, T. C. Laurent*, W. D. Comper & G. J. Checkley

Department of Biochemistry, Monash University, Clayton, Victoria 3168, Australia

Our previous finding that high molecular weight polymers in certain systems can be transported with an unexpectedly high apparent 'diffusion' rate in the presence of a concentrated second polymer has been shown to be due to the formation and movement of organized macroscopic structures in an otherwise convection-free solution. The structures are not formed as part of a normal phase separation but will dissipate with time. Their formation may be understood by recently developed principles of nonlinear nonequilibrium thermodynamics.

OUR studies on the mechanism of macromolecular transport in gels and polymeric networks in solution have been primarily concerned with relating our observations to biological transport and organizational phenomena, in particular to transport phenomena occurring in the extracellular matrices of connective tissues and within passive membranous structures (for reviews see refs 1, 2). We now present results concerning the kinetics and ultimate formation of ordered structures arising from concentration gradients in aqueous multicomponent polymer solutions.

Initial observations of rapid transport of macromolecules in polymer networks

Preston and Snowden[3] observed that polyethylene glycol and polyvinyl alcohol exhibited higher migration rates in polysaccharide solutions than in polysaccharide-free media. Similar experiments with compact globular solutes exhibited reduced transport rates which were explained by hindered diffusion[4–6]. A detailed re-investigation[7] of the ternary polymer–polymer–solvent systems, using a capillary technique[8], confirmed the earlier studies. Some of the results of this investigation have been reported[9,10]. The transport of a linear flexible macromolecule (component 1) in solutions of a polysaccharide (component 2) was found to show a marked dependence on (1) time, (2) molecular weight (MW) and concentration gradient of component 1, and (3) MW and concentration of component 2.

As an example of several systems studied we consider the migration of polyvinylpyrrolidone (PVP) (MW $\sim 3.6\times10^5$; $D = 2.1\times10^{-7}$ cm^2 s^{-1}) as component 1 in a solution of dextran (MW $\sim 10^4$) as component 2. As described previously[7,9,10], at low concentrations of component 2 (C_2), a slight reduction in the transport rate of component 1 was observed. As C_2 was increased, the migration of component 1 increased to a rate 40 times higher than that observed in the absence of component 2,

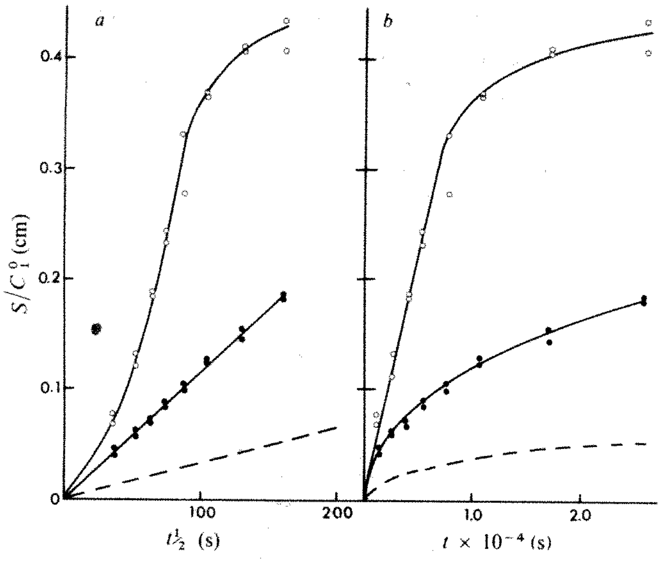

Fig. 1 Transport of ^{3}H-PVP (○) and ^{14}C-sorbitol (●) over a boundary formed by layering 135 mg ml^{-1} dextran (MW ~10^4) over 5 mg ml^{-1} ^{3}H-PVP (MW ~3.6×10^5), 10 mg ml^{-1} ^{14}C-sorbitol and 135 mg ml^{-1} dextran. S is the amount transported per cm^2 of surface area and C_1^0 the initial concentration in the lower compartment. For normal diffusion the transport should be proportional to $(t)^{1/2}$, as shown for sorbitol but not for PVP (*a*). Instead, the PVP transport is directly proportional to time before it levels off (*b*). For comparison, the normal diffusion of ^{3}H-PVP in water is included (– – –). Experiments were carried out at 20 °C.

and then, decreased at still higher values of C_2. When the transport of glucose or sorbitol ($D = 58 \times 10^{-7}$ cm^2 s^{-1}) as a solvent marker was measured simultaneously with the migration of component 1, the behaviour of the low molecular weight solute was normal in that its transport rate was reduced ($D = 39 \times 10^{-7}$ cm s^{-1}) by the presence of component 2. This suggests that gravitational instabilities[11] had not led to macroscopic convectional destruction of the boundary. As ternary polymer–polymer–solvent systems are known to be affected by phase transitions[12], it was possible that the enhanced migration rates were linked to the kinetics of phase transitions. We therefore established[7] that the systems under study were in regions far from phase transitions.

The time dependence of the apparent diffusion rate of component 1 was very marked in the initial stages. The rates reported[10] were those measured after an interval of 41 h, where they exhibited only a slight time dependence. Our qualitative interpretation of these effects was focused on the hydrodynamic and thermodynamic parameters considered important in determining diffusion rates in multicomponent systems[13–15]. This approach has been successful in describing polymer diffusion in binary systems[16–18]. However, we show here the rapid transport of PVP in dextran solutions is not a normal diffusional process.

Time dependence of PVP transport in dextran solutions

When the transport of PVP in dextran solutions was analysed as a diffusional process, it was found that the migration rate was markedly time dependent. However, as the capillary technique used precluded an accurate analysis of transport rates at early times, we used a new technique to investigate time dependence.

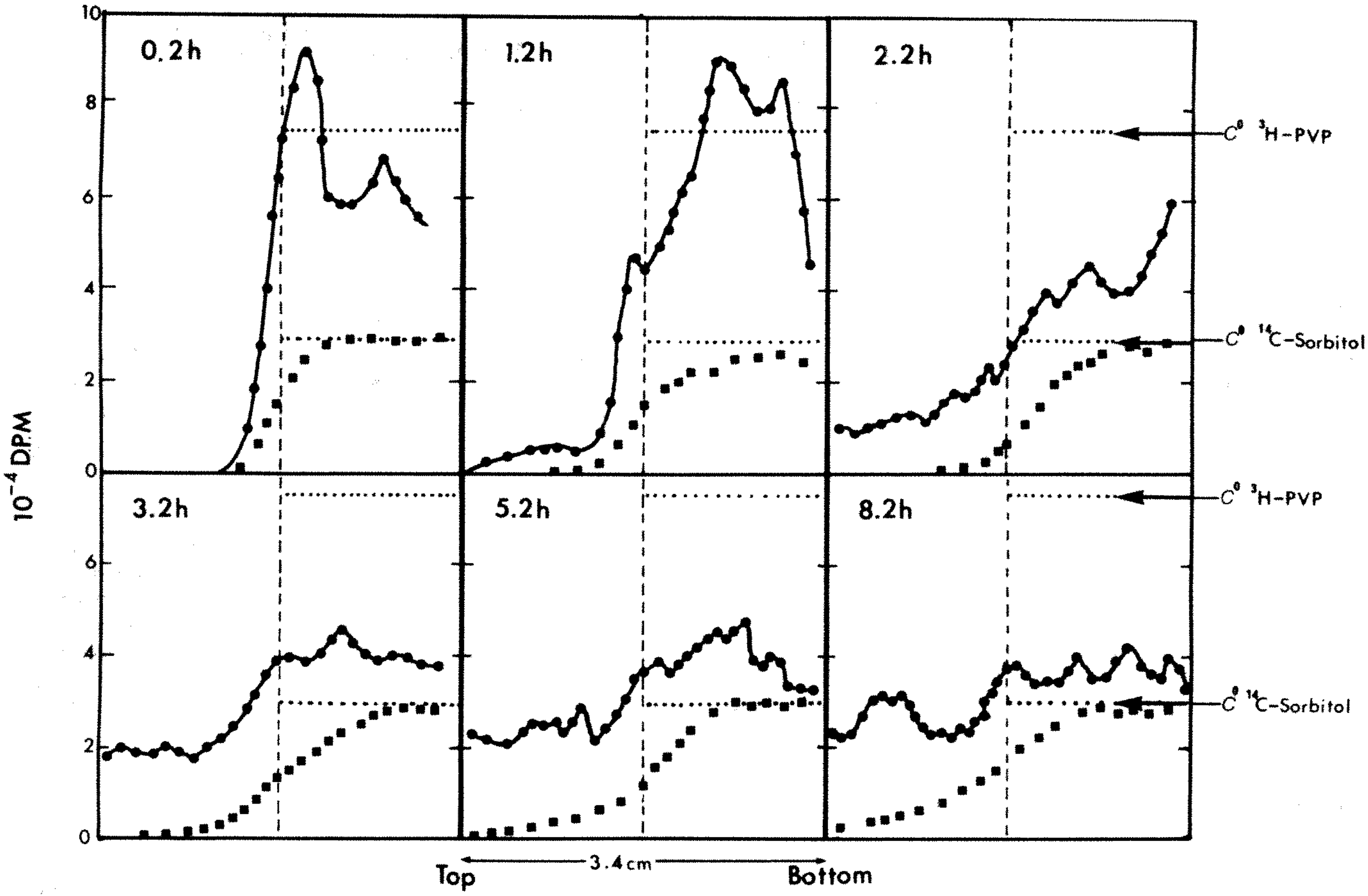

Fig. 2 The solutions described in Fig. 1 were layered in 3.4 cm long plastic tubes. Their contents were fractionated after various times—0.2 to 8.2 h and the distribution of ^{3}H-PVP (●) and ^{14}C-sorbitol (■) determined. The change in concentration of ^{14}C-sorbitol is due to normal diffusion, whereas ^{3}H-PVP spreads more rapidly and exhibits a wave-like distribution. The position of the original boundaries (– – –) and the original concentrations of the components (. . . .) are indicated. The ordinate represents the radioactivity found in each fraction.

The apparatus consists of a diffusion cell (designed by L. -O. Sundelöf) in which a free horizontal boundary is formed by a shearing mechanism between two solutions of comparable volume. Transport of labelled material across the boundary can be directly monitored as a function of time, by using a number of identical cells. For simplicity we will consider the behaviour of the ^{3}H-PVP (component 1) in a dextran (component 2) of concentration, $C_2 = 135$ mg ml^{-1}. This value of C_2 corresponds to a maximal apparent diffusion rate of component 1[10]. Most experiments used a PVP concentration difference of 5 mg ml^{-1} in the presence of a sorbitol concentration difference of 10 mg ml^{-1}, the latter acting as a solvent marker to detect any macroscopic convective flow. Figure 1 shows the time dependence of ^{3}H-PVP and of the ^{14}C-sorbitol flux in this system. The ordinate represents the ratio of the quantity of solute transferred (S) across the boundary per unit cross-sectional area, to the initial concentration of the solute (C_1°) in the lower part of the diffusion cell. When S/C_1° is plotted against (time)$^{1/2}$ ($t^{1/2}$) (Fig. 1*a*), the transport of the ^{14}C-sorbitol follows diffusional kinetics (linear with respect to $(t)^{1/2}$) and corresponds to a diffusion coefficient of $\sim 40 \times 10^{-7}$ cm^2 s^{-1}. The transport of the ^{3}H-PVP follows a sigmoidal pattern, not expected for a normal diffusional process. However, if S/C_1° is plotted against time (Fig. 1*b*), two distinct transport modes are observed for the ^{3}H-PVP. In the first 3 h, about 40% of the polymer moves across the initial boundary, and the transport rate seems to be linearly related to time. At later times, the rate falls to a much smaller value. The striking differences in the behaviour of PVP and ^{14}C-sorbitol confirms the previous results in that no bulk convective flow is occurring in a system in which high rates of ^{3}H-PVP transport are observed. Figure 1 includes comparable data describing the transport of ^{3}H-PVP in the absence of the dextran network.

The linear time dependence of the initial ^{3}H-PVP transport rate suggests that its migration might be mediated by a convectional or gravity-induced process. It is unclear why such movement is not accompanied by a similar behaviour of the solvent marker ^{14}C-sorbitol. However, the diffusion rate of the ^{14}C-sorbitol does increase slightly over that in PVP-free media ($D = 33 \times 10^{-7}$ cm^2 s^{-1}). Although the transport rates increase with temperature, a correction term allowing for the temperature dependence of the viscosity of water makes the rates temperature independent. This indicates absence of any active process in the transport of ^{3}H-PVP, suggesting instead that the transport rate is a function of the viscosity of the system. In agreement with this conclusion, we previously reported[10] that the rapid transport is a function of the molecular weight of the network component, we now relate this to the macroscopic viscosity of the system.

To study the spatio-temporal relationships of the process, the experiment was carried out in a vertical centrifuge tube. After layering the dextran solution onto a solution containing dextran, ^{3}H-PVP and ^{14}C-sorbitol, the tube was allowed to stand for varying periods of time, and was then fractionated by displacement with a dense fluid (tetrabromoethane). The profiles of the distribution of material as a function of time are shown in Fig. 2*a*–*f*. Two features of the time evolution of this system are evident: (1) the migration of ^{3}H-PVP results in a wavelike distribution of material propagating throughout the solution; and (2) ^{14}C-sorbitol shows no comparable behaviour, developing a normal gaussian-like distribution.

Effect of parameters influencing the density differences over the boundary

The direct influence of gravity on PVP transport in dextran solutions was established by monitoring PVP migration in the analytical ultracentrifuge by UV absorption. The boundary conditions (see Fig. 1 legend) were similar to those in experiments performed at unit gravity. We found that the PVP transport rate increased with the centrifugal force acting on the system; however, the relationship was not a simple one. For example, at unit gravity the rate was 1.4 mm h^{-1}, at 1,077 *g* it was 3.8 mm h^{-1} and at 44,000*g* 9.0 mm h^{-1}.

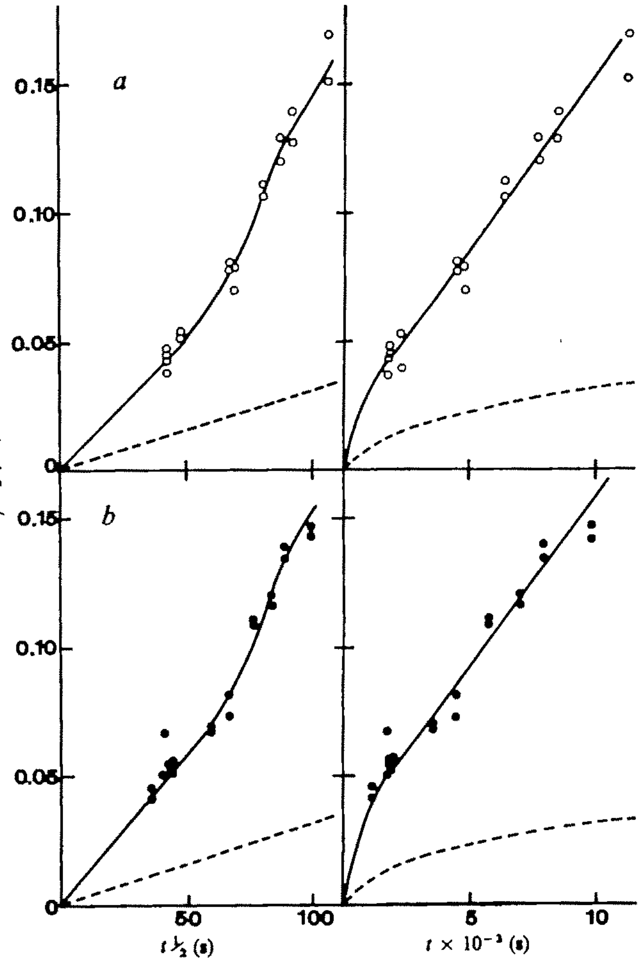

Fig. 3 The upward (*a*) and downward (*b*) fluxes of dextran over a boundary similar to that described in Fig. 1 legend except that PVP is unlabelled and dextran labelled with ^{3}H. For comparison, the normal (trace) diffusion of dextran in a system containing 135 mg ml^{-1} dextran but no PVP has been included (- - -). The dextran fluxes in the presence of PVP are much higher than in normal diffusion and do not obey diffusion kinetics. Experiments were carried out at 20 °C.

Our attempts to stabilize the boundary with density differences by conventional means did not always produce a 'stabilization' in terms of reducing the enhanced PVP transport. The presence of a sorbitol concentration of 10 mg ml^{-1} in the lower solution or the use of D_2O in the lower solution did not affect the magnitude of the PVP transport. These results suggest that the 'instabilities' caused at the boundary are not affected by the macroscopic density of the solutions as derived from low molecular weight solutes or dense solvents.

Conversely, the PVP transport rate seems to depend critically on the concentration gradients of macromolecular species across the boundary. Variation of the PVP concentration gradient markedly affects the subsequent transport rates[7]. At low PVP concentration gradients no anomalous transport was seen.

Dextran flux in the system

The unidirectional transport rates of ^{3}H-dextran were measured in both directions across the PVP boundary, and indicated that dextran was also rapidly transported and, as with PVP transport, was essentially linear with time (Fig. 3*a*, *b*). The unidirectional rates were of similar magnitude; this means there was only a small resultant downward flux of dextran over the boundary. Figure 3*a* and *b* also show the unidirectional transport rates of the dextran in the absence of any PVP gradient; this represents the self (or tracer) diffusion behaviour of dextran at $C_2 = 135$ mg ml^{-1} ($D = 3.6 \times 10^{-7}$ cm^2 s^{-1}).

Direct visualization of the PVP transport

Direct visualization of the fluxes involved was achieved using a blue-labelled PVP obtained by coupling PVP to remazol brilliant blue (see Fig. 4 legend). When a free boundary was formed in either a thermostatted Tiselius diffusion cell or by manual methods in a test tube or glass cuvette, a striking series of events was seen. After an initial period, a number of uniformly spaced blue vertical 'fingers' or spikes appeared at the boundary (Fig. 4*a*). These spikes grew at a rate comparable in magnitude to the PVP transport rates given earlier and were associated with a concomitant development and propagation downwards of colourless fingers. In view of our earlier observations, it is tempting to suggest that the polymeric components of the blue advancing fingers are PVP and dextran and that the descending structures contain only dextran. After 2–3 h, the system seemed to reach a 'stable' state in which a regular pattern of alternate blue and colourless lines extended through the whole volume (Fig. 4*b*). The pattern resembles the salt fingers observed in the double-diffusion system of Turner[19].

To observe the formation of these structured flows from above, the experiments were performed in a Petri dish (32 mm diameter). The dextran solution containing the blue-labelled PVP was layered under a dextran solution of similar concentration but without the PVP. The ensuing series of events was again complex but briefly consisted of the initial formation of needle-like structures of relatively intense blue colour at the perimeter of the dish and directed radially towards the centre (Fig. 5*a*), followed by the formation of several concentric circles of blue colour parallel to the perimeter of the dish (Fig. 5*b*). The two patterns then merged to yield a very complex mosaic-type appearance (Fig. 5*c*). Within 20 min the regular pattern had begun to disperse and within 2 h a homogeneously coloured solution was obtained.

Variants of the two behaviours described above can be created by using D_2O in the lower solution, which seems to prevent the downward growth of structures, or by changing the boundary conditions (different container shapes). The experiments were also carried out in the dark with similar results, indicating that these events were not light induced, arising from absorption effects.

The apparent generalization of these phenomena or closely related events has been suggested by comparable observations in various ternary polymeric systems under similar constraints.

A tentative explanation of the phenomenon

Our physical picture of the phenomenon supposes concentration inhomogeneities occur in the volume proximal to the initial boundary, so that regions of differing densities are formed. Regions of relatively high density would sink and subsequently displace regions of lower densities; conversely, the low density regions may float and displace regions of higher density. Possible mechanisms leading to density inhomogeneities include a net water flux downwards due to osmotic pressure differences across the boundary, or a net movement of dextran upwards due to the chemical potential gradient induced in the uniform dextran matrix by the presence of the PVP[20]. This latter effect would increase the concentration of matrix dextran immediately above the initial boundary with consequent sinking

Fig. 4 The formation of structures at the boundary between 135 mg ml^{-1} dextran (top) and 5 mg ml^{-1} blue PVP, 135 mg ml^{-1} dextran and 10 mg ml^{-1} sorbitol (bottom). Blue PVP was prepared by heating PVP (5 g) and remazol brilliant blue (0.75 g) in NaOH (200 ml, 0.05 M) at 50 °C for 3 days. The coloured polymer was purified by repeated washings with distilled water in Amicon ultrafiltration apparatus equipped with a PM 10 membrane filter, under a pressure of 60 p.s.i. The boundary was formed in the centre of a 6.0 cm long Tiselius cell and photographed 30 min (*a*) and 8 h (*b*) after layering. The structures remained in the cell for at least 24 h. × 3.

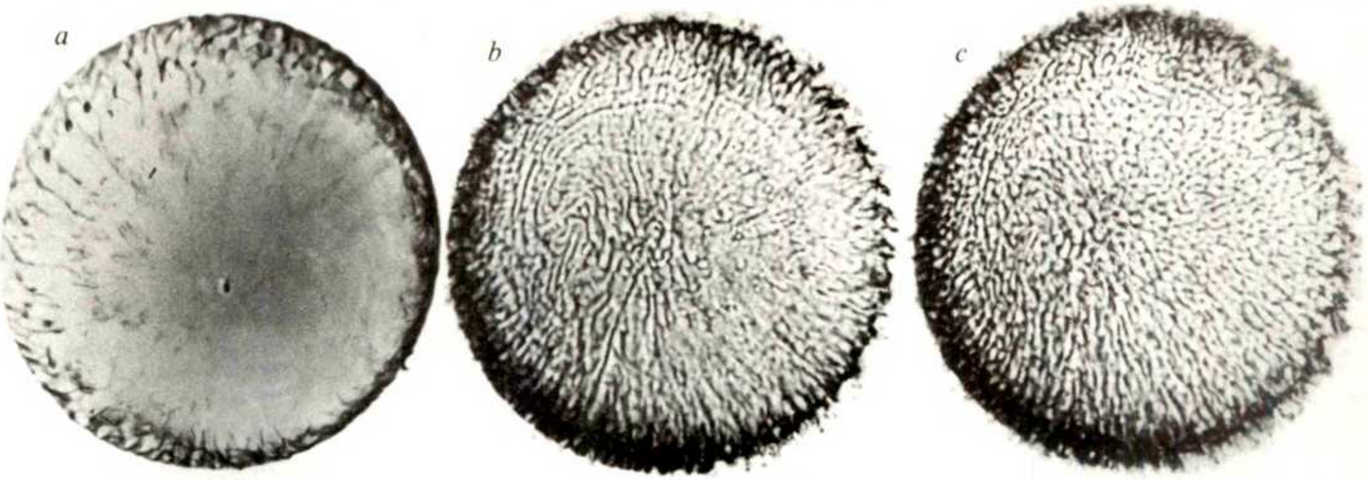

Fig. 5 The formation of structures in a Petri dish seen from above. A boundary between the same solutions described in Fig. 4 legend was formed by layering 1 ml of blue solution under 1 ml of clear dextran solution with a needle. The photographs were taken *a*, 4 min; *b*, 12 min; and *c*, 20 min after the layering. × 2.

of the regions of PVP-free solutions through the layers of solution below the boundary. Alternatively, the intrinsic compositional differences in regions close to the boundary due to thermal fluctuations in polymer concentrations could, without invoking any initial transport across the boundary, create unstable regions which would coalesce and grow—a non-equilibrium nucleation phenomenon of the kind described by Nicolis and Prigogine[21].

Whatever the precise mechanism of formation, the dense regions may start a downward movement of fingers and displace regions of PVP-containing solution upwards. The slow diffusional characteristics of the PVP will retain this polymer in the upward-going structures and its vertical transport rate will be rapid and basically determined by the bulk movement of the structures. Low molecular weight solutes such as sorbitol will, however, undergo a rapid lateral diffusive exchange between the upward- and downward-moving structures and hence the net transport in the vertical directions will be low and governed by the lateral diffusional process. The observation that high concentrations of low molecular weight solutes (sorbitol or D_2O) in the solution below the boundary do not inhibit the rapid transport of the PVP can be understood in terms of a rapid equilibrium of these solutes between regions close to the boundary where initial polymer concentration inhomogeneities exist. Furthermore, these small molecular weight solutes may equilibriate rapidly between the upward- and downward-moving structures, thereby limiting their 'stabilizing' effect.

Are dissipative structures involved in these systems?

Glansdorff and Prigogine[22], through a general formulation of nonequilibrium statistical mechanisms, have concluded that two basic conditions are required for the formation of ordered coherent structures in an open system. First, factors must operate on the system to drive it further from an equilibrium state. Second, nonlinear mechanisms must act between the various elements of the system. When these conditions are met, certain types of fluctuation can be amplified and drive the system to a new regime which differs from the initial reference state. This regime is characterized by the appearance of organizations (called dissipative structures) whose probabilities of occurrence at equilibrium would be negligible. It is important to recognize that nonequilibrium unexpectedly may be the source of order-producing coherent behaviour in space and time.

It seems that the two basic requirements for the formation of self-organizing coherent behaviour are present in our system. First, the PVP concentration gradient will induce a chemical potential gradient in the dextran network, where no actual dextran concentration gradient exists. Such an induced chemical potential gradient would cause the dextran, initially at uniform concentration, to migrate, thus forcing the system further from the equilibrium state. Second, it is well recognized that the thermodynamic parameter describing the interactions occurring in concentrated polymer systems is nonlinear. We thus tentatively conclude that the observed structures in the ternary systems are an example of dissipative structures.

We believe that our demonstration of self-organization occurring merely by intrinsic heterogeneities in polymer concentration is an important concept for an understanding of the organization and transport of high molecular weight solutes in biological systems. Furthermore, similarities exist between the presently described phenomenon and the 'finger' instabilities arising from the penetration of a fluid into a porous medium containing a more viscous fluid[23]. These instabilities are gravity or pressure induced and, when considered in conjunction with our observations, may be particularly relevant to an understanding of the complex transport effects found in the nerve axon.

Isolation of a yeast centromere and construction of functional small circular chromosomes

Louise Clarke & John Carbon

Department of Biological Sciences, University of California, Santa Barbara, California 93106

The centromeric DNA (CEN3) *from yeast chromosome III has been isolated on a 1.6 kilobase-pair segment of DNA located near the centromere-linked* CDC10 *locus of* Saccharomyces cerevisiae. *When present on a plasmid carrying a yeast chromosomal replicator,* CEN3 *enables that plasmid to function as a chromosome both mitotically and meiotically. Minichromosomes containing* CEN3 *are stable in mitosis and segregate as ordinary yeast chromosomes in the first and second meiotic divisions.*

In an attempt to isolate and characterize yeast centromeric DNA, the techniques of overlap hybridization[1], complementation of mutations in yeast through transformation[2,3], immunological screening[4,5], and complementation of auxotrophic mutations in *Escherichia coli*[6] have been used in our laboratory to obtain a number of hybrid plasmids containing DNA segments from around the centromere-linked *leu2*, *cdc10*, and *pgk* loci on chromosome III of *Saccharomyces cerevisiae.* A contiguous region of about 25 kilobase pairs of DNA that extends from the *LEU2* gene to the *CDC10* gene has been obtained on a set of overlapping plasmids[1,3]. Among these is the plasmid pYe(*CDC10*)*1*, which contains the yeast *CDC10* gene included on an 8 kilobase-pair segment of yeast DNA[3]. This plasmid was selected by complementation of the *trp1* and temperature-sensitive *cdc10* lesions in strain XSB52-23C from a pool of hybrid plasmid DNAs composed of segments of sheared yeast DNA joined by poly (dA · dT) connectors into the *E. coli*-yeast shuttle vector, pLC544 (ref. 3). This vector contains the yeast *TRP1* gene along with the chromosomal replicator, *ars1* (ref. 7).

Unlike other *ars1* bearing plasmids described by Stinchcomb *et al.*[7], Kingsman *et al.*[8], and below, pYe(*CDC10*)1 is relatively stably maintained through mitotic and meiotic cell divisions in yeast. We have investigated the nature of this stability both biochemically by localization and preliminary sizing of the stabilizing segment of DNA, and genetically by examining the behaviour of pYe(*CDC10*)1 and its derivatives in mitosis, meiosis, sporulation and germination. The stabilizing segment is confined to a 1.6-kilobase pair region on the left (*LEU2*) side of the *CDC10* locus. Its presence on plasmids that also carry a yeast chromosomal replicator [*ars1* (ref. 7) or *ars2* (ref. 9)] permits those plasmids to behave mitotically and meiotically as minichromosomes. Genetic markers on a minichromosome act as linked markers. They segregate in the first meiotic division as centromere-linked genes, are thus present in the two sister progeny of the second meiotic division, and are unlinked to genetic markers on other chromosomes. We conclude that the stabilizing DNA segment from pYe(*CDC10*)1 is a functional centromeric DNA sequence, the centromere of chromosome III (*CEN3*).

Plasmid pYe(*CDC10*)1 is mitotically stable

We have reported previously that in cultures of individual XSB52-23C/pYe(*CDC10*)1 transformants growing at 37 °C in the absence of tryptophan (selective conditions) only about 1–2 cells in 500 examined microscopically have lost the plasmid and express the easily distinguished Cdc10$^-$ phenotype[3]. Using overlap hybridization[1], a number of other plasmids have now been identified from our pLC544(*TRP1 ars1*)-yeast DNA genomic library that carry DNA segments from the *cdc10* region of chromosome III (Fig. 1). One of these, pYe98F4T, carries the *CDC10* locus because it complements the *cdc10* mutation in strain XSB52-23C, and it also contains additional DNA in the direction of *PGK*, but lacks about 3.5 kilobase pairs of DNA in the *LEU2* direction that is found on pYe(*CDC10*)1. Microscopic examination of cultures of individual XSB52-23C/pYe98F4T transformants (growing selectively) reveal that approximately one-half of the cells express the mutant Cdc10$^-$ phenotype, indicating extensive plasmid loss and instability. The degree of mitotic stability of pYe(*CDC10*)1, pYe98F4T, and two other *TRP1 ars1* plasmids containing DNA from near the *CDC10* locus, pYe65H3T and pYe101C3T (Fig. 1), was further examined by growing individual cultures of XSB52-23C transformants containing each of these plasmids on rich medium at 23 °C (nonselective conditions). After approximately 20–30 generations of nonselective growth, individual clones of the original transformants were scored for loss of plasmid (loss of the Trp$^+$ phenotype). As seen in Table 1, 97% of the clones derived from transformants harbouring pYe(*CDC10*)1 retained the plasmid after this extensive period of nonselective growth. Plasmids pYe98F4T, pYe65H3T, and pYe101C3T are completely segregated, however, in the same conditions. The parent vector in the above plasmids, pLC544 (ref. 8), other *TRP1 ars1* plasmids such as YRp7 and YRp7–Sc2604 (ref. 7), plasmids containing the chromosomal replicator (*ars2*; ref. 9), and many plasmids containing 2 μm DNA replicators[10] are also mitotically unstable.

Plasmid pYe(*CDC10*)1 is meiotically stable and segregates as a chromosome

Because stability in mitosis is a predicted property of a replicating unit carrying a functional centromere, the unique mitotic stability of pYe(*CDC10*)1 encouraged us to examine the behaviour of this plasmid through meiosis and sporulation. Strain XSB5223Cα/pYe(*CDC10*)1(*cdc10 leu2 trp1*/*CDC10 TRP1*) was crossed with X2928-30-1*A*a(*trp1 leu1 ade1 met14*), diploids were sporulated and the resulting asci were dissected for genetic analysis. Data from 16 tetrads (cross 1, Table 2) indicate that the plasmid (marked by the wild-type *TRP1* allele) in at least 60% of the asci segregates in the first meiotic division as a chromosome and is thus found in the two sister spores, the products of the second meiotic division. Only parental ditype and nonparental ditype asci were obtained in this cross using as

0028–0836/80/410504—06$01.00

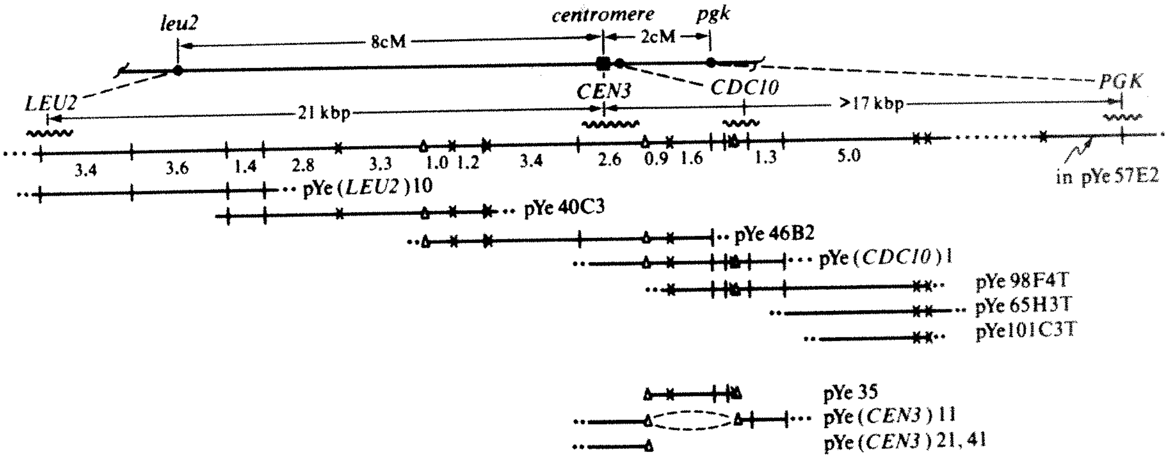

Fig. 1 Genetic and physical maps of the centromere region of *S. cerevisiae* chromosome III. The restriction map gives the location of *Eco*RI (—|—), *Hin*dIII (—×—), and *Bam*HI (-Δ-) sites in the DNA. Numbers denote kilobase pairs (kbp). The order of inserts in various overlapping plasmids is indicated below the restriction map. Small dots at the ends of inserts pertain to those sheared segments of yeast DNA that are joined to their respective plasmid vectors by poly (dA · dT) connectors. The isolation and characterization of plasmids pYe(*LEU2*)10 (ref. 6), pYe40C3 (ref. 1), pYe46B2 (ref. 1), pYe(*CDC10*)1 (ref. 3), and pYe57E2 (ref. 5), have been described. Plasmids pYe98F4T, pYe65H3T, and pYe101C3T were obtained by overlap hybridization and characterized as described by Chinault and Carbon[1], with the modification that a single restriction fragment (from pYe(*CDC10*)1) purified by agarose gel electrophoresis was used as probe in the hybridizations[20]. Plasmids pYe(*CDC10*)1, pYe98F4T, pYe65H3T, pYe101C3T, pYe35, and pYe(*CEN3*)11 all contain the *TRP1 ars1* vector, pLC544 (ref. 8). The vector portion of the remaining plasmids is ColE1.

references the centromere markers *leu1*, *leu2*, *met14*, and *ade1* (complete data not shown). Thus the *TRP1* locus on the plasmid behaves as a centromere-linked marker. The *TRP1* gene on pYe(*CDC10*)1 is unlinked to *ade1*, *cdc10*, *leu1*, *leu2*, or *met14* and is therefore not integrated on chromosomes I, III, VII or XI. The plasmid was completely lost in about 30% of the asci and in one ascus was found in all four spores, but did not segregate either 1+:3− or 3+:1− in any asci analysed in this cross.

A second cross was carried out with one of the progeny of cross 1, SB17*Aa*/pYe(*CDC10*)1(*cdc10 trp1 leu2 ade1*/*CDC10 TRP1*), and strain 6204-18Aα (*cdc10 leu2*). Data similar to that from Cross 1 were obtained (cross 2, Table 2). The plasmid in cross 2 again segregates 2+:2− in the first meiotic division in 92% of the asci and is found in all four spores in one ascus. With *ade1* as the reference centromere marker, again the marker scored on the plasmid (*CDC10* in this cross) is centromere-linked. The plasmid marker, *CDC10*, is unlinked to chromosome IV, because in those tetrads where *CDC10* segregated 2+:2−, *TRP1* (wild-type allele on both the minichromosome and one parental chromosome) segregated both 2+:2− and 4+:0−.

Backcrosses of plasmid-bearing progeny from cross 1 with the original parents XSB52-23C and X2928-3D-1A gave the same pattern of 2+:2− segregation of the wild-type plasmid marker that is independent of the segregation of markers on other chromosomes. In all the above crosses, the two markers on pYe(*CDC10*)1, *CDC10* and *TRP1*, were linked in every ascus scored (data not shown). None of the asci obtained consisted of two viable and two nonviable sister spores. Thus the minichromosome does not appear to pair with any of the other yeast chromosomes.

The centromeric DNA (*CEN3*) is located on the left (*LEU2*) side of the *CDC10* locus

The data presented above indicate that plasmid pYe(*CDC10*)1 contains functional centromeric DNA (*CEN3*) from chromosome III. Making use of the set of overlapping plasmids (Fig. 1) and various reclones from the *CDC10* region, we have attempted to determine the location of *CEN3*. In order to locate the *CDC10* gene on pYe(*CDC10*)1 we had previously constructed two reclones of this plasmid[3]. The first, pYe(*CEN3*)11 (see Fig. 1; referred to as pYe(*CDC10*)1-1 in ref. 3) contains all the yeast DNA in pYe(*CDC10*)1 cloned into pLC544, except the 3.5-kilobase pair *Bam*HI fragment from the middle of the insert. The second, pYe35 (referred to as pYe(*CDC10*)1-2 in ref. 3) contains only this 3.5-kilobase pair *Bam*HI restriction fragment and the vector pLC544 (Fig. 1). Neither plasmid complements the *cdc10* mutation in yeast[3], which indicates that one of the two *Bam*HI sites on pYe(*CDC10*)1 is probably close to or within the *CDC10* gene. Both pYe(*CEN3*)11 and pYe35 DNAs transform Trp$^-$ yeast to Trp$^+$ with high efficiency[3], since

Yeast strains XSB52-23C*a*(*cdc10 gal leu2–3 leu2–112 trp1*) and RH218*a* (*CUP1 gal2 mal SVC trp1*) were transformed with the above plasmid DNAs and in each case several individual transformants were isolated and grown nonselectively overnight on YPD (rich) medium. Each culture was subsequently streaked for single colonies on YPD agar, allowed to grow for 2 days at 23 °C (XSB52-23C) or 32 °C(RH218) and replica-plated onto minimal agar medium with or without tryptophan or leucine, depending on the marker carried by the plasmid. Between 40 and 100 individual clones of each original transformant were scored for plasmid loss after growth at 23 °C (XSB52-23C) or 32 °C (RH218). Preparations of media and transformation of yeast were carried out as described by Hsiao and Carbon[9]. ND, not determined.

they contain a *TRP1 ars1* vector. However, only one, pYe(*CEN3*)11, yields transformants that are all mitotically stable for the Trp$^+$ phenotype (Table 1). When a mating was carried out between XSB52-23C/pYe(*CEN3*)11(*trp1 cdc10*/*TRP1*) and X2928-3D-1A(*trp1 ade1*), data similar to that for crosses 1–4 were obtained (Table 2). In 60% of the asci 2+:2− segregation was observed for the *TRP1* marker on pYe(*CEN3*)11. The minichromosome was lost entirely in 27% of the asci and in 13% was found in all four spores. Again only parental and non-parental ditype asci were obtained with respect to centromere reference markers, indicating centromere linkage of *TRP1*. No linkage of the minichromosome to chromosomes I or III was observed, since pYe(*CEN3*)11 segregated independently of the *ade1* and *cdc10* markers.

Because *trp1* yeast transformants harbouring pYe98F4T are all unstable for the Cdc10$^+$ (and Trp$^+$) phenotype, and those carrying pYe(*CEN3*)11 are all stable for Trp$^+$ (Table 1), the stabilizing or centromeric DNA (*CEN3*) is most probably contained in pYe(*CEN3*)11 (and pYe(*CDC10*)1) on the 1.6-kilobase pair segment which extends from the *Bam*HI site to the end of the insert in the direction of the *leu2* locus (Fig. 1). To test this hypothesis, we recloned the 1.6-kilobase pair yeast DNA segment into the plasmid, pGT12(*LEU2 ars1*)^{11}. The DNA segment was excised from pYe(*CEN3*)11 DNA with the enzymes *Bam*HI and *Hin*dIII. This treatment yields a single *Bam*HI–*Hin*dIII restriction fragment whose *Bam*HI site is derived from the single *Bam*HI site in pYe(*CEN3*)11 and whose *Hin*dIII site is derived from a *Hin*dIII site in the vector (pLC544), located about 400 base pairs from the end of the insert of yeast DNA. The 1.6-kilobase pair segment of interest, which is thus included on a 2.0-kilobase pair *Bam*HI–*Hin*dIII fragment, was then inserted into plasmid pGT12, also cut with a combination of *Bam*HI and *Hin*dIII.

Plasmid pGT12 was constructed by inserting a 1.4-kilobase pair *Eco*RI restriction fragment containing *TRP*1 and *ars*1 (ref. 7) and a 2.2-kilobase pair *Pst*I fragment containing the *LEU2* gene^{11} into the single *Eco*RI and *Pst*I sites of pBR322 (ref. 11). This plasmid also carries resistance to tetracycline. When the 2.0-kilobase pair *CEN3* fragment is inserted into pGT12 cut with a combination of *Bam*HI and *Hin*dIII, both Tet^R and *TRP1* expression are destroyed, but the *ars1* chromosomal replicator is left intact. The resulting plasmid, pYe(*CEN3*)41 (Fig. 2), thus carries both *CEN3* and the replicator *ars1* in addition to the *LEU2* marker.

Plasmid pYe(*CEN3*)41 transforms strain XSB52-23C(*leu2-3 leu2-112*) to Leu$^+$ with high frequency and is stable in the transformants (Table 1). Its behaviour in meiosis (cross 6, Table 2) is essentially the same as that described for pYe(*CDC10*)1 and pYe(*CEN3*)11 in crosses 1–5. Thus the presence of the 1.6-kilobase pair segment (*CEN3*) on a plasmid carrying a yeast chromosomal replicator is all that is required for the plasmid to behave as a chromosome in mitosis and meiosis in the majority of asci analysed.

CEN3 minichromosomes are not integrated into the yeast genome

Genetic data in crosses 1-6 confirm random assortment of *CEN3* minichromosomes with respect to chromosomes I, III, IV, and XI. The possibility that *CEN3*-containing plasmids are integrated near the centromere of one or several other yeast chromosomes was tested both biochemically and genetically. First a mating was performed between two minichromosome-bearing progeny (cross 7, Table 2). In the majority of asci in cross 7, the minichromosomes (both *TRP1*) show the 2+:2− segregation pattern, indicating that the minichromosomes frequently go to the same pole in the first meiotic division and thus do not pair with each other all the time, if at all. This segregation pattern also confirms that pYe(*CDC10*)1 is not integrated into any other single chromosome in the parents in this cross. If it were, all daughter spores should contain plasmid, because the chromosome pair into which the plasmid is integrated would duplicate in meiosis I and go to opposite poles. This point is again confirmed in cross 8 where the minichromosomes are individually marked. In at least two asci both minichromosomes went to the same pole in meiosis I (Tables 2 and 3) and were therefore both found in the same two sister spores.

In addition, biochemical evidence shown in Fig. 3 demonstrates that pYe(*CEN3*)41 is not integrated anywhere in the yeast genome. Crude yeast DNA was prepared from two germinated sister spores that contained the minichromosome

Table 2 Meiotic segregation of the minichromosomes

Genetic cross no.	Minichromosome in cross	Minichromosome marker scored	Distribution in tetrads of genetic marker on minichromosome (%)					Test for centromere linkage of marker on minichromosome			Reference centromere marker (chromosome)

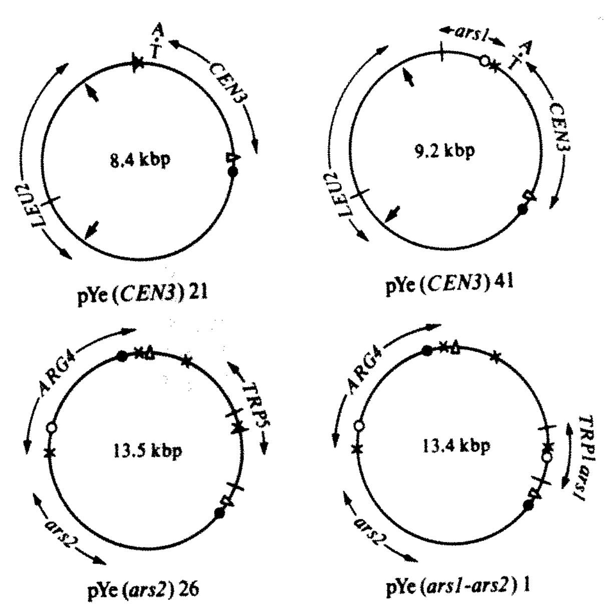
								7	5	0	*cdc10*(III)
7	pYe(*CDC10*)1 × pYe(*CDC10*)1	*TRP1*	6 (35%)	0	9 (53%)	1 (6%)	1 (6%)	ND	ND	ND	—
8	pYe(*CDC10*)1	*TRP1*	10 (24%)	1 (2%)	31 (74%)	0	0	15	16	0	*met14*(XI)
	pYe(*CEN3*)41	*LEU2*	8 (19%)	2 (5%)	24 (57%)	0	8 (19%)	10	14	0	*met14*(XI)
								17	2	0	*TRP1*(mini)

In all the above crosses the marker used to follow the minichromosome was wild type on the minichromosome and mutant in both parents. The crosses were: 1. XSB52-23Cα/pYe(*CDC10*)1(*cdc10 leu2–3 leu2–112 trp1 gal*/*CDC10 TRP1* with X2928-3D-1A*a*(*ade1 gal1 his2 leu1 met14 trp1 ura3*); 2, SB17A*a*/pYe(*CDC10*)1 (*ade1 cdc10 leu2–3 leu2–112 met14 trp1*/*CDC10 TRP1*) with 6204-18Aα(*cdc10 thr4 leu2–3 leu2–112*); 3, SB1C*a*/pYe(*CDC10*)1(*his2 leu1 met14 trp1*/*CDC10 TRP1*) with XSB52-23Cα (*cdc10 leu2–3 leu2–112 trp1 gal*); 4, SB17Bα/pYe(*CDC10*)1 (*ade1 cdc10 leu2–3 leu2–112 met14 trp1*/*CDC10 TRP1*) with X2928-3D-1A*a*; 5, XSB52-23Cα/pYe(*CEN3*)11 with X2928-3D-1A*a*; 6, XSB52-23Cα/pYe(*CEN3*)41 with X3144-1D*a*(*ade2 arg9 can1 his2 his6 leu2 pet8 trp1*); 7, SB14B*a*/pYe(*CDC10*)1 (*ade1 his2 trp1*/*CDC10 TRP1*) with SB17Bα/pYe(*CDC10*)1(*ade1 cdc10 leu2–3 leu2–112 met14 trp1*/*CDC10 TRP1*); 8, SXB52-23Cα/pYe(*CEN3*)41 with SB17A*a*/pYe(*CDC10*)1. Transformation of yeast in the presence of polyethylene glycol^2 results in a high proportion of diploid transformants (a/a or α/α)^8. Diploids are easily recognized by the extremely low spore viability obtained when they are crossed with a haploid, and in this way were eliminated from the group of haploid transformants used in the above crosses. PD, parental ditype; NPD, nonparental ditype; T, tetratype; ND, not determined.



pYe(*CEN3*)21 pYe(*CEN3*)41

pYe(*ars2*)26 pYe(*ars1-ars2*)1

Fig. 2 Physical maps of various plasmid DNAs. The maps show the location of *Eco*RI (—|—), *Hin*dIII (—×—), *Bam*HI (—Δ—), *Pst*I (—┬—), *Sal*I (—●—) and *Bgl*II (—○—) sites in the DNAs and indicate approximate locations of pertinent replicators and genes. The construction and use of these plasmids is described in the text. Their sizes are indicated in kilobase pairs (kbp).

(*LEU2*) and from one of the two sisters in the same ascus that was phenotypically Leu$^-$. This tetrad, in which the minichromosome pYe(*CEN3*)41 segregated 2+ : 2−, was obtained from cross 6 (Table 2). Figure 3 shows an autoradiograph of a Southern blot hybridization[12] in which each of the DNA preparations above was cut to completion with *Sal*I, *Bam*HI, or *Bgl*II. There is a single restriction site for each of these enzymes in the vector portion of pYe(*CEN3*)41 or between the vector and the yeast DNA insert (Fig. 2). In Fig. 3, lanes with DNA from minichromosome-containing progeny (lanes *b* and *c*) show a single band of hybridization to the radioactive probe, [^{32}P]pBR322 DNA. This band has the same mobility regardless of the enzyme used to cut the DNAs, and the mobility is identical to that of linear pYe(*CEN3*)41 generated in the presence of a plasmid-free yeast DNA preparation (lanes *d*) with *Bam*HI or *Bgl*II. The absence of any hybridization bands of sizes other than linear pYe(*CEN3*)41 suggests that this minichromosome is not integrated into yeast genomic DNA. We have not yet attempted to integrate any of the pYe(*CEN3*) plasmids into genomic DNA. Such an event would be expected to lead to dicentric chromosomes and probable mitotic instability[13].

Functional chromosomes require both centromeric DNA and a chromosomal replicator

All the minichromosomes studied and described above contain both *CEN3* and the chromosomal replicator *ars1*. The need for such a replicator with regard to *CEN3* function was tested by inserting the 2.0-kilobase pair *Bam*HI–*Hin*dIII restriction fragment carrying *CEN3* into the plasmid pGT6. Plasmid pGT6 is pBR322 (Tet^r, Amp^r) with a 2.2-kilobase pair fragment carrying the yeast *LEU2* gene inserted into its single *Pst*I site[11]. This plasmid also carries resistance to tetracycline, but not resistance to ampicillin. The 2.0-kilobase pair *Bam*HI–*Hin*dIII *CEN3* fragment was ligated into *Bam*HI–*Hin*dIII cut pGT6 DNA, resulting in the inactivation of Tet^r and yielding the plasmid, pYe(*CEN3*)21, whose structure is shown in Fig. 2.

Somewhat surprisingly, pYe(*CEN3*)21 DNA which contains *CEN3*, but lacks a chromosomal replicator sequence (Fig. 2), also transforms XSB52-23C to Leu+ with a frequency as high as does pYe (*CEN3*)41 DNA. Plasmid pYe(*CEN3*)21 is very unstable mitotically, however (Table 1). When grown under selective conditions in minimal liquid medium without leucine, the doubling time for transformants of pYe(*CEN3*)21 is about 12 hours, as compared to 4 hours for those transformants carrying pYe(*CEN3*)41. In log phase under selective conditions greater than 95% of the cells have segregated pYe(*CEN3*)21, whereas no segregation of pYe(*CEN3*)41 is detected under the same conditions. In general, more than 50% of yeast cells, originally transformed with plasmids carrying chromosomal replicators such as *ars1* (near *TRP1*) or *ars2* (near *ARG4*), lose the plasmid while being grown selectively[7,9]. The high frequency of transformation and high mitotic instability exhibited by pYe(*CEN3*)21 in yeast is perhaps most easily explained by postulating the presence of a weak or partial replication origin on the 1.6-kilobase pair (*CEN3*-containing) segment that permits only enough replication for the plasmid to be transferred to a few daughter cells in the population. It is not known whether this origin plays a role in centromere function.

Plasmids containing two chromosomal replicators are mitotically unstable

Since pYe(*CEN3*)21 DNA does transform yeast with high efficiency in the absence of a chromosomal replicator and seems to have a weak origin of replication of its own, we tested the possibility that any two chromosomal replicators on a plasmid might give mitotic stability to that plasmid in yeast. This notion has been addressed previously by Stinchcomb *et al.*[7], who looked at the behaviour of multimeric forms of *ars1* and found that yeast cultures transformed with monomer, dimer, and trimer *YRp7*(*TRP1 ars1*) were equally unstable mitotically and had identical growth rates.

We have put the *ars1* replicator together on a plasmid with *ars2* (a chromosomal replicator near *ARG4*)[9] in the following way. The plasmid pYe(*ars2*)26 (Fig. 2) contains the yeast *ARG4* and *TRP5* genes and the *ars2* replicator (C. L. Hsiao and J.C., manuscript in preparation). Plasmid pYe(*ars1–ars2*)1 was constructed by treating pYe(*ars2*)26 DNA with *Eco*RI endonuclease and inserting the 1.4-kilobase pair fragment carrying *Trp1* and *ars1* (ref. 7) into the plasmid DNA, thereby partially deleting the *TRP5* gene and replacing it with *TRP1* and ars*1* (Fig. 2). When *trp1* yeast was transformed to Trp$^+$ with pYe(*ars1–ars2*)1 DNA, transformants were as unstable mitotically for the Trp$^+$ phenotype as those transformed with pYe35 which carries only *ars1* (Table 1). In the same experiment, pYe(*CEN3*)11 showed less than 18% loss of the Trp$^+$ phenotype. In addition, the *ars1* replicator segment is in opposite orientations with respect to *CEN3* in pYe(*CDC10*)1 and pYe(*CEN3*)41, and both minichromosomes are equally stable. We conclude that two chromosomal replicators together do not convey mitotic stability upon a plasmid and that *CEN3* is unique

Table 3 Genetic analysis of mating between two haploid parents each carrying an individually marked minichromosome (cross 8)

Distribution in tetrads of markers on minichromosomes		No. of tetrads showing segregation pattern
TRP1(pYe(*CDC10*)1)	*LEU2*(pYe(*CEN3*)41)	(% of total)
4+ : 0−	4+ : 0−	3 (7%)
4+ : 0−	2+ : 2−	4(10%)
4+ : 0−	0+ : 4−	3 (7%)
3+ : 1−	2+ : 2−	1 (2%)
2+ : 2−	4+ : 0−	5(12%)
2+ : 2−	3+ : 1−	2 (5%)
2+ : 2−	2+ : 2−	19(45%)
2+ : 2−	0+ : 4−	5(12%)
	Total no. of asci analysed	42(100%)

Strains in cross 8 are described in Table 2, where the meiotic segregation patterns of the minichromosomes are summarized. Among the 19 asci where both minichromosomes segregated 2+ : 2−, both went to the same pole in the first meiotic division in 2 asci and to opposite poles in 17 asci.

in its stabilizing effect. This conclusion is further verified by the observation that *CEN3*, when isolated on a 5.1-kilobase pair *Eco*RI fragment derived from plasmid pYe46B2 (Fig. 1) and inserted into the *Eco*RI sites at the *TRP5* locus on pYe(*ars2*)26 (Fig. 2), mitotically stabilizes this *ARG4 ars2* plasmid for the Arg$^+$ phenotype (C. L. Hsiao and J.C., unpublished result).

Minichromosomes do not always pair in the first meiotic division

The absence of asci with two viable and two nonviable sister spores in crosses 1–6 indicates that the minichromosomes do not pair at the first meiotic division with any of the 17 yeast chromosomes. Cross 8 (Tables 2 and 3) was performed with two strains, each harbouring a *CEN3 ars1* plasmid marked with either *LEU2* or *TRP1*. Both parents in cross 8 have mutations at both *leu2* and *trp1*, therefore the behaviour of each minichromosome can easily be followed individually. A detailed analysis of this cross is given in Table 3, from which the following conclusions can be drawn. Each plasmid individually exhibited the 2+ : 2− segregation pattern in more than 60% of the tetrads examined. In the 19 asci where both plasmids segregated 2+ : 2−, the minichromosomes went to opposite poles in the first meiotic division in 17 asci, but they did assort to the same pole in 2 asci. These numbers support the notion that the minichromosomes do not always pair, but there is a strong preference for them to go to opposite poles in the first division. Otherwise, they seem to segregate randomly and independently with respect to one another, and all combinations of 4+ : 0−, 2+ : 2−, and 0+ : 4− are seen (Table 3). For example, both minichromosomes were found in all four spores in three tetrads; in five tetrads pYe(*CEN3*)41 was found in all four spores, but pYe(*CDC10*)1 segregated 2+ : 2−; in three asci pYe(*CDC10*)1 was in all four spores, but pYe(*CEN3*)41 was completely lost. Thus two minichromosomes together in the same sporulating diploid show the same meiotic behaviour as either one exhibits alone.

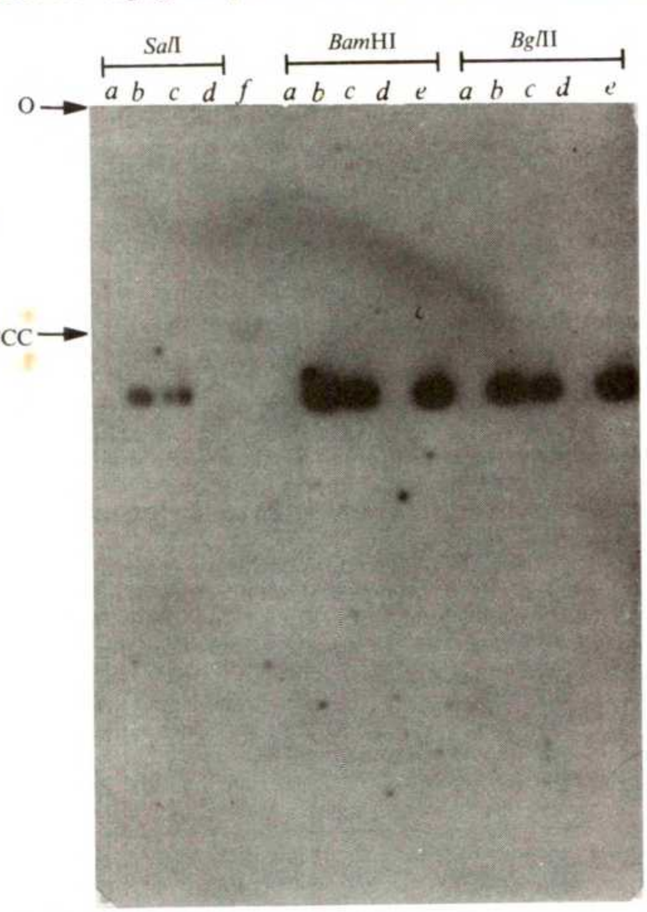


Fig. 3 Southern blot hybridization autoradiograph of total yeast DNAs from pYe(*CEN3*)41-containing strains with $[^{32}P]$pBR322 DNA as probe. Crude yeast DNA was prepared as described by Stinchcomb *et al.*[7] from one Leu$^-$ progeny (lanes *a*) and two Leu$^+$ progeny (lanes *b* and *c*) of a single 2+ : 2− ascus in cross 6 and from a Leu$^-$ progeny of a 3+ : 1− ascus in the same cross (lanes *d*). Approximately 2 μg of each DNA preparation was digested with *Bam*HI, *Sal*I, or *Bgl*II and electrophoresed in 0.75% agarose. Other lanes on the gel contained 2 ng of pYe(*CEN3*)41 DNA mixed with 2 μg of crude Leu$^-$ yeast DNA, either undigested (lane *f*) or digested (lanes *e*) with restriction enzyme. Blot hybridization was carried out according to Southern[12], with the following modifications. The fragments were transferred from the gel to nitrocellulose as described by Wahl *et al.*[21] and hybridization conditions were those of Cameron *et al.*[22]. The probe was pBR322 DNA labelled *in vitro* by nick translation[23] as described by Chinault and Carbon[1]. The origin (O) and position of covalently-closed circular pYe(*CEN3*)41 DNA (CCC) are indicated on the autoradiograph.

Discussion

We have identified a small DNA element (*CEN3*) from *S. cerevisiae* chromosome III that when present on a plasmid with a chromosomal replicator (*ars1* or *ars2*) allows the plasmid to behave as a functional chromosome in yeast. Minichromosomes containing *CEN3* are stable in mitosis, and in most cases segregate as chromosomes in the first meiotic division and are thus found in the two sister progeny of the second meiotic division. The *CEN3* element is therefore capable of controlling copy number, thereby ensuring proper meiotic segregation. In approximately 15% of the tetrads analysed in crosses involving *CEN3* plasmids, the minichromosome is lost completely. Generally, in yeast strains that are aneuploid for one or more chromosomes, the extra chromosomes are also somewhat unstable[14]. Tetrads in which a *CEN3* minichromosome segregates 1+ : 3− are rare, therefore the minichromosome is more stable through the second meiotic division than in the first.

In approximately 20% of the tetrads analysed, the minichromosome is found in all four spores after meiosis. This may be a result of selective diploidization of the *CEN3* plasmid or could indicate a loss of control of minichromosome replication. Inability of minichromosomes to pair may cause a certain instability in their attachment or involvement in the meiotic apparatus. Thus control over plasmid replication may be eliminated in some cases resulting in multiple copies that are distributed to all four spores. The 4+ : 0− tetrads are not a separate class, since the same 4+ : 0−, 2+ : 2−, 0+ : 4− patterns are exhibited by the progeny after further matings. Moreover, data from cross 8 (Tables 2 and 3) show that one minichromosome can segregate 2+ : 2− while another in the same meiotic event is distributed 4+ : 0−.

The genetic data show that minichromosomes do not pair with any of the normal yeast chromosomes, since asci containing two non-viable sister spores are not seen. However, two minichromosomes in the same diploid exhibit a strong preference to migrate to opposite poles in the first meiotic division. To determine exactly how much DNA, or which regions of DNA are involved in pairing of chromosomes at the first meiotic division, increasingly larger segments of DNA may be added *in vitro* to either or both ends of the *CEN3* segment on a plasmid. Pairing could then be assayed by genetic analysis.

Because plasmid pYe98F4T complements the *cdc10* mutation in yeast and plasmids pYe(*CEN3*)11 and pYe35 do not (Fig. 1), we have concluded that the *CDC10* gene is probably located in the region of the single *Bam*HI site in pYe98F4T. The *cdc10* locus had previously been placed directly next to the centromere of chromosome III (refs 15–17). The data presented here indicate that *cdc10* is located about 3 kilobase pairs from the centromere on the right arm of chromosome III. There are approximately 25 kilobase pairs of DNA between the *LEU2* and *CDC10* genes[3]. The genetic map distance between *leu2* and centromere is about 8 cM (refs 3, 16 and 17). Thus there is an average of about 3 kilobase pairs cM^{-1} from *leu2* across the centromere to *cdc10*. This number is close to the 2.7 kilobase pairs CM^{-1} determined by Strathern *et al.*[18] for very large distances on the circular chromosome III, indicating that the centromere does not appreciably distort recombination frequencies in the *leu2–cdc10* region.

We have shown previously that within the limits of a standard Southern blot hybridization, plasmid pYe(*CDC10*)1 contains only unique DNA[3]. By this same criterion, all the DNA between *leu2* and *cdc10* is unique DNA[1]. Work in progress is expected to define further the size of the centromeric DNA segment and its nucleotide sequence. Whether centromeric DNA sequences are unique for each chromosome may eventually be determined by sequencing other centromeres obtained in the same way.

The small circular chromosomes we have constructed around the *CEN3* element have many properties that mimic those of the much larger parental chromosomes. They are stable both in mitosis and through the first and second divisions of meiosis, probably because *CEN3* is providing an attachment site for spindle structures, a site that may be unique for each chromosome. A chromosomal replicator must accompany the *CEN3* segment to permit proper centromere function, but the replicator alone, or a combination of chromosomal replicators, do not stabilize a plasmid. Therefore the minichromosomes, like the larger chromosomes, require both an attachment site and one or more replicators. Unlike the parental chromosomes, the small circular chromosomes do not always pair, but, as is the case in sporulating aneuploid yeast strains, absence of pairing does not prevent the chromosomes from segregating in meiosis. Although we have no evidence that the weak replicator in the *CEN3* region is involved in centromere function, it is intriguing to speculate that it may be a specialized replicator for that region, perhaps serving to drive sister chromotids apart in a final burst of DNA synthesis, as suggested by DuPraw[19].

The *CEN3* minichromosomes are excellent probes for the study of events in mitosis and meiosis, particularly with regard to the protein–nucleic acid interactions occurring between the centromere and the mitotic and meiotic spindle structures. Minichromosomes with a functional centromere will be useful as well for studies of chromatin structure and the organization of DNA-associated proteins in the centromere region.

Finally, the mitotic stability of *CEN3* plasmids make them especially suitable cloning vehicles. Studies of expression of cloned genes on minichromosomes would not be complicated by the variable mitotic stability displayed by other vectors constructed for cloning in yeast. The functional centromeric sequence, *CEN3*, is not altered by propagation in *E. coli*, since all the *CEN3* minichromosomes were originally isolated in that bacterium before being put into yeast, and the absence of any gross alterations in DNA sequence in cloned segments from around the *CEN3* region has been previously confirmed by Southern blot hybridizations to restriction digests of total yeast genomic DNA[1,3]. It will also be of considerable interest to determine if the yeast centromere will function when introduced into other cell types on the appropriate self-replicating DNA vectors.

We thank Dr Terrance G. Cooper for many helpful discussions about the genetic data, Dr Robert K. Mortimer for introducing us to the intricacies of yeast genetics and for constructing strain XSB52-23C, Robert Gimlich for technical assistance and Drs Craig Chinault, Ronald Hitzeman, and Alan Kingsman for isolating many of the overlapping plasmids around centromere-linked loci on chromosome III. This research was supported by a grant (CA-11034) from the NCI, NIH.

A low resolution structure for the histone core of the nucleosome

A. Klug, D. Rhodes, J. Smith & J. T. Finch

Image reconstruction to 22 Å resolution of the histone octamer $(H3)_2(H4)_2(H2A)_2(H2B)_2$ shows it to have a 2-fold axis of symmetry, and the overall shape of a left-handed helical spool on which to wind about two turns of a flat superhelix of DNA in the nucleosome. From this structure and the results of various cross-linking studies, we have deduced the arrangement of the individual histones. We propose that the $(H3)_2(H4)_2$ tetramer forms a dislocated disk which defines the central turn of DNA, while the two H2A–H2B dimers lie one on each face, each associated with about one half a turn.

THE fundamental unit of chromatin structure is the nucleosome[1] which consists of a stretch of DNA wound about a histone core. With the knowledge that the arginine-rich histones H3 and H4 existed in solution as tetramers[2,3], the lysine-rich histones H2A and H2B as dimers[2,4], and that the four histones occur in chromatin in equimolar amounts, Kornberg[5] proposed that the core of the nucleosome was a histone octamer of composition $(H3)_2(H4)_2(H2A)_2(H2B)_2$. Octamers of histones in chromatin were demonstrated by chemical cross-linking, and the octamer was also shown able to exist free in solution in 2 M NaCl, which displaces the DNA[6,7]. The octamer in 2 M NaCl was later characterized by hydrodynamic and other methods[8–10].

While attempting to crystallize the histone octamer we have produced regular fibres at high ionic strength, and have used electron microscopy and the image reconstruction method[11,12] to produce a low resolution three-dimensional density map of the octamer. It has 2-fold symmetry. The nature of the octamer structure suggests its orientation relative to that of the superhelix of DNA in the nucleosome, corresponding with that demonstrated by neutron diffraction studies of nucleosome core particle crystals[13]. We have used the results of Mirzabekov *et al.*[14] on the chemical cross-linking of histones to nucleosome core DNA, and the information on histone–histone proximities given by cross-linking, to assign regions of density in the octamer map to particular histones. This constitutes a proposal for the spatial arrangement of histones in the nucleosome core, from which it can be seen that the $(H3)_2(H4)_2$ tetramer defines the basic fold of the nucleosome DNA and the H2A–H2B dimers continue it.

Preparation and electron microscopy of histone octamer tubes

The histone octamer was prepared from rat liver as described earlier[8], in 2 M NaCl–100 mM Tris Cl, *p*H 7.0, or 2 M NaCl–137 mM sodium borate, *p*H 9.0. When a solution of the octamer is brought to >40% saturation with ammonium sulphate at 4 °C, keeping the NaCl and buffer concentrations constant (final concentration of octamer 2 mg ml^{-1}), a precipiate forms over a period of days that contains all four histones in their original equimolar amounts. Electron micrographs of negatively stained samples of the precipitate fixed with glutaraldehyde show sheaf-like aggregates of a dozen or so hollow tubular structures, of external diameter about 300 Å and several micrometres long. If fixing is omitted, the tubes break down to short lengths, some so short that they lie on the grid end-on to give an annular image (Fig. 1*a* arrow). Specimens more suitable for image analysis may be obtained by adding the stain to the precipitate before applying it to the grid. This dissociates the sheaves but maintains the length of the individual tubes (Fig. 1*b*, *c*). Essentially identical tubes were grown using histone octamer from turkey erythrocytes and beef kidney.

The state of aggregation of the histones in conditions where tubes form was checked by cross-linking with dimethyl suberimidate[6,15] and shown to be octameric, the time course being similar to that described previously for the free octamer in 2 M NaCl[16]; as expected there is also some evidence of octamer–octamer cross-linking. (Because cross-linking of amino groups cannot be carried out in ammonium sulphate, we used instead dipotassium hydrogen phosphate (0.5M)-potassium pyrophosphate (0.615M) which also promotes aggregation into tubes [B. Rushton, J.T.F. & A.K., unpublished results].)

Moreover, comparison of cross-linked dimers at comparable stages of cross-linking shows that the arrangement of histones in the octamer is essentially the same for the octamer in the tubes, the octamer free in solution, and the octamer in the nucleosome; these dimers are those reported previously in the nucleosome[6,7] and H3–H2B. For the tubes, the same dimers are formed at roughly the same relative rates and are present in similar relative amounts, the main differences being consistent with unmasking of a higher proportion of amino groups in H3 and H4 than in H2A and H2B on going from the nucleosome to the octamer in high salt. We therefore believe that extrapolation from the model for the octamer present in the tubes (Fig. 4) to the octameric core of the nucleosome (Fig. 5) is valid.

Image analysis and 3-dimensional reconstruction

The transverse striations, of spacing about 65 Å, across the hollow tubes indicate that they are built from rings of (octamer) units. The annular images are evidently short stacks of rings seen end-on, and sometimes a regular series of protuberances can be seen around the circumference. The number of units per ring cannot be counted unequivocally, but is in the range 10–12. The number can be estimated by viewing the images of the long tubes obliquely from the bottom of the page. At this angle, the units can be seen to lie on long-pitch helices. The number of parallel helices on one side of the tube appears to be five rather than six indicating 10 units per ring. A more reliable estimate is obtained by close inspection of the edge-on views in the long tubes: the succession of superposition patterns seen—and such patterns are not as sensitive to distortions as are quantitative analyses—is characteristic of 10 units per ring. The value 10 was confirmed by the Fourier analysis described below. Another class of tube was occasionally found of slightly larger diameter, containing 11 units per ring, but they were less well ordered than the 10-fold tubes and gave poorer maps.

We have investigated the structure of the octamer tubes by Fourier transform techniques[11,12], using computer programs developed for correlating helical particles[17]. Optical transforms were used initially to select well ordered particles, then the best were processed by computer to give phase information for a quantitative assay of the state of specimen preservation, and again from among these were selected a smaller set of particles which correlated well with one another, after allowance was made for their different orientations. The data from a final set

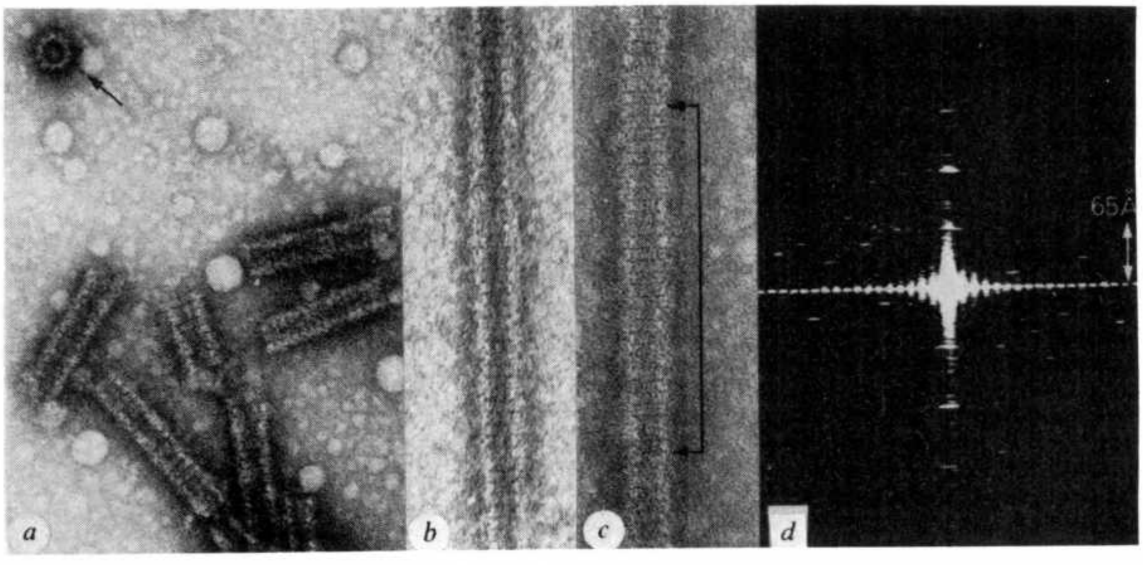

Fig. 1 Electron micrographs of tubes of histone octamers, negatively stained with 0.1% uranyl acetate; in *a*, the stain was applied after the specimen was applied to the grid, and in *b* and *c*, beforehand. Oblique helical lattice lines of pitch about 280 Å can be seen clearly in *b*, in which the contrast of one side of the particle dominates. *d*, Optical diffraction pattern of the length marked in *c*; the first meridional reflection is at an axial spacing of 65 Å. The strong second order of this reflection indicates that the projected density in the rings is roughly divided into two layers, as is evident in the images themselves. Magnifications: *a*, 175,000×; *b*, 236,000×; *c*, 242,000×.

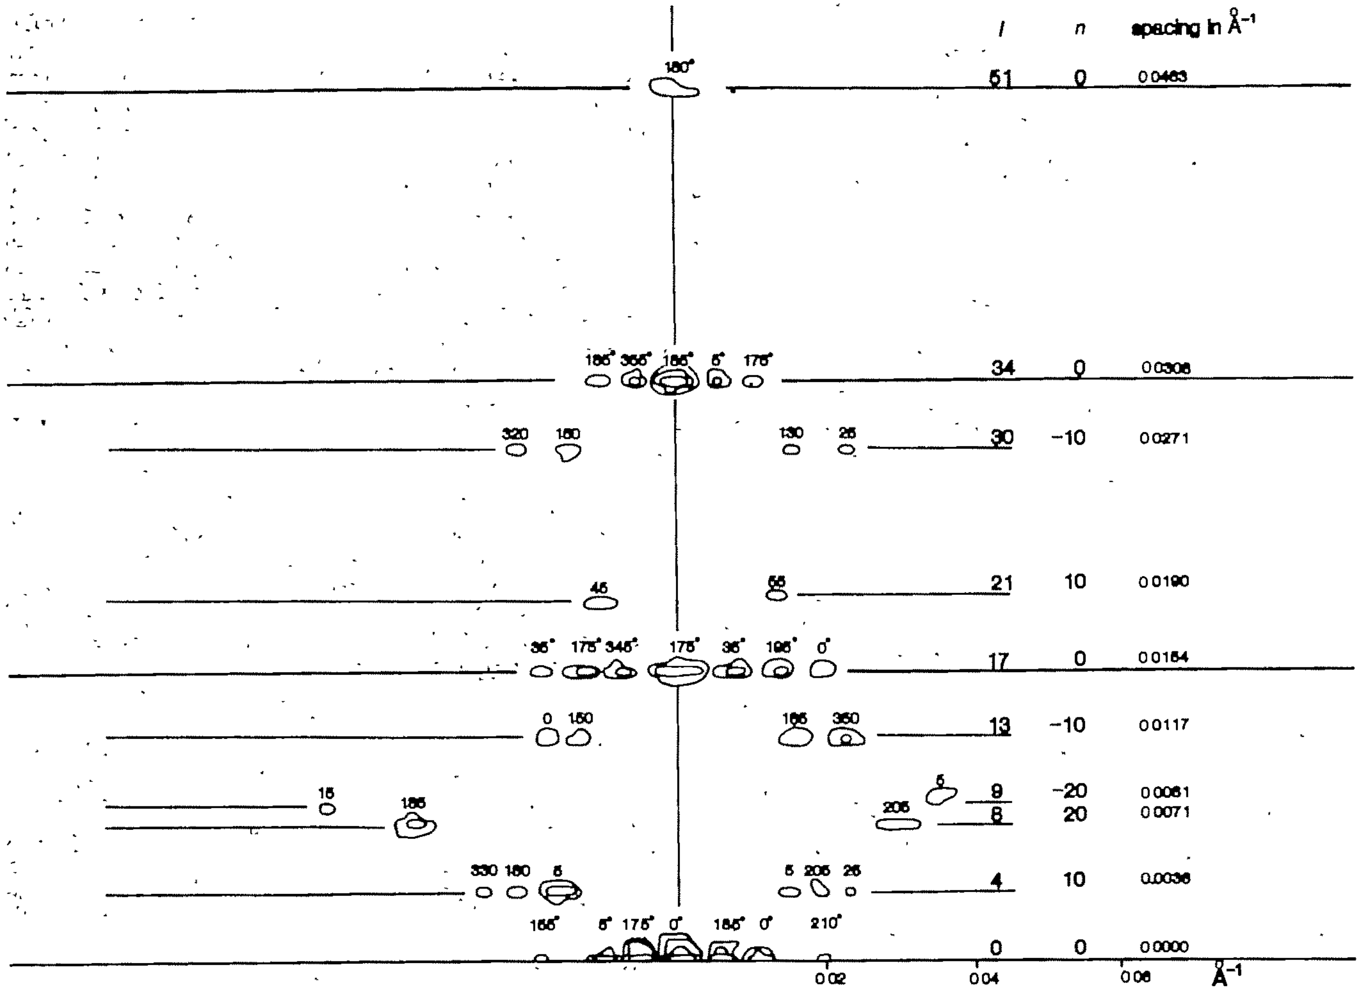

Fig. 2 A map of the amplitudes and phases in the computer Fourier transform of the octamer tube in Fig. 1*c*. The image was densitometered on a raster with a spacing equivalent to about 2.5 Å. The layer lines are marked by an index l corresponding to the simplest rational approximation to the helical repeat. The helical selection rule for the diffraction pattern is $n = 10n'$ where n' is given by $l = 4n' + 17m$; the orders n of the Bessel functions on each layer line are indicated. Because the rotational symmetry is of even order (10-fold), the phases of corresponding peaks on left and right sides should ideally be the same, and the discrepancy between them is a measure of the state of preservation of the specimen. The presence of radial dyads was tested for by searching for the position of putative dyads in the image which make the phases as close as possible to 0° or 180°. The lowest value of the (weighted) residuals found (corresponding to the Q-type of residual (of ref. 17) for the three best particles were individually 41°, 38° and 18°, and 31° for the average, showing that dyads are present. The best particles were found by examining the correlation between the two sides of their transform (near and far sides of the particle) and the correlation between different particles. During this analysis, a radial scale factor is computed to help compensate for variations in magnification and particle shrinkage during drying; most such scale factors varied by less than 10% from the average. When there is no overlap of different helical contributions on the same layer line, as here, each Fourier transform yields two independent data sets, corresponding to the near and far sides of the particles. Separate radial scale factors were used for the two sides to allow for differential shrinkage, the J_0 contributions being omitted for the determination of the scaling factor, but apportioned afterwards, one half to each side.

were combined to calculate Fourier components for a three-dimensional synthesis.

An optical diffraction pattern and computer transform of one of the best tubes are shown in Figs 1*d* and 2 respectively. The axial reflection on a layer line of spacing 65 Å corresponds to the thickness of a ring. Off-meridional intensity occurs on a layer line of spacing about 280 Å, and corresponds to helical lines of pitch 280 Å running obliquely across the particles (Fig. 1*b*). The absolute hand (left) of this helical family, and hence of the whole structure, was found from electron micrographs of shadowed specimens. The relative rotation of successive rings is reflected in the ratio of the spacings of the 280 Å and 65 Å layer lines, which varies between 4.0 and 4.4 for different particles and different regions along the same particle. An average of 4.25 ($=\frac{17}{4}$), corresponding to a rotation of $2\pi/10\times(4/17)$ between successive rings, was adopted as the simplest rational approximation for numbering the layer lines in Fig. 2.

Analysis of the computer transforms of images of the tubes showed that, to the resolution of the micrographs, the histone octamer itself possesses a 2-fold axis of symmetry. Transforms were correlated with each other[17] to bring all the particles into a common registration, to permit data averaging. During this fitting procedure, a phase residual is calculated which gives a measure of how well correlated any two particles are. No significant differences in the residuals were found between the best fits of particles either way up, showing that the tubes were non-polar and so possessed radial dyad axes. The final map (Fig. 3), comprising the average data from three particles, has a nominal resolution of about 20 Å in both axial and radial directions, but all contributions at less than about 30 Å are weak. The three particles chosen were those that correlated best with each other, and also individually showed equally good preservation in their near and far sides.

Description of the structure

The map of the octamer tube reconstructed from the averaged data with imposed 2-fold symmetry is presented in Fig. 3. The rings of the tube are divided into ten distinct units, each presumably representing an octamer; the division between rings is also clear, and thus, except for small boundary regions, the density corresponding to one octamer can be unequivocally dissected from the map. A model of this density is shown in Figs 4*a* and 7*a*: the contour cutoff in constructing the model was

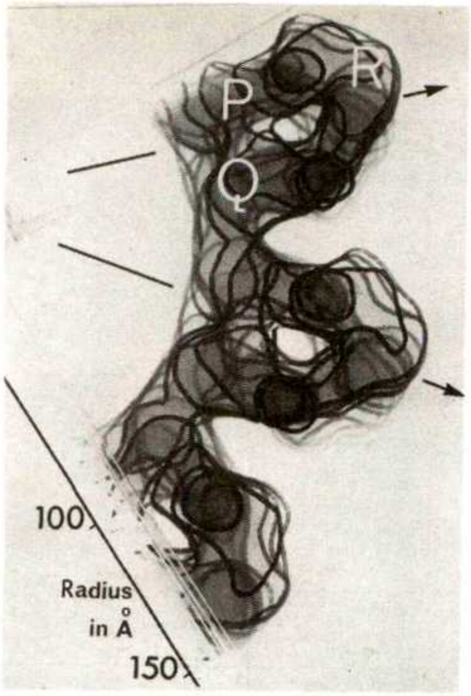

Fig. 3 Three-dimensional reconstruction of the histone octamer tube, plotted as sections through the map. The region shown corresponds to $2\frac{1}{2}$ octamers, that is a 90° sector of the tube of height 65 Å, and is viewed in a direction tilted slightly away from the tube axis. The lowest contour level has been chosen to give the appropriate hydrated molecular volume of the octamer. The dyad axes of symmetry passing through the octamers are marked by arrows.

chosen to give a hydrated molecular volume of 137,000 Å^3, taking $M_r = 110{,}000$ and assuming a density for hydrated protein of 0.8 daltons Å^{-3} (ref.18).

Figure 4*a* shows the wedge-shape appearance of the model, whereas Fig. 7*a* shows that at its broadest aspect the particle has a roughly circular outline of approximate diameter 70 Å. At right angles to this the particle is 56 Å at its thickest point. These are suitable dimensions to form the histone core of a nucleosome core particle of external diameter 110 Å and thickness 55 Å (ref. 19): subtracting the DNA from the outside would leave a cylindrical inner space of about 70×55 Å.

The correspondence goes further. The nucleosome core is a wedge-shaped particle, of bipartite character[19], and the octamer also has a similar wedge shape, split into two and twisted somewhat about its dyad axis. This is best seen in Fig. 3 where the wedge is viewed approximately sideways on. The two ridges at the thick end, marked P and Q, slope up in an opposite direction to the ridge at the thin end, marked R, so that they, together with the ridges on the sides of the wedge, form a rough helical ramp, of pitch about 25 Å, whose course is marked in Fig. 4*b*. The ridges forming the ramp are rather broken up, and there is some variation in individual image reconstructions, but the continuity is not in doubt. The sense of the ramp is left-handed, as expected if the DNA superhelix is to wind around the octamer.

The octamer shape revealed here resembles that found in the density map of the protein moiety of the nucleosome core, produced from a neutron diffraction study of crystals of nucleosome core particles, using the method of contrast variation (Fig. 2*c* of ref.13). That study also gave a map of the DNA, and hence the orientation of the 'wedge' of $1\frac{3}{4}$ turns of DNA[19] relative to the wedge formed by the histone core. This orientation is the same as that shown in Fig. 4*b*. It is thus the octamer that determines the architecture of the nucleosome. The 2-fold symmetry of the DNA superhelix allows it to interact with its octameric histone core along a common twofold axis.

Note that the map identifies the stain-excluding regions, so that the model presumably depicts the hydrophilic surfaces of the particle, which are exposed to the negative stain, and is thus dependent on the way in which the stain actually interacts with (and possibly distorts) the surface of the histone molecules and penetrates the gaps between them. At low resolution, the individual histone molecules are not resolved, yet our map shows protuberances presumably corresponding to exposed portions of the individual molecules making up the oligomer, and channels corresponding to the spaces between them.

Clearly the octamer has fairly large cavities in it accessible to the negative stain. These run irregularly through the structure to a hollow centre, and, together with the overall flat shape, could surely account for the anomalous frictional ratio of about 1.3, found from hydrodynamic observations[8], even without a contribution from any flexible N-terminal tails[20].

When a superhelix (representing the DNA) is wound smoothly at a mean radius of about 45 Å on the helical spool formed by the octamer, as in Fig. 5, it fits snugly at the thick and thin ends of the wedge, but does not hug the sides so well. Although this might be an artefact, it could reflect true disorder arising from flexible N-terminal regions of the histones, which might be lost to view in the stain and would certainly be lost in the averaging procedure. The differential fit may be related to the differential cutting along the DNA of the nucleosome core shown by DNAse I. We noted earlier that the regions of low cutting frequency lie at two diametrically opposite areas, corresponding to the 'sites' −4 and +4 on one side, and −1 and +1 on the other (Fig. 8 of ref. 19). It is likely that this increased protection is associated with tighter contact with the histone core at the two ends of the wedge. Indeed, the distribution of diffuse intensity in X-ray diffraction patterns of the nucleosome core crystals shows that the DNA on these two 'ends' of the nucleosome core is held more rigidly than that at the 'sides' (J.T.F. and A.K., unpublished results). A stiff molecule like DNA wound neatly on to a spool need not have equal contact all along its length; it need only be fixed at a few points and the bending stiffness will do the rest.

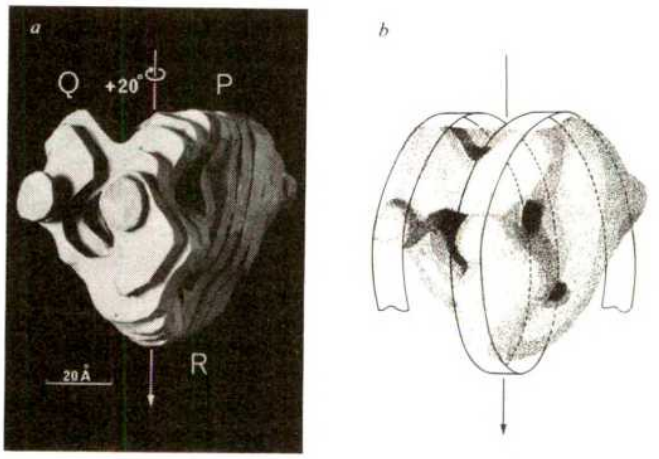

Fig. 4 *a*, Model of histone octamer obtained by cutting out solid sections of the map in Fig. 3. The dyad axis is marked by an arrow, and the view is at an angle of about 20° to that in Fig. 3, as can be seen from the inclination of the sections. *b*, A drawing of *a* showing how the ridges on the periphery of the octamer model form a more or less continuous helical ramp of external diameter about 70 Å and pitch about 27 Å, on which about $1\frac{3}{4}$ turns of a superhelix of DNA of the appropriate dimensions[19] could be wound. In a further reconstruction, not included here, there is a lower density at one of the ends of the ridges P and Q (between the marks $H4^1$ and $H2B^1$ in Fig. 5*a*) but the continuity of the ramp is clear.

Assignment of histones to regions of the map

We have used histone–DNA cross-linking results, which map the sites of interaction of histones relative to the 5′-end of a DNA strand, and information on histone–histone proximities from cross-linking studies, to assign individual histones to particular regions of the density map. Our main assumption is that the histones are too small to be multi-domain proteins, although they could still have flexible N-termini. Others[14,21,22] have suggested three-dimensional arrangements of histones within the nucleosome core, using similar chemical evidence, but an interpretation based on such results alone is ambiguous because neither type of cross-linking study distinguishes between the two copies of each histone present. Our three-dimensional density map restricts the number of possibilities. Thus, for example, the ridge R (Fig. 4*a*) which lies in the region of DNA sites −1 to +1 (Fig. 5*a*) is too narrow to accommodate more than one thickness of a histone molecule, and other models are not compatible with this feature. The proposed arrangement is the only one we can find that both fits the major cross-linking data and is compatible with the shape of the octamer.

Histone–DNA cross-linking

The points of contact of histones along the DNA strands determined by histone–DNA cross-linking studies[14] are not sufficient to fix the spatial arrangement of the histones in the nucleosome core. Using the three-dimensional structure in Fig. 4 we have distinguished between the two copies of each histone as shown in Fig. 5. If the two copies of each histone are designated by superscripts 1 and 2, then the results of Mirzabekov *et al.*[14] may now be written more specifically as shown in Fig. 6. Thus, for example, the H3 that makes contact with the DNA 75 bases from the 5′ end is H3^1, whereas the H3 that lies close to the 3′ end (see also ref. 23) is H3^2.

Note that we do not always assume that the pattern of histone–DNA cross-links observed by Mirzabekov *et al.*[14] directly reflects the linear order of histones along the DNA. Even if the major contact of a histone is with a particular DNA segment, it is entirely possible (because the distance between the two superhelical turns is only about 28 Å, that is, roughly the dimensions of a histone molecule) that a histone may also make a less frequent, or minor, contact with the turn of DNA above or below it. Thus, to reconcile our model with the finding[14] of a contact between H2A and the DNA 75 bases from the 5′-end (between sites 0 and 1 in Fig. 5), we have assigned this contact to H2A^1, which also lies close to the DNA turn above, near the segment 0–20 bases from the end (sites −7 and −6). No histone–DNA cross-link corresponding to this contact is observed[14], but an H2A molecule is required there by symmetry, because of the contact at 135 base pairs (between sites 6 and 7); the absence of a cross-link need not be significant and might arise through lack of suitably disposed lysine side chains in the region of contact.

Recently[24] Mirzabekov and his colleagues have refined their results and have assigned particular histone–DNA contacts to individual DNA strands. However, the weak spots on gels identified in that work need not arise from oscillations of linkages between strands as suggested and can be accommodated into our spatial arrangement with the reasonable assumption that a particular histone can cross-link to either one of the neighbouring DNA strands of the double helix. We attempt here only to associate a histone with a particular region of the DNA double helix, without regard to strand.

If the DNA superhelix in the model (Fig. 5) were unfolded, the linear arrangement of the histones along the DNA would be:

$$\mathrm{H2A^1{-}H2B^1{-}H4^1{-}H3^1{-}H3^2{-}H4^2{-}H2B^2{-}H2A^2}$$
$$(\text{site } -7 \rightarrow \text{site } +7)$$

This might seem to be at odds with the contacts broken when the nucleosome unfolds at low ionic strength, or in urea or urea/2M NaCl[25-27]. However, in the first case [25], although two particular residues (Cys 110 in the C-terminal region of the H3s) move apart, the basic N-terminal regions of the proteins may not behave in the same way; and in the other cases[26,27], loss of particular cross-links generated by 'zero-length reagents' could result from only small local perturbations, because these reagents require very precise contacts and juxtapositions for cross-linking.

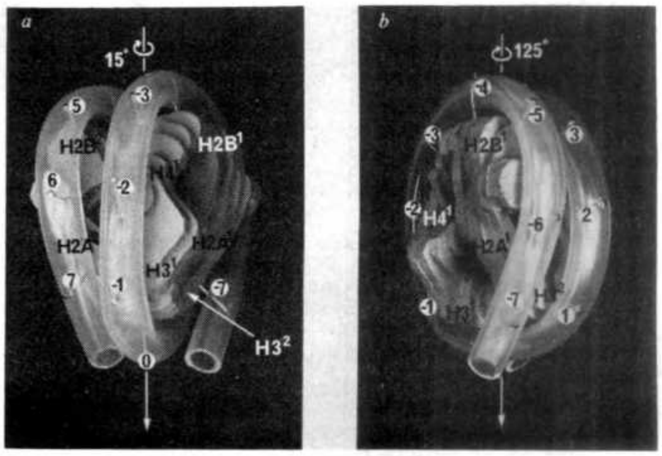

Fig. 5 *a*, The histone octamer structure with two turns of a DNA superhelix wound on it. The assignment of the individual histones to various parts or features of the model is described in the text. (For clarity the DNA double helix is represented by a plastic tube of somewhat smaller diameter than it would actually have.) Distances along the DNA are indicated by numbers −7 to +7 (taking the dyad axis as origin), to mark the 14 repeats of the double helix contained in the 146 base pairs of DNA of the nucleosome core. The positions of the numbers correspond approximately to the sites of attack, that is local maxima in the frequency of cutting by the enzyme DNase I (compare with Fig. 8*b* of ref. 19). The superscripts in the numbering of the histone molecules follows the direction of ordering of the DNA sites, so that the helical ramp of the octamer is formed by the histones in the order H2A^1–H2B^1–H4^1–H3^1–H3^2–H4^2–H2B^2–H2A^2. *b*, Another view of *a*, rotated further by 110°; the direction of view is similar to that in Fig. 7*a*.

Histone–histone cross-linking

Cross-linking of histones indicates proximities between them with limits defined by the lengths of the reagent used and the nature of the residues cross-linked, for example, a cross-link formed with dimethyl suberimidate indicates that ε-amino groups of two lysine residues (each amino group being about 7 Å from the protein backbone) are within about 12 Å of each other. If two histones can be cross-linked with zero-length reagents they must be in contact. Again, the cross-linking results do not distinguish between the two copies of each histone, but in the model in Fig. 5 this distinction is made.

Five cross-linked histone dimers were originally emphasized (together with histone–DNA cross-linking results) in making the histone assignment in Fig. 5, as follows. With dimethyl suberimidate the cross-linked dimers $(\mathrm{H3})_2$, H3–H4, H2A–H2B, H4–H2A and H4–H2B were found[6,7]. Of these, $(\mathrm{H3})_2$ is also formed by mild oxidation[28] showing that the single cysteine —SH groups of the two H3 molecules in the chicken erythrocyte nucleosome are close enough to permit oxidation to the disulphide[53]. H3–H4, H2A–H2B and H4–H2B are cross-linked with zero-length reagents[29-31]; and $(\mathrm{H3})_2$, H3–H4 and H2A–H2B with a short cross-linker (methyl acetimidate)[32]. The four dimers $(\mathrm{H3})_2$, H3–H4, H2A–H2B and H4–H2B formed with both long and short reagents of very different specificities and requirements must reflect major histone–histone interactions: these are clearly accommodated in Fig. 5. The pairs H3/H4, H2A/H2B and H4/H2B were also found to interact strongly in solution by physical studies[33]. The fifth cross-linked dimer, H4–H2A, produced in roughly the same yield as H4–H2B with dimethyl suberimidate[6], and also found in a later study with a different reagent of similar length[34], is also accommodated in Fig. 5.

Figure 5 places the two H3s in contact and represents a strong interaction about the dyad axis as already proposed[25,28,35,36]. The two H2As are placed on opposite faces and on opposite sides of the wedge-shaped particle; the two H2Bs are also on opposite faces but at the same end of the wedge. H2A and H2B are thus placed as heterodimers, H2A–H2B, consistent with the identical rates of cross-linking of H2A and H2B in chromatin[6]. Our assignment brings H2A and H2B into juxtaposition along, rather than across, the helical ramp, and so accommodates the

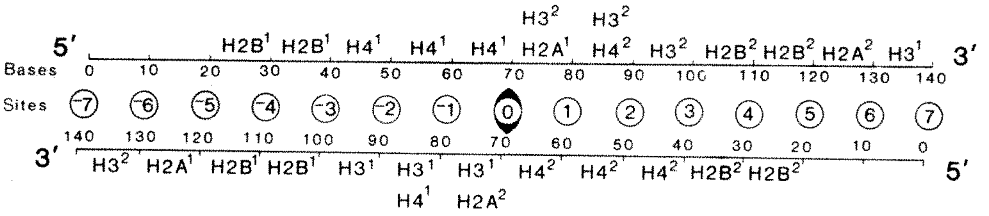

Fig. 6 Assignment of DNA–histone cross-links to individual histone molecules. The diagram is adapted from Fig. 4 of Mirzabekov *et al.*[14] whose results show which histone type can be cross-linked to which location on the DNA, but which cannot distinguish between the two copies of each histone type. Based on the models of the octamer and nucleosome core particles (Figs 4 and 5), we have assigned superscripts 1 and 2 to the pattern of Mirzabekov *et al.*[14] to distinguish the two copies. Note that the action of the overall dyad of the nucleosome is to turn one DNA strand into the other, and to interchange the superscripts on the histones. We have kept the same number in bases along a DNA strand as that used by Mirzabekov *et al.*, although these should be increased by 4% (ref. 66). The diagram incorporates the average stagger of two bases found for the DNAse I cutting sites on the opposite strands of the DNA[67,68].

finding that on UV irradiation H2A and H2B are linked to each other through a short piece of DNA[37]. The two H4s, which interact with the two H3s, but weakly, if at all, with each other (see also below), are placed along the sides of the wedge-shaped particle because they interact with both H2A and H2B. An important cross-linked product accounted for by Fig. 5 is the trimer H2A–H2B–H4 generated by successive treatments of chromatin with UV light and tetranitromethane[38].

Note that, in the histone arrangement proposed, where the linear order is H2A–H2B–H4–H3–H3–H4–H2B–H2A (Fig. 5), the four major dimers $(H3)_2$, H3–H4, H4–H2B and H2B–H2A, are all neighbours along the helical ramp. This would be expected from a bifunctional lysine reagent which would have a high probability of cross-linking lysines abundant on a protein surface. As the major function of the lysines of the histone core is to bind the DNA, we would expect them to be particularly abundant in the surface regions where the DNA is bound. The dimers that appear on cross-linking will therefore, as it were, mark out the path of the DNA.

Our assignments accommodate the five major cross-linked dimers referred to above. We now discuss other dimers that have been found (with the longer reagents, 12–15 Å span). Dimers found in reasonable yields are H3–H2B (refs 22, 34, 39, and J. O. T., unpublished results), H3–H2A[39], and $(H2A)_2$ and $(H2B)_2$[22]. Although H3–H2A is clearly consistent with Fig. 5, the others are less obviously so. However, the histone shapes are not known, and the H3–H2B dimer can be accommodated if the $H2B^1$ and $H3^1$ molecules are elongated to meet each other near the centre of the particle face (see Fig. 5). Likewise H2B molecules of sufficient width could account for an $(H2B)_2$ dimer; and $(H2A)_2$ dimers could arise by cross-linking with long reagents across the central cavities.

In addition to the nine cross-linked dimers discussed above, $(H4)_2$ is also possible in principle, and has been found as 1% of the total dimers generated by formaldehyde[40]. (However, all ten possible dimers are produced with this reagent, and the nature of the cross-linking species is unclear [formaldehyde itself is not bifunctional].) Although $(H4)_2$ does not seem to represent a major contact, it can be accommodated in the model in Fig. 5 if the H4s are elongated (extended into the 'no-man's land' in Fig. 7*b*; see below), or it might arise by transient contacts generated as the structure 'breathes'.

Relation of H1 to the other histones in the nucleosome

Electron microscopy[41], DNase I digestion[42] and UV cross-linking[37] suggest that in the nucleosome H1 'seals' a two-turn 166-base pair[19] nucleosome core by binding to the DNA where it enters and leaves the nucleosome. Consistent with this, Mirzabekov and his colleagues[43] observe strong cross-linking of H1 to 175-base pair DNA over a stretch close to the ends.

By extrapolation from the 146-base pair structure to a complete two-turn particle as in Fig. 5, H1 would bind to the DNA near the $(H3)_2$ dimer region. This location would explain the H1–H3 cross-link reported in nuclei and chromatin[44] (in fact two H3s per H1 are suggested) and also, as H1 is extended, at least in solution[2,45], the H1–H2A cross-link found in mononucleosomes (refs 46, 47, and J.O.T., unpublished results). The extended shape of H1 is also invoked[43] to explain the cross-linking of H1 at intervals along almost the whole length of the DNA in the 175-base pair nucleosome as well as the major interaction at the ends, but it is not easy to imagine the nature of such binding.

Dissection of the octamer into the $(H3)_2(H4)_2$ tetramer and H2A–H2B dimers

The histones assigned as above fall naturally into an arginine-rich tetramer and two lysine-rich dimers, and thus accord with the mode of disproportionation of the free octamer in solution[6,7,9,10], that is:

$$\text{H2A H2B.(H3)}_2\text{(H4)}_2\text{.H2A H2B} \rightleftharpoons$$

$$\text{H2A H2B.(H3)}_2\text{(H4)}_2 + \text{H2A H2B} \rightleftharpoons$$

$$\text{(H3)}_2\text{(H4)}_2 + 2 \times \text{H2A H} \times 2\text{B}$$

The finding of an intermediate hexamer shows that the two H2A–H2B heterodimers can dissociate independently, consistent with their location on opposite faces of our model of the core particle (compare with ref. 48).

If these two heterodimers are removed from the octamer model in Fig. 7*a* the remaining $(H3)_2(H4)_2$ tetramer is revealed as a 'distorted horseshoe' (one H4 being above the plane of the other) or, if the H4s meet, as a 'dislocated disk', the uncertainty being reflected in the no-man's land in Fig. 7*b*. The highly asymmetric shape of the tetramer, if it persists in solution, might explain its anomalously low sedimentation coefficient ($s^{\circ}_{20,w}$ = 2.81S) and resulting high frictional ratio ($f/f_0 = 1.63$)[49]. Others have attributed the slow sedimentation to freely mobile N-terminal regions extending from a more compact globular core[50], and a contribution from such effects cannot be ruled out.

In the dislocated horseshoe model (Fig. 7*b*) the two H4 molecules do not touch, and indeed no $(H4)_2$ is observed on cross-linking the free octamer (J. O. T., unpublished results) or the nucleosome core, except for a few per cent in one study with formaldehyde (see above). However, the $(H3)_2(H4)_2$ tetramer free in solution, on treatment with dimethyl suberimidate, does give some cross-linked $(H4)_2$, in about the same amount as $(H3)_2$ (H3–H4 being the major cross-linked dimer)[2]. This could be due to 'contraction' of the tetramer when the DNA is removed and/or increased possibilities for cross-linking of H4 to itself (and to H3) in the absence of the lysine-rich histones H2A and H2B. As already noted, we do not know where the histone boundaries lie, but probably H4 is elongated since it interacts with the DNA in the nucleosome at three sites about 10 bases apart[14] (see Fig. 6). Whatever the details, the tetramer emerges as a disk-shaped object of approximate thickness 27 Å, consistent with spacings observed in electron micrographs and X-ray patterns of fibres made of H3/H4 histones[51].

The central role of the arginine-rich histone tetramer in the nucleosome

There is now much evidence supporting the proposal of Kornberg[5] that the arginine-rich tetramer $(H3)_2(H4)_2$ is critical in forming the nucleosome. As first shown by Felsenfeld and co-workers[52], and subsequently by others[53–58], H3 and H4, without H2A and H2B, can confer nucleosome-like properties on DNA when assessed by various criteria. These properties were assumed to arise from one tetramer combined with a nucleosome core length of DNA. However, it was subsequently found that H3 and H4 alone can form both tetrameric and octameric complexes with DNA[59,60] and therefore this interpretation has had to be re-examined. Although it has now been shown[61] that tetramers alone, like octamers, can generate folded complexes about the size of nucleosomes, with long DNA, they do not confer complete resistance of 140 base pairs to nuclease digestion[60], and the question of just how much a tetramer contributes to the supercoiling of the DNA is not yet settled[36,53,55,56].

The structure deduced for the tetramer in Fig. 7*b* and its location with respect to the DNA (Fig. 5*b*) explains some of the properties it confers on the DNA in the absence of H2A and H2B. The tetramer spans the diameter of the nucleosome and can be regarded as 'measuring out' the DNA in a turn, agreeing with our earlier suggestion[19]. (In the interaction of the tetramer with the central region of the DNA in a nucleosome, the structure resembles 'model 2' of ref. 52 [their Fig. 13].)

Thus a disk-shaped tetramer (Fig. 7*b*) would be expected to protect the 80 base pairs of DNA in the central turn of the nucleosome from attack by nucleases. This is consistent with the results of Stockley and Thomas[60] who showed that digestion of long chromatin that had been stripped of all histones except H3 and H4 resulted in two classes of nucleoprotein complexes containing protected DNA; one class contained single H3/H4 tetramers associated with DNA about 70 base pairs long, the other containing an octamer of H3 and H4 and about 140 base pairs of DNA. This explained why micrococcal nuclease limit digests of reconstitutes prepared at an H3/H4 : DNA weight ratio of 0.5 : 1 showed a strong pattern of bands up to about 70–80 base pairs, but only weak or fleeting protection between 80 and 140 base pairs[52], as at this histone : DNA ratio the nucleoprotein complexes were mainly tetrameric, with only a little octamer[59]. Moreover, the proposed interaction of the tetramer with a turn of DNA would probably mean that a single tetramer alone could induce a degree of supercoiling in relaxed, closed circular DNA, although an octamer of H3 and H4 may be necessary to develop the full number of superhelical turns characteristic of true nucleosomes containing all four histones[62].

In our model, the tetramer constrains the central 80 base pairs of DNA into one physical superhelical turn, but it can presumably also bind loosely the two additional half-turns in nucleosome-length DNA, because compact tetrameric complexes of nucleosome size and containing about 145 base pairs are formed when $(H3)_2(H4)_2$ tetramers are reconstituted on to SV40 DNA at low histone : DNA ratios[61], these complexes being less dense than their octameric counterparts. Such folded tetrameric complexes may also be intermediates in reconstitution experiments with 140-base pair DNA, in which 'primed' complexes of H3, H4 and DNA bind H2A and H2B at low ionic strength to regenerate nucleosome cores[36,48,52,53,63].

The central role of the $(H3)_2(H4)_2$ tetramer in nucleosome structure as it emerges from this study is to organize the DNA into the central turn of a 'primary particle'. In nucleosome assembly H2A and H2B could then add to this intermediate as two heterodimers, stabilizing it by binding firmly the two extra half-turns of DNA previously bound loosely in the H3/H4–DNA complex, thereby completing the 166-base pair nucleosome core. H1 would then bind to the core to seal the two turns, and also provide a binding site for an adjacent length of linker DNA. The nucleosome would thus be complete. Such a sequence of events would provide a physical rationale for the temporal order of assembly of histones on to newly replicated DNA[64,65].

We thank Dr L. Amos for help and Drs A. D. Mirzabekov and C. W. Carter for sending us preprints of their papers (refs 22, 24 and 43). J. O. T. acknowledges the support of the SRC.

Received 5 May; accepted 15 August 1980.

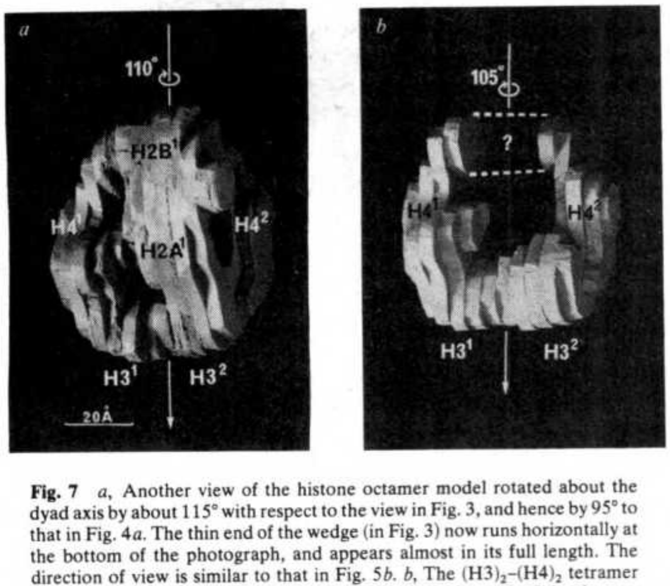

Fig. 7 *a*, Another view of the histone octamer model rotated about the dyad axis by about 115° with respect to the view in Fig. 3, and hence by 95° to that in Fig. 4*a*. The thin end of the wedge (in Fig. 3) now runs horizontally at the bottom of the photograph, and appears almost in its full length. The direction of view is similar to that in Fig. 5*b*. *b*, The $(H3)_2$–$(H4)_2$ tetramer dissected out of the octamer model, the view being about 5° off that in *a*, to show the shape in its broadest aspect. The boundaries between the tetramer and the two dimers of H2A–H2B removed from the front and back of it have been chosen at the regions of slenderest connection so as to give approximately the appropriate volumes. The region marked ? is a no-man's land which cannot be assigned unambiguously to one or other of the H4 and H2B molecules which border it. The tetramer has the shape of a distorted horseshoe or dislocated disk, so that its periphery constitutes about one turn, or somewhat less, of a flat left-handed helix. The stretch of DNA associated with it runs from about sites −4 to +4. The hole in the middle may be exaggerated by the staining (see text).

High time-resolution photometry of the proposed optical counterpart (Star 30)[1] of the X-ray source[2] 2S1254 – 690 is reported here. An event of high statistical significance was observed from the star that has all the temporal characteristics of an X-ray burst (see, for example, ref. 3). 2S1254 – 690 has not previously been identified as an X-ray burst source, but its optical counterpart shows properties in common with this class of objects. We also derive the X-ray spectrum of 2S1254 – 690 using data obtained with the HEAO 1 satellite. The spectrum can be fit in the energy range 0.18–30 keV by a power law of photon index –2.5, modified by interstellar absorption.

2S1254 – 690 Star 30 was observed with the 4-m telescope at CTIO as part of a systematic survey of the photometric properties of X-ray source counterparts. The star was observed in white light with a cooled EMI 9658 R photomultiplier tube with an S 20 photocathode (red extended by prismatic reflection). Data were taken with a 5-arc s diameter aperture and at a time resolution of 10 ms. The observation lasted ~45 min and began at 23.50 UT on 24 June 1979. A total count rate of ~2,400 counts per s (c.p.s.) was recorded on the star, of which ~1,700 c.p.s. were due to the sky background.

At approximately 00.10 UT on 25 June, the total count rate from star plus sky was observed to increase rapidly to ~3,200 c.p.s. on the real time monitor in the 4-m telescope control room. This represents an increase of a factor of two in the stellar count rate. A visual check of the TV guider confirmed that the equipment continued to function normally and the sky conditions were stable. The data collected during this time are plotted in Fig. 1 accumulated in intervals of 0.2 s. The event observed is remarkably similar to the X-ray bursts identified in several galactic sources. It has a rise-time of ~1.7 s and then decays more slowly, having a total duration of ~20 s. The data are consistent with a morphology that has either a relatively flat maximum, or alternatively a second peak in flux that occurs about 5 s after onset. Again, such a multiply peaked, or flat-topped, structure has been observed in X-ray bursts[3]. No other event of this kind was observed during the remainder of the observation of 2S1254 – 690.

Because of the marked similarity in structure between the optical burst we have detected from 2S1254 – 690 Star 30 and X-ray bursts, we believe that we probably observed the optical counterpart of such an X-ray burst from 2S1254 – 690. Optical bursts of lesser statistical quality have been reported from three burst sources, MXB1735 – 44 (ref. 4), MXB1837 + 05 (ref. 5) and MXB1636 – 53 (ref. 6) coincident with X-ray bursts. The observation of burst-like behaviour from 2S1254 – 690 Star 30 is consistent with its identification as the optical counterpart of the X-ray source. No X-ray bursts have been reported from 2S1254 – 690 thus far, and this means that it is the first bursting source to be catalogued in the optical region of the spectrum. However, we note that 2S1254 – 690 does lie within the 12° radius error circle of an X-ray burst observed by Apparao with the SAS-3 rotation modulation collimator, whose position was reported by Lewin and Clark[3].

We have searched for evidence of periodic modulation in the light from 2S1254 – 690 Star 30 by constructing Fourier transforms of the data. No spike due to periodic modulation above the 1.2% pulsed fraction level was observed from 0.02 to 50 Hz in a power spectrum constructed from the entire data-set.

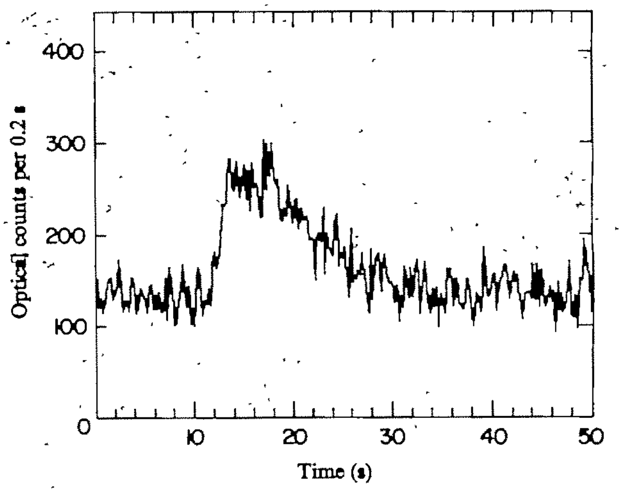

Fig. 1 Time series obtained in white light on the CTIO 4-m telescope in the vicinity of the burst-like event observed from 2S1254–690 Star 30. Data are accumulated in 0.2-s intervals and time is measured on the abscissa in seconds from 25 June 00. 08. 43 UT. The ordinate shows the excess count per 0.2-s bin above sky background registered on the star.

0028–0836/80/410516—03$01.00

Table 1 HEAO 1 0.18–20 keV spectral fits for 2S1254 – 690

Spectral model	α/kT	$\log(N_H)$	Line Energy	 EW	 FWHM	χ^2 min	D.f.
Power law	2.38	21.44	—	—	—	132	71
Exponential + gaunt factor	—	—	—	—	—	363	71
Black body	—	—	—	—	—	~1,000	71
Power law + narrow line	2.46	21.48	6.4	0.4	—	99	69
Power law + broad line	2.47	21.51	6.5	0.6	1.6	92	68

However, when data only from the immediate vicinity of the burst are considered, a peak is found at a frequency of 36.40 Hz that is 12.6 times the average power at neighbouring frequencies. The *a priori* probability that any bin in our 4,000-point transform would have this much power as a result of a random statistical fluctuation is 1%, so that the peak at 36.40 Hz is statistically an unusual event. The periodicity is present in the 20 s of data taken during the burst and also in a data-set that includes the 7-s interval preceding the burst and the 13-s interval following it. The mean pulsed fraction is ~5% of the mean count-rate from the star.

The pulsation is too weak to enable us to determine its properties more precisely although if the effect is confirmed, the implied size of the optical emission is only ≤0.3 light s. Experimenters using the A1 experiment on the HEAO 1 satellite have reported an 83-Hz periodicity in one X-ray burst from MXB1728 – 337 (Sadeh and Wood, personal communication). The period of the pulsation, which was detected both before and during the burst, changed by a significant amount during the time it was observed, and was not seen in three other bursts observed from the same source. High time-resolution observations of bursts to investigate the nature of these pulsations clearly deserve more attention.

The known optical characteristics of 2S1254 – 690 Star 30 are summarized elsewhere[1]. The star ($V = 19.1$) has a UV excess, and may exhibit line emission at λ 4,640 Å corresponding to the C III–N III blend often seen in X-ray sources. These properties are similar to those of several galactic X-ray source counterparts, including several bursters.

We have investigated the X-ray properties of 2S1254 – 690 using scanning data taken with the proportional counters of the A2 experiment[7] on HEAO 1 in August 1977, February 1978 and August 1978. The source was visible for periods of 2.5, 5.0 and 5.0 days respectively on these occasions. The overall flux of 2S1254 – 690 was constant throughout to within ~15% on time scales of ~1 h. The sensitivity of the experiment to short time-scale bursts is, however, low because the source is within the largest field of view of the instrument (6° FWHM) for at most one minute every ~30-min satellite rotation period.

To investigate the X-ray spectral properties of 2S1254 – 690, we have examined the pulse height analyser data taken with the low, medium and high energy detectors (LED, MED and HED respectively) of the A2 experiment. These data have been modelled in turn with power-law, exponential plus gaunt factor and black-body models, allowing for absorption in the interstellar medium in each case using the elemental absorption cross-sections given by Brown and Gould[8].

The results of fitting these models to the combined data from the LED (0.18–2.5 keV) and MED (2.0–20 keV) detectors, which together provide data in 75 energy channels, are summarized in Table 1. The relative normalization of the spectrum in the two detectors is a free parameter in the fits in order to allow for small uncertainties in their relative effective area. Of the three simple models tried, only a power law gave a reasonable fit to the data (minimum χ^2 of 132 for 71 d.f.). This is true also when the MED and HED (2–60 keV) data are analysed separately. The quality of the power law fit was further improved by the addition of an emission line at ~6.5 keV. For the combined LED and MED data, a model that included a narrow line resulted in a minimum χ^2 of 99 for 69 d.f., while the best fit for a power law plus a broad line gave a minimum χ^2 of 92 for 68 d.f. The line had a best-fit energy of 6.5±0.5 keV, an equivalent width of 0.6±0.1 keV, and a FWHM of 1.6±0.5 keV. It may be fluorescent iron line emission similar to that found in some pulsating X-ray sources (see for example ref. 9). The allowed range of power law slope is expressed in Fig. 2 as a function of low energy absorption column density. Figure 2 also shows the best-fit spectral model, which has a photon spectral index of $\alpha = -2.47$ (energy index -1.47) and a column density, N_H, of 3.2×10^{21} equivalent H atoms cm^{-2}.

The HEAO 1 spectral measurements of 2S1254 – 690 are consistent with the work of Jones[10] on this source. The spectrum is similar in overall slope to the X-ray spectra of most burst sources that have been studied[11] (an exception is the burster 2S1916 – 053 which has a hard spectrum[12]). The form of the spectrum, however, a power law, is notable. The HEAO 1 data show that a power law representation of the spectrum of 2S1254 – 690 is clearly preferred over simple exponential or black-body models in the energy range 0.18–20 keV (Table 1). Furthermore, data from the 2–60-keV HED detectors of the A2 experiment confirm that the power law measured from the LED

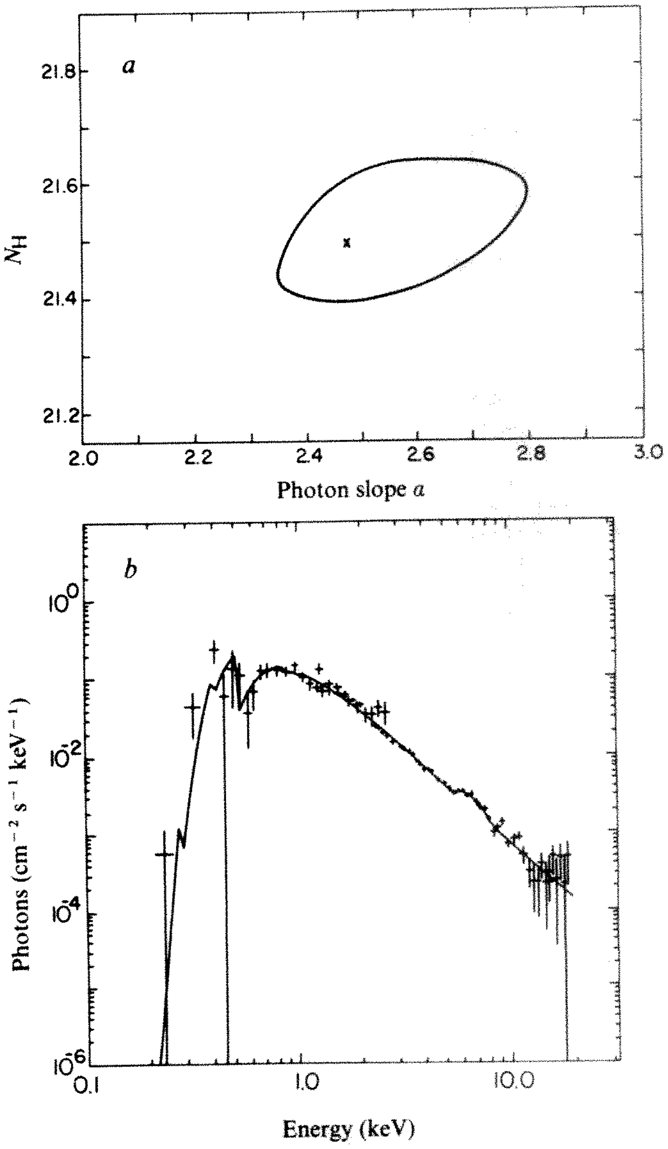

Fig. 2 The 0.18–20-keV spectrum of 2S1254 – 690 derived from data obtained with the HEAO 1 A2 experiment. *a*, Allowed range of photon index and absorption column density for a power law model plus a broad line. The solid line encloses the 90% confidence region. *b*, Best-fit photon spectrum shown relative to the corrected MED and LED data.

and MED data adequately describes the spectrum of 2S1254−690 up to an energy of at least 30 keV. In general, the incidence of power law spectra among the 'population II' X-ray sources that have been studied to date is low (see, for example, refs 13, 14). One X-ray source whose 2–12-keV spectrum sometimes has a power law distribution is 4U0614+09, which is also suspected of being a burster[15]. 4U0614+09 was observed on two occasions by the collimated proportional counter[16] on Ariel V. During the first observation which lasted ~2 days the source was relatively steady, varying by less than 10% on a time scale of ~100 min. The integrated 2–12-keV count spectrum from this observation has been modelled by one of us (K.O.M., unpublished). A power law spectrum, although not statistically acceptable (due in part to systematic uncertainties in the detector response at low energies and in part to a probable excess near ~6.5 keV), yields a minimum χ^2 value which is a factor of three below that obtained by fitting an exponential plus gaunt factor shape. The best-fit power law photon index was $\alpha = -2.6$, close to that found for 2S1254−690. During the second Ariel V observation[16] of 4U0614+09, the source was more active and showed variations in intensity by up to a factor of two. The OSO 8 satellite detected a burst from the vicinity of 4U0614+09 during the same period[15]. The variation in the strength and spectrum of the source precluded addition of data from more than one orbit, but on an orbit by orbit basis, exponential+gaunt factor spectra provided consistently better fits to the Ariel V data than a power law, in contrast to the first observation (see also ref. 14).

Thus we have evidence that at least one optical burst source, 2S1254−690, and a suspected X-ray burst source, 4U0614+09, occasionally emit power law X-ray spectra. Power law X-ray spectra are usually associated with non-thermal mechanisms (for instance, synchrotron radiation) or inverse compton radiation from a hot relativistic accretion disk[17]. If X-ray bursters are accreting neutron stars, this goes against naive expectations that X-ray emission from such stars should be essentially thermal in shape[18–20]. However, it is also possible that a suitable combination of thermal spectra of different temperatures might simulate a power law distribution over a limited energy range. The detailed observation and classification of X-ray source spectra could be a useful way to investigate the nature of these objects, but a better theoretical understanding of emission from compact stars[21] is probably required before such studies can be used to constrain the physical processes occurring there.

K. O. M. and J. M. were visiting astronomers at the Cerro Tololo Interamerican Observatory. We acknowledge support from the Miller Institute for Basic Research, NASA grant NAGW-44 and NSF grant AST78-06873 (K.O.M.) and the US Department of Energy (J. M. and J. E. N.) We thank Dr Kent Wood for discussing the HEAO-1 A1 data on MXB 1728-337, and Drs W. H. G. Lewin and L. Cominsky for discussing SAS 3 burst data.

The 3.4-μm interstellar absorption feature

D. T. Wickramasinghe

Royal Observatory, Edinburgh EH9 3HJ, UK

D. A. Allen

Anglo-Australian Observatory, Epping, Australia

Estimation of the organic component of interstellar grains has provoked considerable interest[1,2]. Recently Duley and Williams[2] concluded from an absence of the 3.4-μm CH absorption band in obscured IR sources that organic compounds in grains account for ≤10% of carbon in the interstellar medium. We report here the detection of a 3.4-μm absorption feature in three IR sources and hence argue that an appreciable mass fraction of interstellar grains are predominantly organic in character.

The presence of a possible absorption feature in the wavelength region 3.3–3.5 μm in the published spectra of some highly obscured IR sources was considered by Hoyle and Wickramasinghe[3] to be evidence for the ~3.4-μm stretching vibration band of CH, which is characteristic of most organic molecules. In most cases for which data have been available the 3.4-μm feature is seen in the wing of a broad, strong water-ice band centred at 3.1 μm. Although the difficulty of matching the extended red wing of the 3.1-μm feature by water ice alone has been noted[4], the presence of CH absorption has not been established. In deriving their limit, Duley and Williams[2] used an uncertain upper limit of optical depth $\tau(3.4) \leq 0.05$ for a visual extinction $A_V = 70$ mag which they estimated to be consistent with current astronomical data. We now discuss observations of five IR sources having $10 < A_V < 35$ which lack the 3.1-μm ice absorption band and determine or place strong limits on the strength of the 3.4 μm CH absorption feature.

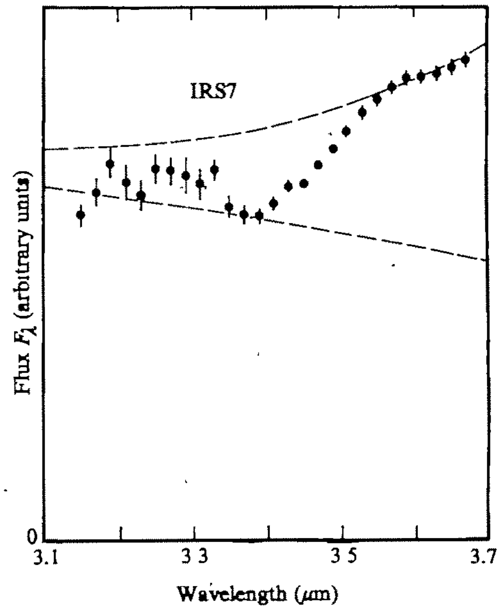

Fig. 1 Spectrum of the galactic centre source IRS7 showing the 3.4-μm absorption band. The upper and lower curves are discussed in the text.

The observations were made in February and April 1980 with the 3.9-m Anglo-Australian Telescope and the IR photometer-spectrometer. The IR sources, all optically invisible, include two in the galactic centre region[5], two in the Coalsack[6], and one recently discovered by Jones and Caswell (personal communication) coincident with an OH source at the 1950 coordinates 17 h 46 min 12.5 s, −27° 41′ 03″. For all sources we acquired photometry at 1.25, 1.65 and 2.2 μm, and spectra with $\lambda/\Delta\lambda \sim 50$ in the wavelength regions 2.0–2.5 and 3.1–3.7 μm. Stellar spectral types were derived from our shorter wavelength spectra, and these were combined with the photometry to derive values of A_V, using the interstellar extinction data of Jones and Hyland[7]. The latter data partly parallel other published values, and the agreement is good except that for the galactic centre sources we find somewhat earlier spectral types (and hence larger extinction) than Neugebauer *et al.*[8]. The longer wavelength spectra were searched for absorption near 3.4 μm. Table 1 details the results. The 3.1–3.7 μm spectrum of IRS 11 has a low signal-to-noise ratio. The limit $\tau(3.4)/A_V \leq 0.004$ for the Ophiuchus dark cloud[9] may be added to the data of Table 1.

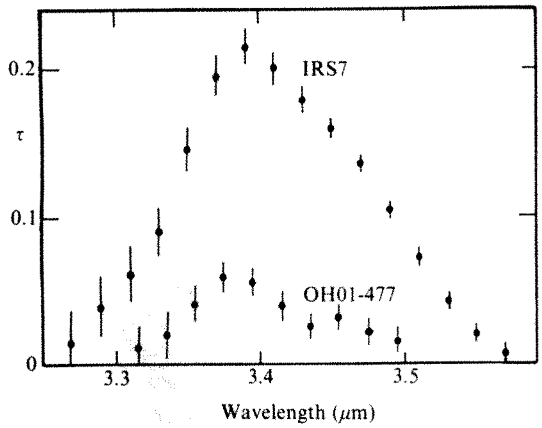

Fig. 2 Band profiles in IRS7 and OH01 − 477. The optical depth τ is calculated as described in text.

Figure 1 shows the 3.4-μm absorption feature in the source IRS7. The lower continuum in Fig. 1 is the expected flux for the M4 supergiant extrapolated from our 2-μm data with the Jones and Hyland reddening law assuming $A_V = 34$ mag. The observed excess is clearly due to circumstellar dust. We estimate the excess in this wavelength region to correspond to a reddened 300 K black body on the basis of the spectrophotometry data of Willner *et al.*[11]. The resulting continuum fitted at 3.6 μm is shown as the upper curve in Fig. 1 and demonstrates that the observed feature is an absorption at 3.4 μm. The residual structure in the first five points of Fig. 1 probably reflects the failure to correct wholly for the strongest of the telluric water vapour bands at 3.2 μm. The presence of a possible absorption feature near 3.4 μm in the spectrum of IRS7 has already been reported[10,11]. Our data provide unambiguous evidence for the existence of this band and define its characteristics.

Figure 2 is a plot of the band shape smoothed to a resolution of 0.08 μm. In deriving the optical depth we have allowed the continuum at the short wavelength region to be lowered to fit our data at 3.2–3.3 μm. This may have artificially steepened the short wavelength edge of the band but the central wavelength is not affected. We find the wavelength of the peak absorption to be 3.99 ± 0.02 μm, the equivalent width to be 330 Å and the intrinsic FWHM to be 0.13 μm. A similar procedure was adopted with OH01 − 477. The band shape included in Fig. 2 is the weighted mean of two observations. We have not attempted to deduce a band shape for IRS11 because the detection of the 3.4-μm feature in this source is at the 3σ level.

Table 1 Derived values of A_V and $\tau(3.4)$ for the programme sources

Source	Spectral type	A_V	$\tau(3.4)$	$\tau(3.4)/A_V$
Coalsack 3-1	M6	11	≤0.06	≤0.005
Coalsack 2-2	M0	15	≤0.06	≤0.004
OH01 − 477	M4	19	0.06	0.003 ± 0.001
GCIRS11	M4	30	0.2:	0.006:
GCIRS7	M4I	34	0.22	0.006 ± 0.001

We believe that the 3.4-μm absorption arises in the general interstellar medium. The main arguments against a circumstellar origin are: (1) The feature is present in the three most highly obscured sources. (2) We find no evidence of 3.4-μm absorption in the M supergiant VX Sgr, nor in M giant stars. Moreover we expect none in oxygen-rich stars such as those we consider here where carbon preferentially forms CO. (3) Becklin *et al.*[12] argued from the similar colours of the bluest galactic centre sources that most of the reddening towards IRS7 is interstellar.

We discount an origin in the dense molecular clouds, where absorption due to other CH and CC bonds is known to arise[13] because: (1) sources known to be obscured by molecular clouds show absorption at 3.1 μm; and (2) The line of sight towards IRS 7 and 11 does not pass through the molecular clouds mapped by Solomon *et al.*[14]. Finally the width of the 3.4 μm absorption feature argues against an origin in the gaseous phase in low temperature diffuse interstellar clouds.

Using laboratory data on the strength of the 3.4-μm CH band in various common organic molecules, Duley and Williams[2] have related the optical depth τ(3.3–3.4 μm) at peak absorption to the total visual extinction A_V assuming that all the carbon is in the form of a particular organic species. We may now use these results and our observations to estimate the fraction of carbon that is required to be organic material. We find that ~10% may exist in alkanes, whereas the unsaturated hydrocarbons (alkenes, alkynes or aromatics) would account for the visual extinction as well as the 3.4-μm absorption with no requirement for any other grain material.

The difficulty of fitting the extinction curve at all observed wavelengths using a distribution of grains of one specific composition is well known. A grain model based entirely on organic molecules is also clearly ruled out on the basis of the high depletions observed for gas phase metals in the interstellar medium. The present observations do, however, suggest that an appreciable fraction of the observed IR and visual extinction may arise from grains that are largely organic in character.

We thank Bob Carswell for permission to take some of the daytime observations, and Harry Hyland and Terry Jones for drawing to our attention OH01 − 477. D.T.W. thanks Professor Chandra Wickramasinghe for pointing out the significance of establishing the presence of a 3.4-μm interstellar extinction feature, and Professors F. Hoyle, P. M. Solomon and K. Nandy for valuable discussions.

Lunar asymmetry and palaeomagnetism

D. J. Stevenson*

Department of Earth and Space Sciences, University of California at Los Angeles, Los Angeles, California 90024

The compositional asymmetry between the nearside and farside of the Moon and the natural remanent magnetism (NRM) of lunar rocks are poorly understood. The compositional asymmetry is indicated by the 2-km offset towards the Earth of the centre of mass relative to the centre of figure and the concentration of both KREEP and mare basalts on the nearside. Wasson and Warren[1] recently noted that these asymmetries may be better explained by an asymmetric crystallization of a primordial magma ocean than by the often proposed[2-4] greater thickness of farside anorthositic crust. The NRM[5] has been attributed to an ancient lunar dynamo[6,7]. I propose here a model for the early lunar evolution in which the preferred gravitational energy state consisted of an asymmetric accumulation of a liquid iron alloy (Fe–Ni and a small amount of sulphur) which displaces upwards the cold, primordial, undifferentiated core. The resulting depth asymmetry of the outer partially molten zone leads eventually to the subcrustal accumulation of light, magnesium-rich pyroxenes and olivine, preferentially in one hemisphere, sufficient to explain the offset and also indirectly providing a possible explanation for the nearside concentration of KREEP and mare basalt. Meanwhile, slow downward migration of the iron releases gravitational energy sufficient for convection and dynamo generation in an iron layer for about 10^9 yr. The proposed present state of the Moon has a symmetrically placed iron core (radius ≃ 500 km), unlike a previous model for the lunar asymmetry[8].

A crucial assumption in the model is an early Moon consisting of a cold interior region and a hot outer region, consistent with (but not limited to) conventional accretion models[9,10]. The outermost few hundred kilometres are frequently modelled as fully molten (the putative magma ocean) but this is neither geochemically essential nor geophysically plausible. A balance of likely accretional energy input with the outward heat flow suggested by Nusselt–Rayleigh number convection recipes[11] suggests that this region will self-regulate to a viscosity within a few orders of magnitude of 10^{16} P, for which substantial partial melting (essential to explain the anorthosite crust and KREEP) may be needed[12]. For such a viscosity, the convective heat transport is then ~100-fold greater than the present heat output, sufficient to eliminate the excess accretional energy input in about 10^8 yr. Boundary layer theory[13] then predicts a convective overturn time ~10^5 yr, sufficiently smaller than the evolution time scale to ensure lateral homogenization.

The absence of siderophiles in lunar rocks and the low oxygen fugacity of lunar magmas enable metallic Fe-Ni (ref. 14) to be present, although the lunar density, moment of inertia and magnetic measurements[15] limit the amount to ≲5% by mass. Iron droplets (maintained at least partially liquid by a small amount of sulphur) can readily precipitate to form a thin layer above the cold, undifferentiated primordial core. However, this situation is spontaneously unstable because a lower gravitational energy U can be achieved if the iron accumulates on one side, forming a crescent-shaped region and displacing the much less dense primordiel core upwards (Fig. 1). For a displacement h, the change in U is approximately $\Delta\rho_1 g\pi R_c^2 h^2 - \Delta\rho_2 g V_{Fe} h$, where $\Delta\rho_1 \equiv \rho_c - \rho_m$, $\Delta\rho_2 \equiv \rho_{Fe} - \rho_m$, ρ_c is the primordial core density, ρ_m is the (partially molten) mantle density, ρ_{Fe} is the liquid iron alloy density, g is the gravitational acceleration, R_c is the primordial core radius and V_{Fe} is the volume of precipitated iron. As compressional effects are negligible, the preferred h is given by minimizing U and is therefore approximately $1/2(\Delta\rho_2/\Delta\rho_1)V_{Fe}/\pi R_c^2$. More detailed, rigorous calculations change this approximate result by ≲30%.

For $\rho_c = 3.34\ \mathrm{g\ cm^{-3}}$, $\rho_m = 3.15\ \mathrm{g\ cm^{-3}}$ (corresponding to 25% partial melt, an arbitrary choice), $\rho_{Fe} = 7.0\ \mathrm{g\ cm^{-3}}$, $R_c =$ 1,300 km and $V_{Fe} = 3 \times 10^{23}\ \mathrm{cm^3}$ (that is, 5% iron by mass), the predicted value of h (~600 km) exceeds the depth of the mantle. This means that the primordial core could be displaced to the lunar surface. If a true magma ocean were possible ($\rho_m =$ $2.8\ \mathrm{g\ cm^{-3}}$), h would be ≃200 km, still a large effect. This asymmetry would have no lasting consequence if the iron could migrate to the centre in ≲10^8 yr. However, core formation in the Moon was much less rapid than in the other terrestrial bodies because of the low gravity (implying low deviatoric stresses associated with the asymmetry) and the low free iron abundance. The sinking layer[16] and Rayleigh–Taylor (Elsasser droplet[17]) core formation modes are slow (~10^9 yr) because the primordial core is cold and downward transport of heat is inefficient[18]. Stresses associated with the asymmetry are 0.1–1 kbar (limited in part by the low stress level for an $l = 1$ spherical harmonic of the load[19]) but the resulting cold deformation will not eliminate the asymmetry.

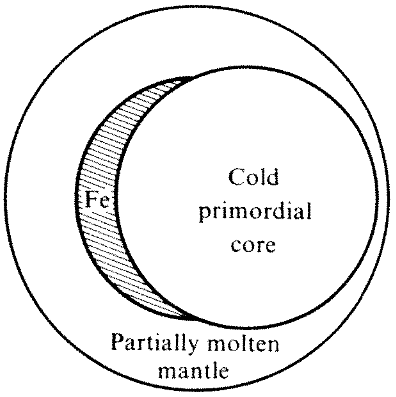

Fig. 1 Schematic representation of the energetically preferred asymmetric arrangement of matter within the early Moon, after precipitation of a liquid iron alloy from the partially molten mantle. The magnitude of the asymmetry is not well known but could be large (see text). The right-hand side is identified with the present nearside of the Moon (but the early orientation is irrelevant because the Moon's orbit has already tidally evolved to a large Earth–Moon separation).

As the asymmetry develops, partially molten mantle will flow into the deep region above the iron layer. Because the mantle adiabat is much less steep than the liquidus or solidus[20], this material will undergo some pressure-induced freezing. Subsolidus, high-viscosity material tends to be stagnant (an analogous situation is observed in convection experiments on fluids with strongly temperature-dependent viscosity[21]) and there will be a tendency for the least fusible solid fraction to accumulate preferentially in the deepest mantle regions. These are the magnesium-rich pyroxenes and olivine[20] (less dense than the average Moon by ~2%, but more dense than the early, partially molten mantle). Subsequently, at about 4,200 Myr BP, when the degree of partial melt in the outer regions has decreased (because of gradual cooling as surface bombardment decreases) and the anorthositic crust has formed, these light crystallites will rise to beneath the farside crust. A layer of thickness $d \lesssim 200$ km on the farside, thinning to zero thickness beneath the nearside crust, gives an offset between centre of mass and centre of figure of about $1/2(\Delta\rho/\rho)d$, about the right amount for a density contrast $\Delta\rho \simeq 0.06\ \mathrm{g\ cm^{-3}}$ between the light crystallites and the rest of the upper mantle. The characteristic time scale for lateral

---

spreading of this layer is about $3\mu R^2/\Delta\rho g d^3$ (a generalization of ref. 22), where R is the radius, and this time scale exceeds 5×10^9 yr provided the viscosity $\mu \gtrsim 10^{22}$ P. This constraint should be satisfied as the material has a high solidus temperature and is within the thermal boundary layer, even that of 4×10^9 yr ago[11]. The low stress level for an $l = 1$ spherical harmonic of the load also helps prevent efficient lateral spreading[19]. The upwelling of crystallites may also sweep the last dregs of partial melt (from which KREEP was presumably derived[23]) around towards the nearside, thereby perhaps explaining the asymmetric KREEP distribution. The nearside predominance of mare basalts later in the evolution can be attributed to the presence of primordial, more fusible material and greater radiogenic heating in the nearside mantle[1].

Meanwhile, silicate grains detach from the deep side of the primordial core and float upward through the iron layer. The detachment rate is determined by the slow downward heat transport[18] (the time scale of iron core formation T_c may be as long as 10^9 yr) and the total gravitational energy released is about 1×10^{35} erg (ref. 24). Although insignificant if averaged over the whole Moon, this energy release is important for the iron layer. For an adiabatic temperature gradient of 2×10^{-6} K cm^{-1} and a thermal conductivity of 5×10^6 K^{-1} cm^{-1}, the integrated conductive heat transport along a liquid iron adiabat is 5×10^{25} T_c erg (T_c in yr), less than the energy released provided $T_c \lesssim 2\times10^9$ yr. Superadiabaticity and convection must ensue in the iron layer, and an application of mixing length theory[25] suggests a convective velocity $v \sim 0.1$ cm s^{-1}. The corresponding magnetic Reynolds number $R_M \equiv vd/\lambda \sim 10^2$ for a layer depth $d \sim 10^7$ cm and the magnetic diffusivity $\lambda \sim 2\times10^4$ cm^2 s^{-1} appropriate to liquid iron. Even for the slow rotation of the Moon (angular velocity $\Omega \sim 2\times10^{-6}$ s^{-1}), $v \ll \Omega d$, so the Coriolis force is dynamically important and dynamo generation should be possible[26]. The integrated ohmic dissipation is about $10^{23}H^2T_c$ erg for a characteristic current $\sim H/d$, and as this is of the order of 10^{34}–10^{35} erg, it follows that $H \sim 10$ G (the Carnot efficiency factor being irrelevant for gravitational stirring[27]). This may be the toroidal field, but it is energetically possible to have an external field comparable to that inferred from palaeofield studies, without invoking exotic energy sources such as superheavy elements[28].

Because g and the rate of gravitational energy release decrease as the iron approaches the centre, the field H decreases with time and dynamo generation will cease (for lack of an energy source sufficient to drive convection) once a central iron core forms, at ~3,000 Myr BP. However, several problems remain in relating lunar magnetism to an ancient lunar dynamo[29], and the model presented here does not attempt to resolve them all. More important than the details of the model are the basic ideas: an inevitable asymmetry and the likelihood of an ancient lunar dynamo. The model is testable (in principle) by lunar seismic studies designed to detect nearside–farside mantle variations and the existence (still hypothetical) of an iron core.

Radar meteor rates and atmospheric density changes

C. D. Ellyett & J. A. Kennewell

Department of Physics, University of Newcastle,
New South Wales 2308, Australia

As a way of explaining the evidence linking recorded radar meteor rates with solar activity, it has been suggested that variations of the atmospheric scale height at meteor ablation altitudes, themselves controlled by the Sun, may be responsible. A quantitative examination of a theoretical treatment by Kaiser (personal communication) now shows that the above suggestion is certainly plausible, and details the necessary scale height changes as a function of the meteor mass exponent.

Using observations made in New Zealand, Canada and Sweden, Lindblad[1] and C.D.E.[2,3] have provided evidence suggesting a link between the apparent radar meteor echo rate and the solar cycle. The phase of this correlation is such that the apparent radar meteor rate increases towards the time of solar minimum. Lindblad has also claimed a connection relevant to short-term periodicities[4]. This variation in meteor rate seems to be an atmospheric effect, and the explanation proposed[5] is a Sun-controlled variation of the atmospheric density gradient at meteor ablation heights (80–120 km), probably modulated by solar X-ray flux. However, an anomalous increase in the meteor rate was recorded around 1963, greater than that ascribed to the solar effect[6,7]; this has been ascribed[5] to an abrupt decrease in solar X-ray output. We, however, consider that this anomaly shows a much higher correlation, both spatially and temporally, with an increase of particulate matter in the atmosphere[8]. Nevertheless, we believe that a change in atmospheric scale height must be responsible for the observed change in echo rate.

A decrease of atmospheric scale height (that is, an increase of density gradient) will bring about this ablation of a meteroid of a given size over a shorter path length. (Correlation with path length has in fact been noted[5].) It might thus be reasonably expected that, because the total energy release is (relatively) independent of path length, the shorter path length would be brighter, with a concomitant increase of linear electron density.

With regard to radar observations, however, an increase of linear electron density is offset by the shorter path length, although Lindblad[1] (who was monitoring both trail length and echo amplitude) has not observed this to be the case. The absence of a quantitative treatment of this problem has made some workers sceptical of the suggested link between scale height and observed rate. Baldwin and Kaiser[9] have suggested that variability in D-region ionospheric absorption may be a more important factor. However, our quantitative study shows that, at least for larger values of the mass exponent s, the large variation in observed meteor rate that C.D.E. requires[3] can be accounted for by appropriate changes of density and scale height.

0028–0836/80/410521—02$01.00

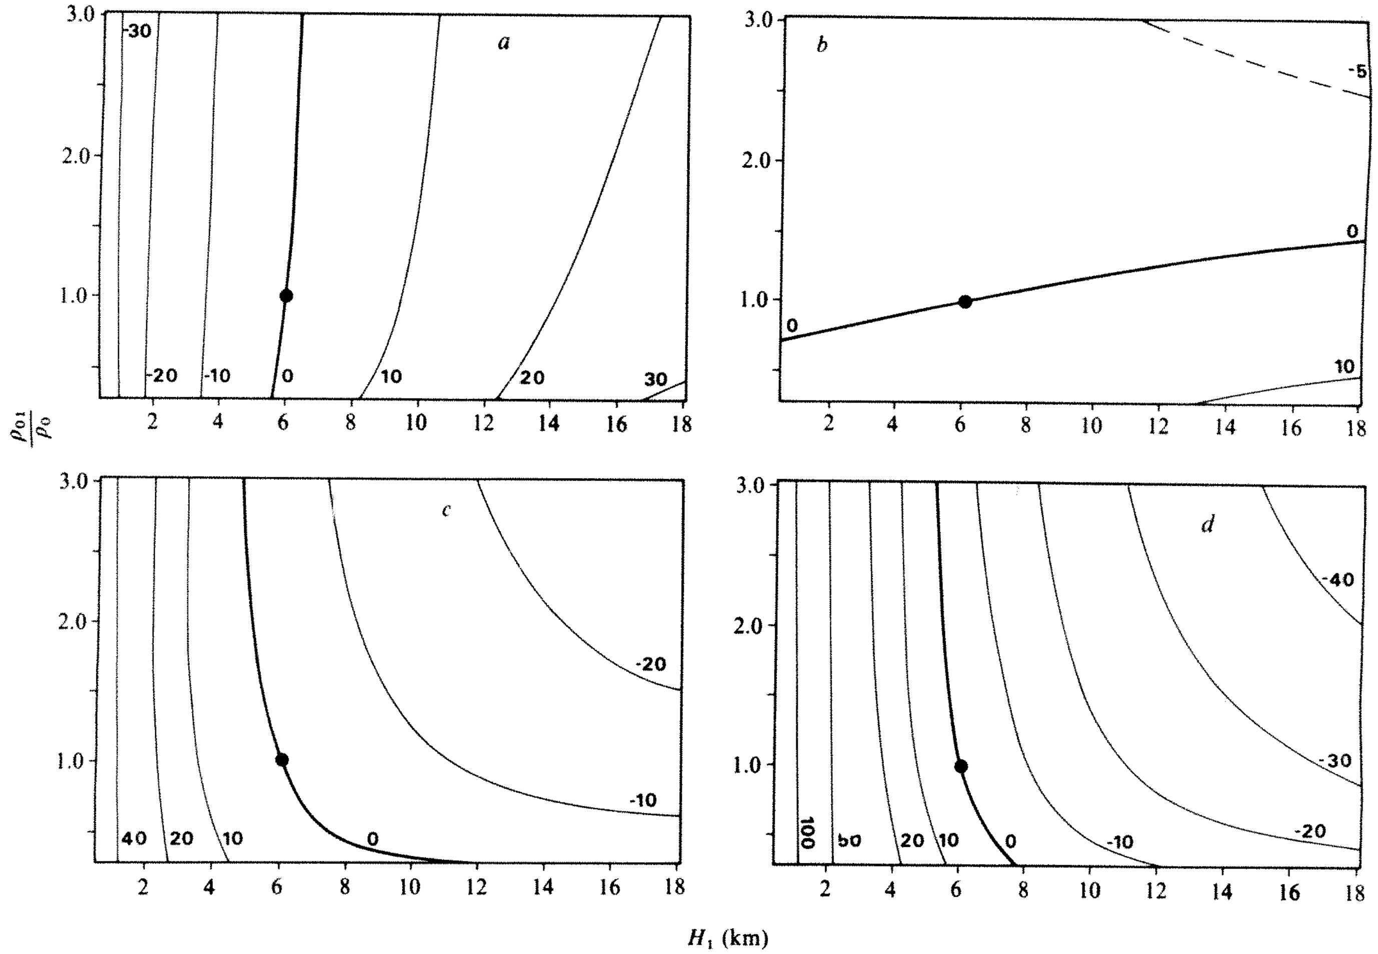

Fig. 1 Percentage change in observed meteor echo rate as a function of atmospheric parameters and meteor mass exponent s where $s = 1.8(a)$, $2.0(b)$, $2.2(c)$ and $2.4(d)$. Change is expressed as $(100(N_1 - N)/N)$ where N is the observed rate at a scale height of 6 km and density ρ_0 at height 100 km, and N_1 is observed rate for a scale height H_1 and density ρ_{01}.

Using classical ablation theory for compact meteoroids[10–14], Kaiser has shown that

$$\frac{N_1}{N} = \left[1 + \left(\frac{5-3s}{2}\right)\left(\frac{H_1}{\bar{h}} \ln\frac{\rho_{01}}{\rho_0} - \frac{H_1}{3\bar{h}} \ln\frac{H_1}{H}\right)\right]\left(\frac{H_1}{H}\right)^{2-s}$$

where N is the observed rate at a density scale height of H, $\bar{h}$ is the mean height (determined by atmospheric parameters) around which the meteor reflection points are distributed, ρ_0 is the atmospheric density at $\bar{h}$ for the rate N, N_1 is the observed rate for a new density scale height of H_1 and a density ρ_{01} at $\bar{h}$, and s is the exponent in the meteor mass distribution curve, which for sporadic meteors has been expermentally determined to lie between about 2.0 and 2.3. (Simek and McIntosh[15] have obtained a value of $s = 2.35 \pm 0.1$ for the radar sporadic background in the magnitude range of interest.)

A computer analysis of this equation has been carried out to ascertain the percentage change in observed meteor rate as a function of the three variables ρ_{01}, ρ_0, H_1 and s. These results are presented graphically in Fig. 1 for values of s between 1.8 and 2.4. The values for $\bar{h}$ and H have been taken to be 100 km and 6 km, respectively.

It is immediately evident from Fig. 1 that the percentage change of observed meteor radar rate is sensitive to s. For $s = 2.0$, no combination of density scale height and absolute density change will produce much more than a 5% change of meteor rate. As might be expected from an inspection of the equation, $s = 2.0$ represents the point about which the graphical contours exhibit a marked change of form. For $s < 2.0$ a decrease of scale height actually results in a decrease of meteor rates, contrary to simple expectation. However, as s increases above 2, the magnitude of the rate increase with decreasing scale height quickly grows.

The maximum rate increase to be accounted for, excluding the abnormal 1963 peak, is about 24%, and for $s \geq 2.2$, such an increase is possible. A halving of scale height from 6 km to 3 km will produce this percentage increase with $s = 2.3$. At this reduced scale height, which corresponds, of course, to a doubling of the air density gradient, the rate is relatively independent of the absolute air density. For $s = 2.5$, only a 30% decrease in scale height is necessary to produce the required increase of meteor rate.

In conclusion, it is possible for change of atmospheric density gradient at meteor ablation heights to have produced the changes noted in the observed radar meteor rate. Further and continuing measurements of the relevant atmospheric parameters in the meteor region are desirable in order to throw further light on this problem.

A laboratory study on the formation of nitrous oxide by the reaction $N_2(A^3\Sigma_u^+) + O_2 \rightarrow N_2O + O$

Edward C. Zipf

Department of Physics and Astronomy, University of Pittsburgh, Pittsburgh, Pennsylvania 15260

Metastable $N_2(A^3\Sigma_u^+)$ molecules are produced copiously in auroral substorms by the impact of low-energy secondary electrons on N_2 and by the absorption of cosmic rays and solar X-rays at *E*-region altitudes and below. The major loss process for $N_2(A^3\Sigma_u^+)$ molecules below 100 km is collisional deactivation by O_2. We present here the results of a detailed study of the reaction $N_2(A^3\Sigma_u^+; v' = 0, 1, 2) + O_2 \rightarrow N_2O + O$, and we show that N_2O is formed with an effective yield of 0.6 with a probable absolute error of ±30%.

Harteck and Dondes[1] have shown that the irradiation of air by high-energy neutrons produces N_2O quite efficiently with an energy cost of 33 eV/N_2O molecule. Cylindrical shock wave studies simulating lightning have produced similar results[2]. However, neither of these investigations sheds light on the details of the reaction(s) leading to the synthesis of nitrous oxide. In a recent study in which N_2–O_2 mixtures were bombarded by 14 MeV neutrons, only two products, $N^{13}N$ and $N^{13}NO$, were observed[3]. Malcombe-Lawes[3] suggested that the reaction

$$N_2(A^3\Sigma_u^+) + O_2(X^3\Sigma_g^-) \rightarrow N_2O(X^1\Sigma) + O(^3P) + 3.0\ \mathrm{eV} \quad (1)$$

was the principal source of the observed nitrous oxide.

We have carried out a detailed study of this process, and we find that reaction (1) forms N_2O with a quantum yield of 0.6±30%. As metastable $N_2(A^3\Sigma_u^+)$ molecules are formed efficiently by electron impact with a total cross-section which is quite large[4] ($\sim 1.4 \times 10^{-16}\ \mathrm{cm}^2$ at 15 eV), these energy-rich molecules (and in turn N_2O) will be produced copiously by the low-energy electrons created by cosmic rays in the mesosphere and stratosphere, by solar X-ray and *EUV* absorption in the *D* and *E* regions and by the secondary electrons produced by high-energy particles precipitating into the auroral zone.

A block diagram of the plasma spectroscopy apparatus and a detailed description of the techniques used in this study are given elsewhere[5]. Only a brief summary of these techniques will be presented here. $N_2(A^3\Sigma_u^+)$ molecules were formed inside a cylindrical stainless steel cavity by a periodically pulsed microwave discharge. The behaviour of the $N_2(A^3\Sigma_u^+)$ molecules in the discharge and afterglow period was monitored by measuring the absolute intensity and the three-dimensional spatial distribution of the Vegard–Kaplan bands $[A^3\Sigma_u^+ \rightarrow X^1\Sigma_g^+]$ (see Fig. 1). With a typical power pulse width of 200 μs and a repetition rate of 20 pulses per s, $N_2(A^3\Sigma_u^+)$ concentrations of $>2 \times 10^{11}$ molecules cm^{-3} were produced by the end of the discharge period in a mixture consisting of 6.0 torr argon, 120×10^{-3} mm Hg nitrogen, and 1.0×10^{-3} mm Hg oxygen. Pulse counting and coherent summing techniques were used to observe the temporal behaviour of the *VK* emission during the afterglow period. The experiment was generally allowed to accumulate photon counts until the decay of the *VK* bands originating from each of the $v' = 0$, 1, and 2 vibrational levels that were detectable could be followed over an intensity range of at least three orders of magnitude (Fig. 2). The absolute sensitivity of the entire optical system was determined using standard lamps (both tungsten ribbon and deuterium lamps) calibrated by the National Bureau of Standards and by the Optronics Laboratory. The absolute accuracy of the calibration of the optical system approaches that of the standard lamps themselves (~5%). From the time-dependent data, the quenching coefficients for the depopulation of $N_2(A^3\Sigma_u^+)$ in a specific vibrational level by O_2, $k(v')$, could be evaluated. From these results $[k_0 = 1.9 \times 10^{-12}\ \mathrm{cm}^{-3}\ \mathrm{s}^{-1},\ k_1 = 4.0 \times 10^{-12}\ \mathrm{cm}^{-3}\ \mathrm{s}^{-1}]$ and from the absolute intensity and spatial distribution measurements, the total $N_2(A^3\Sigma_u^+)$ loss rate within the volume of the microwave cavity from reaction with and/or quenching by O_2

$$L(A^3\Sigma_u^+) = \frac{1}{\tau_0} \sum_{v'} k_{v'}\, n(O_2) \int_0^{\tau_0} \int_{\mathrm{volume}} M_{v'}(\vec{r}, t)\, \mathrm{d}t\, \mathrm{d}\vec{r}^3 \quad (2)$$

was determined. In this expression, $M_{v'}(\vec{r}, t)$ is the local $N_2(A^3\Sigma_u^+; v')$ concentration at a specific time during the discharge or afterglow while $n(O_2)$ is the molecular oxygen density, and τ_0 is the power-pulse repetition period.

The buildup of N_2O as the result of reaction (1) was observed by a quadrupole mass spectrometer which sampled the gas

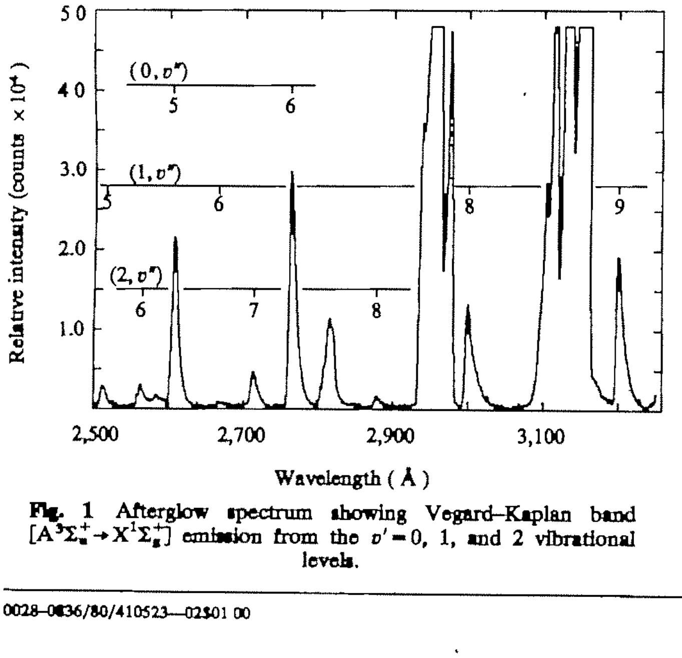

Fig. 1 Afterglow spectrum showing Vegard–Kaplan band $[A^3\Sigma_u^+ \rightarrow X^1\Sigma_g^+]$ emission from the $v' = 0$, 1, and 2 vibrational levels.

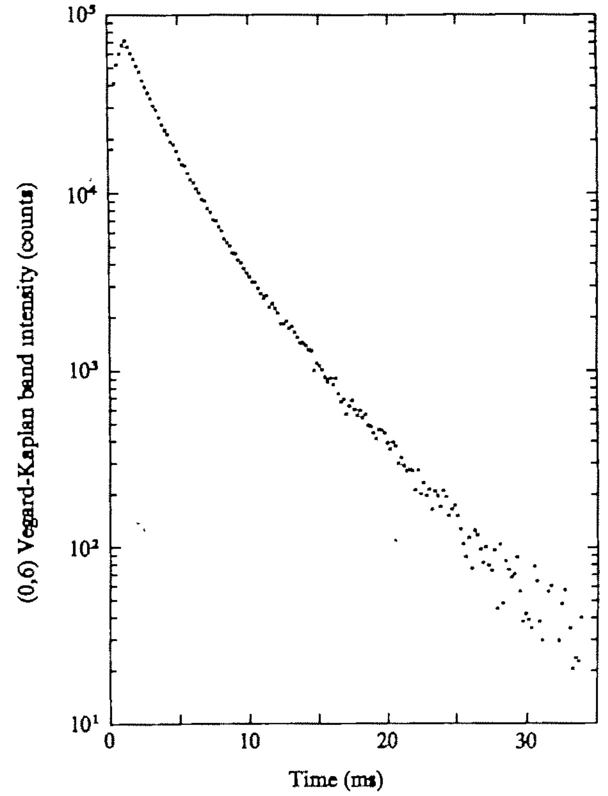

Fig. 2 The temporal behaviour of the (0, 6) Vegard–Kaplan band. The buildup of the $N_2(A^3\Sigma_u^+; v' = 0)$ concentration during the 1.0 ms microwave discharge can be seen readily. From the decay of the (0, 6) band intensity during the afterglow period, the total O_2 quenching coefficient for $v' = 0$ could be evaluated.

0028-0836/80/410523—02$01.00

through a small aperture in the side of the cavity (Fig. 3). Typical N_2O steady-state concentrations of 2×10^{12} molecules cm^{-3} were observed. The limiting sensitivity of the mass spectrometer to N_2O in the conditions of the experiment was $\sim10^9\ cm^{-3}$ so that accurate measurements of the N_2O concentration could readily be made. The N_2O signal was corrected for a small contribution (<10%) due to carbon dioxide whose concentration could be determined accurately from the magnitude of the mass peak at 22 AMU. The later is due almost exclusively to CO_2^{2+} ions and not N_2O^{2+} because the ratio of the effective ionization efficiency for these species in the conditions of the experiment was $CO_2^{2+}/CO_2^+ = 1.29\times10^{-2}$ and $N_2O^{2+}/N_2O^+ < 5\times10^{-5}$, respectively.

In the present work, particular attention was paid to the potentially undesirable effects of impurities either in the gases used or as outgassing by-products from the vacuum system itself. To minimize these difficulties, the vacuum system was constructed entirely of stainless steel using metal gaskets where components were joined, and it was baked until the background pressure was 5×10^{-10} torr, and the virtual leak rate for the entire vacuum system was reduced to less than 10^{-10} torr s^{-1}. The neutral mass spectrometer was also used to determine the actual composition of the gas in the microwave cavity including other oxides of N_2 (NO and NO_2). These measurements showed quite clearly that the local $n(O_2)$ concentration in the microwave cavity was reduced significantly (15–20%) as the result of reaction (1), and it underlines the importance of measuring the absolute, *in situ* concentration of all reactants in a yield measurement.

The N_2O molecules formed by reaction (1) are removed from the microwave cavity chiefly by pump-out through the aperture servicing the mass spectrometer and, to a minor extent, by reactions in the discharge and afterglow periods. The total nitrous oxide loss rate, $(V/\tau_1)N$, when the discharge was on, was determined from the N_2O rise-time data (τ_1), the volume of the microwave cavity, V, and the N_2O concentration, N, measured by the mass spectrometer. The relationship between the steady-state N_2O and $N_2(A^3\Sigma_u^+)$ loss rates is

$$(V/\tau_1)N = \varepsilon L(A^3\Sigma_u^+) \qquad (3)$$

where ε is the efficiency of reaction (1). In conditions where τ_1 is kept constant, equation (3) predicts that the steady-state N_2O concentration will be directly proportional to the total number of $N_2(A^3\Sigma_u^+)$ molecules observed per cycle (equation (2)). This behaviour is shown quite clearly by the data of Fig. 4. By varying τ_0, $n(O_2)$ and the microwave power-pulse width, the N_2O concentrations predicted by equations (2) and (3) were further verified, and the efficiency, ε, was evaluated. The results of this study show that $\varepsilon = 0.6$ with a probable absolute error of ±30%.

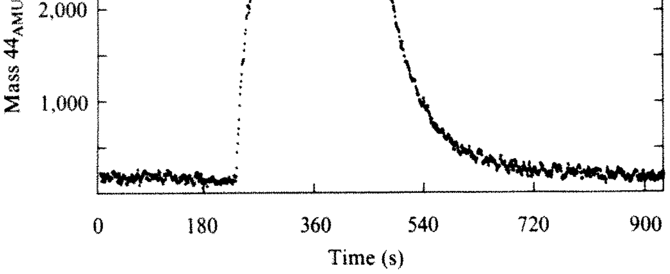

Fig. 3 Mass 44 AMU neutral mass spectrometer signal showing the buildup of nitrous oxide when the periodically pulsed microwave discharge is turned on and its subsequent pump-out when the discharge is turned off.

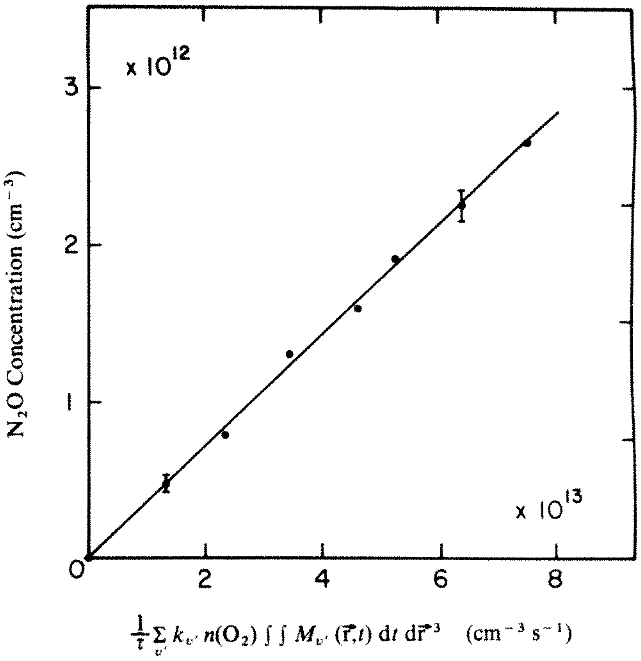

Fig. 4 A plot of the measured N_2O concentration versus the total $N_2(A^3\Sigma_u^+)$ loss rate.

The present study confirms the suggestion by Malcombe-Lawes[3] that N_2O is formed efficiently when metastable $N_2(A^3\Sigma_u^+)$ molecules react with O_2. Some nitric oxide was also observed in our experiment [$NO \sim 0.2\ N_2O$] possibly as the result of the reaction of N_2O with $O(^1D)$ atoms formed in the microwave discharge. The observed NO_2 concentration was less than $10^{10}\ cm^{-3}$ even though NO_2^+ was a major afterglow ion. This suggests that the NO_2 buildup is rate-limited by ion-molecule reactions which rapidly convert NO_2 molecules to NO_2^+ ions that subsequently recombine dissociatively to form NO.

Recent rocket-borne studies of $N_2(A^3\Sigma_u^+)$ excitation in auroral substorms[6–9] indicate that energetic electrons degrading in air at low pressure ($p < 10^{-3}$ torr) form ~0.35 $N_2(A)$ molecules per electron–ion pair. These results, when combined with the present study, indicate a minimum energy cost of ~157 eV per N_2O for $A^3\Sigma_u^+$ molecules in the $v' = 0$ and 1 vibrational levels. The lower energy cost reported by Harteck and Dondes[1] (33 eV per N_2O) may be a consequence of the high pressures used in the neutron experiments. In the conditions of their experiment, many metastable and excited states which are formed copiously by particle bombardment and which relax radiatively in our afterglow experiment would be collisionally deactivated. This process might result in enhanced $N_2(A)$ production (and thus N_2O) at atmospheric pressure or these species [for example, $N_2(a^1\pi_g)$] might react directly with O_2 to form nitrous oxide. Thus, when the A-state is formed by particle precipitation in auroral substorms, an energy cost of ~157 eV per N_2O is probably realistic. But, when the A-state is formed by X-ray and cosmic ray absorption in the stratosphere and below, a yield of one N_2O per electron–ion pair may be a better estimate.

Production of nitrous oxide in the auroral *D* and *E* regions

E. C. Zipf

Department of Physics and Astronomy, University of Pittsburgh, Pittsburgh, Pennsylvania 15260

S. S. Prasad

Jet Propulsion Laboratory, Pasadena, California 91103

Metastable $N_2(A^3\Sigma_u^+)$ molecules are formed efficiently in auroral substorms by electron-impact excitation of N_2. In the auroral *D* and *E* regions, $N_2(A^3\Sigma_u^+)$ molecules react rapidly with O_2 to form N_2O at a globally averaged rate that could be as high as $2\times10^{27}\ s^{-1}$. We report here that in favourable substorm conditions, the N_2O density at 100 km could be as large as $10^9\ cm^{-3}$.

Metastable $N_2(A^3\Sigma_u^+)$ molecules are produced copiously in auroral substorms by the impact of low-energy electrons[1,2]. Above 120 km, quenching by atomic oxygen

$$N_2(A^3\Sigma_u^+)+O \rightarrow N_2(X^1\Sigma_g^+)+O \qquad (1a)$$

$$N_2(A^3\Sigma_u^+)+O \rightarrow NO+N \qquad (1b)$$

and radiation of the Vegard–Kaplan bands

$$N_2(A^3\Sigma_u^+) \rightarrow N_2(X^1\Sigma_g^+)+h\nu \qquad (2)$$

are the dominant $N_2(A^3\Sigma_u^+)$ loss mechanisms, while below 100 km collisional deactivation by O_2 rapidly becomes the principal depopulation process[3,4]. Because a recent laboratory study[7] shows that the reaction

$$N_2(A^3\Sigma_u^+;\ v'=0,1,2)+O_2 \rightarrow N_2O+O \qquad (3)$$

produces nitrous oxide with an efficiency of 0.6±30%, the auroral borealis will produce significant quantities of N_2O poleward of latitude 55°.

Detailed studies of the excitation of $N_2(A^3\Sigma_u^+)$ molecules in auroral substorms have provided some insight into the maximum N_2O production rate in an auroral arc[1–4]. Although there is some disagreement concerning the absolute magnitude of the pertinent excitation cross-sections and the shape of the auroral secondary-electron flux, the recent work of Sharp *et al.*[1,5,6] shows that the ratio of the $N_2(A^3\Sigma_u^+)$ production rate to the total ion-pair production rate, *q*, is ~0.35. Thus, in view of the $N_2(A^3\Sigma_u^+)$ laboratory results, the N_2O production rate, $P(N_2O)$, could be as much as 0.21 *q*. As the globally averaged energy deposition rate due to particle bombardment during periods of maximum solar activity[8] is $\sim6\times10^{29}\ eV\ s^{-1}$, the maximum N_2O production rate would be $\sim4\times10^{27}$ molecules s^{-1} if reaction (3) was the only A-state loss mechanism.

Table 1 N_2O loss processes and chemical lifetimes at 100 km

	Reaction	Lifetime for IBC I aurora (s)
R(1)	$O(^1D)+N_2O \rightarrow 2NO$ or N_2+O_2	1.1×10^7
R(2)	$N(^2D)+N_2O \rightarrow NO+N_2$	1.3×10^8
R(3)	$O^++N_2O \rightarrow O_2^++N_2$	1.0×10^9
R(4)	$N^++N_2O \rightarrow NO^++N_2$	3.6×10^7
R(5)	$N_2^++N_2O \rightarrow NO^++N_2+N$	1.3×10^7
R(6)	$N_2^++N_2O \rightarrow N_2O^++N_2$	7.1×10^6
R(7)	$e+N_2O \rightarrow N_2O^++2e$	1.2×10^8
R(8)	$e+N_2O \rightarrow$ dissociation products	1.2×10^8
R(9)	$N_2O^++O_2 \rightarrow O_2^++N_2O$	1.1×10^{-3}
R(10)	$N_2O^++e \rightarrow$ dissociation products	6.0×10^{-2}

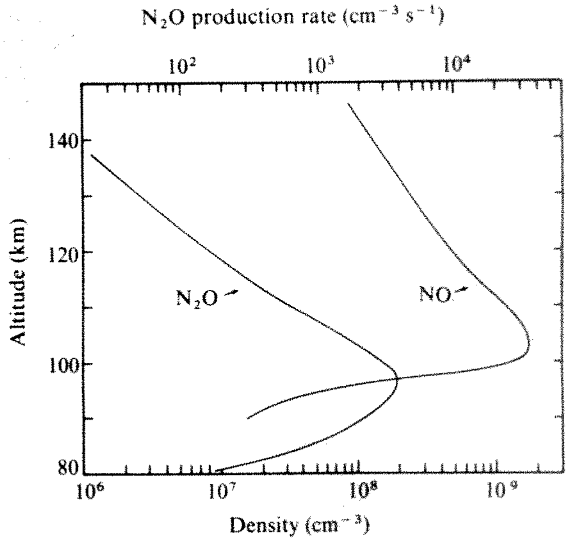

Fig. 1 The N_2O production rate in an IBC I aurora[5] [I(3,914 Å) = 4 kR]. The N_2O density assuming constant energy deposition for 5×10^4 s is compared with the NO values calculated by Gerard and Rusch[11] for the same aurora and equal integration times.

Although reaction (3) does control the $N_2(A^3\Sigma_u^+)$ chemistry below 95 km, most of the energy deposited by precipitating auroral electrons is above 95 km where processes (1) and (2) are also quite important. Thus, the effective N_2O production rate will be somewhat less than the upper limit obtained above. A more realistic assessment can be made from *in situ* measurements of the volume emission rate of the (0, 0) first negative band of N_2^+, η(3,914 Å), in typical IBC I and II⁺ aurora. This emission feature is frequently used to monitor the energy deposited in the auroral ionosphere by precipitating particles because its volume emission rate is directly proportional to the local ionization rate[9,10],

$$\eta(3{,}914\ \text{Å}) = \frac{q}{14.7}\,\frac{0.88[N_2]}{0.88[N_2]+0.5[O]+[O_2]}$$

The local N_2O production rate is related to η(3,914 Å) by

$$P(N_2O) \simeq 6.2\ \eta(3{,}914\ \text{Å})\left\{\frac{\varepsilon k_3[O_2]}{k_1[O]+k_3[O_2]+0.52}\right\} \qquad (4)$$

where [O], $[O_2]$, and $[N_2]$ are the atomic oxygen, O_2 and N_2 concentrations, respectively, ε is the efficiency for producing N_2O by reaction (3), and k_1 and k_3 are the total reaction rate coefficients for $N_2(A^3\Sigma_u^+)$ deactivation by O and O_2, respectively. Figure 1 shows the N_2O production rate calculated from published λ 3,914 Å data for an IBC I aurora[5] with k_1, $k_3(v'=0)$, and $k_3(v'=1)$ equal to $1.2\times10^{-10}\ cm^3\ s^{-1}$, $1.9\times10^{-12}\ cm^3\ s^{-1}$, and $4.0\times10^{-12}\ cm^3\ s^{-1}$, respectively[5,7]. Table 1 lists the principal N_2O loss processes and the effective N_2O chemical lifetime at 100 km for each loss channel in the IBC I aurora studied by Sharp *et al.*[5]. None of these processes is an effective nitrous oxide sink on the time scale of a typical auroral substorm. The N_2O diffusion lifetime is also quite long (days). Thus, the local N_2O buildup in the auroral *D* and *E* regions is determined by source functions such as that shown in Fig. 1 integrated over the total amount of time that the auroral activity lasted (minutes to hours). As an example we have assumed in Fig. 1 that the energy deposition in the IBC I aurora remained constant for 5×10^4 s. The maximum predicted N_2O density, $2\times10^8\ cm^{-3}$, is nearly an order of magnitude smaller than the NO concentration measured by Sharp[12] and estimated by Gerard and Rusch[11] assuming an equal integration period. With still longer integration times, the N_2O density would continue to increase relative to NO because the latters growth is ultimately rate-limited by

0028–0836/80/410525—02$01.00

the reaction $N+NO \rightarrow N_2+O$. Thus, N_2O concentrations greater than 10^9 cm^{-3} could be produced in IBC III aurora or by lower-level activity lasting for many hours, and, in favourable conditions, the N_2O concentration could actually exceed the local nitric oxide density.

The total N_2O column production rate in Fig. 1 is 6.3×10^9 cm^{-2} s^{-1} for an IBC I aurora in which the λ3,914 Å overhead intensity was 4.0 kR. These results imply an effective energy cost of ~330 eV per N_2O molecule in the aurora studied. Thus, a more realistic upper limit on the globally averaged N_2O production rate from auroral activity would be $\sim 2\times 10^{27}$ s^{-1}. Table 1 implies that the chemical lifetime in the auroral *D* region is quite long. Thus, the buildup of N_2O in the polar region is probably rate-limited by transport processes. Although vertical diffusion will carry some of the nitrous oxide into the polar mesosphere, the horizontal winds which were invoked by Cravens *et al.*[13] to explain the longitudinal distribution of NO in the *E* region, would also transport much of the N_2O equatorward where sunlight and reactions with O(^{1}D) would slowly decompose it.

Chemical evolution and ammonia in the early Earth's atmosphere

A. Henderson-Sellers

Department of Geography, University of Liverpool,
Liverpool L69 3BX, UK

A. W. Schwartz

Department of Exobiology, University of Nijmegen, The Netherlands

A constraint on research into the evolution of the Earth's atmosphere may have been resolved by recent work on the photochemical reduction of atmospheric nitrogen by a naturally occurring form of TiO_2 (ref. 1). We show here that this source could have provided a small but vital abiological supply of ammonia in the early atmosphere of the Earth. Locally the levels of NH_3 produced by this mechanism satisfy the requirements of origin-of-life biologists whilst global levels do not conflict with chemical and physical constraints on the surface/atmosphere system nor with geological evidence for early Precambrian conditions.

It has become increasingly difficult from the viewpoints of exobiology and astrogeology to harmonize theories on the evolution of the Earth's atmosphere. The problem centres around the existence and/or abundance of reduced constituents in the early atmosphere[2]. Originally both astronomical and biochemical theories[3] supported the hypothesis that the initial atmosphere of the Earth was composed primarily of chemically reduced compounds. However, Rubey's work[4] and more recent geological (the oldest rocks yet discovered, from the Isua belt in West Greenland[5,6], are dated at (at least) 3,800 Myr and imply deposition conditions similar to the present-day) and astronomical[7,8] evidence argue strongly for a scenario in which degassing from a volatile-rich surface veneer leads to atmospheres composed mainly of carbon dioxide and water vapour (with smaller amounts of nitrogen and carbon monoxide) on all the terrestrial planets[9–12]. The origin and subsequent evolution of life on Earth is easier to explain if a small mixing ratio of more reduced compounds such as methane and ammonia existed in the early Earth's atmosphere[2]. Significant amounts of reduced gases could have been produced by the pyrolysis, during this early period of outgassing, of material similar to that still surviving in type I carbonaceous chondrites (survival of large quantities of intact organics during this process seems unlikely). However, a highly reducing atmosphere around the Earth, even if so produced, could not have persisted for any significant length of time[13]. The problem is particularly severe for ammonia. It has been argued that photodestruction of ammonia would have been substantially complete in <1 Myr (ref. 14). Kuhn and Atreya[15] have concluded more recently that a mixing ratio $\leq 10^{-4}$ of ammonia would have been "irreversibly" converted to N_2 in <40 yr. The photodestruction of NH_3 is an important problem as most models of chemical evolution require significant concentrations of NH_3 and NH_4^+ in solution for the synthesis of amino acids and other biochemicals. Bada and Miller[16], for example, estimate that NH_4^+ concentrations must be $>10^{-3}$ M to permit an equilibrium of equal concentrations of amino acids and the corresponding hydroxy acids at *p*H 8.

None of the studies of photolytic NH_3 destruction has considered the possible role of mechanisms for the resynthesis of NH_3. The synthesis of HCN at high efficiency by means of spark discharges in mixtures of N_2 and CH_4 offers an attractive route to biologically important molecules[17,18]. Aside from the question of the possible source and concentration of methane, clearly such syntheses may also involve the participation of NH_3, although it is produced *in situ* through the decomposition of HCN in aqueous solution (always the major process at any reasonable concentration of HCN in water). Consequently, it is not clear whether NH_3 produced by this route alone in bodies of water on the Earth's surface would have escaped ultimate photolytic destruction, although reactions in liquid inclusions in frozen lakes could have been an exception[19]. However, this would not have been the only available pathway for the synthesis of NH_3. Recent work on the direct photolytic reduction of N_2 on natural, semiconductor catalysts suggests a massive process which would have operated to increase steady state concentrations of NH_3 near ground level and, more importantly, in associated sources of ground water.

A systematic study of catalytic mechanisms of nitrogen fixation has established that titanium dioxide is an effective catalyst for the photochemical reduction[20,21] of N_2 to NH_3. A detailed investigation of naturally occurring areas rich in titanium revealed that certain deserts (such as the Imperial Sand Dunes, California) possess an extraordinary activity in the conversion[1] of atmospheric nitrogen to NH_3. It is estimated that one acre (~4,047 m^2) of this type of desert sand generates between 1 and 10 kg of NH_3 in a year. Thus the current global production may be estimated at between 6.8×10^9 and 6.8×10^{10} kg per year. We suggest that this process would provide a significant abiotic source of ammonia on the primitive Earth. This source of NH_3 can only resolve the conflict between astronomers and biochemists if it supplies adequate amounts of this reduced gas to localized areas whilst not perturbing the surface/atmosphere system (especially the surface temperature and chemical nature of the troposphere) beyond the fairly close constraints imposed by geological data. Our results suggest that both these sets of constraints are satisfied by this source of ammonia. The rate of nitrogen reduction is obviously a function of the total area of a suitable catalyst and the type of irradiation that it suffers. It seems reasonable to assume that early in the history of the Earth the level of surface irradiation by UV light was considerably increased. Even if, as has been suggested[22], the oxygen content of the atmosphere was within a factor of 10 of its present level 2,000 Myr ago, the earliest stages of surface/atmospheric

0028-0836/80/410526—03$01.00

Table 1 The greenhouse effect caused by ammonia in the early Earth's atmosphere for the addition of 10^{13} kg NH_3

Time (Myr BP)	p_{CO_2} (mbar)	10^{13} kg NH_3 ΔT (K)
4,250	310	17.2 (327.2)
3,500	70	15.1 (311.1)
2,500	18	13.7 (305.7)

Temperatures (in parentheses) are values from ref. 11 with the NH_3 increment added.

interaction probably included a significant effect of NH_3 fixation by desert sands, particularly as near-UV light is also effective[20]. Note that the measured production rates in these experiments indicate a substantially greater rate for the surface-catalysed production process than for the noncatalytic reverse oxidation. Thus a net accumulation of NH_3 in the vicinity of the catalyst would have been inevitable. We calculate, on the basis of an experiment described by Schrauzer[1], that the ammonia produced would have corresponded to a solution 0.01 M in the absorbed water of the desert sand tested. Thus the minimum requirements for the origin and subsequent evolution of life can be achieved, at least, locally. (The NH_3 mixing ratio in equilibrium with this concentration is *p*H dependent, but could not exceed 10^{-4}.)

However, are likely global levels of NH_3 consistent with the recognized climatological and geological data? We suggest that an upper limit for the global level of NH_3, assuming a production rate enhanced by two orders of magnitude together with a residence time against chemical destruction in the atmosphere of between 10 and 100 yr, is 10^{13} kg in the early atmosphere of the Earth. Higher levels than this seem unlikely for several reasons: (1) ammonia dissolves readily in water and thus a large mixing ratio of NH_3 in an atmosphere known to be in contact with considerable areas of surface liquid water throughout the Precambrian[23] is difficult to sustain; (2) photochemical oxidation of NH_3 rapidly removes it from the bulk atmosphere; (3) surface temperatures are a direct function of the abundance in the atmosphere of any gas which possesses IR absorption bands. Ammonia's strong absorption in the IR, caused earlier speculations concerning the atmosphere of the early Earth to include relatively large mixing ratios of ammonia[24]. There is clearly an important relationship between the likely production rates, the removal by photolysis and global temperatures.

The addition of even small amounts of a gas which possesses strong features in the IR part of the spectrum to atmospheres which are already in equilibrium with a surface at a temperature close to the present-day value (between 285 and 290 K) may pose serious problems to any atmosphere/surface evolution model. This is why we have computed the extra 'greenhouse effect' due to addition of 10^{13} kg of ammonia to the atmosphere. The precise global level of ammonia is extremely difficult to estimate as the destruction rate depends on the ground level mixing ratio, the eddy diffusion coefficient and the opacity of the atmosphere at the appropriate wavelengths[14,15]. However, this new source seems to be of the same order of magnitude as previously computed destruction rates[15] and thus the global budget of NH_3 could be enhanced. Geological evidence pertaining to the ambient surface temperatures[5,23] is now an important source of information. The extra temperature increment has been calculated using computer programmes described in detail elsewhere[25]. The numerical model includes the major regions of NH_3 band absorption (that is, 2.8–3.2; 5.5–7.2; 8.0–15.0 and longwave of 35.0 μm) plus the effects of broadening both by neutral gases and other absorbers. The solution of the radiative transfer equation is approximate but the accuracy and usefulness of the model over evolutionary time scales has been demonstrated[10,26]. Particular attention has to be paid to the regions of overlap between absorption bands (in this case the bands of water vapour and ammonia). We have followed Goody[27] in taking the transmission in regions of overlap as the product of the fractional transmissions of the individual bands. This is more appropriate than the use of an empirical relationship for application to atmospheric evolution over geological time periods. The variation in the solar luminosity, planetary flux factor, albedo and partial pressure of all atmospheric constituents is included. Table 1 lists the 'greenhouse increments' for the addition of 10^{13} kg of ammonia to an evolving atmosphere of CO_2 with the present-day level of water vapour. (The effect of adding this amount of NH_3 to atmospheres more recently than 2,500 Myr ago has not been calculated as there are conclusive geological data against such high levels[28] and the irradiation of the surface by UV light would by this time have decreased considerably, thus reducing the fixation rate.) This carbon dioxide atmosphere is described in detail elsewhere[11]. The resulting surface temperatures (that is, the temperatures of their model plus our calculated increment) are shown in parentheses in Table 1. (There is an interesting feedback effect associated with this mechanism for abiological nitrogen fixation—if surface temperatures rise in response to the addition of NH_3 to the early atmosphere then it is possible that larger areas of desert sands suitable for the catalytic reaction described by Schrauzer[1] may occur, thus producing a positive feedback cycle.) There are, of course, other climatological parameters which could be perturbed by such changes. The most difficult of these to consider is the possible perturbation in cloud cover. It has been suggested[29] that over geological time periods the percentage cloud cover may have remained approximately constant.

The computed average global surface temperatures in Table 1 seem to be rather high. Compare the value at 4,250 Myr ago with the early temperature of Venus calculated from the simple radiation balance equation

$$\frac{S}{f}(1-A)=\sigma T_e^4 \tag{1}$$

where *S* is the solar flux (Wm^{-2}), *f* the planetary flux factor[26], *A* the albedo, and σ the Stefan-Boltzman's constant.

At the time of planetary formation and assuming an increase in solar luminosity of between 40 and 45%, the effective temperature of Venus from equation (1) is between 295 K (for $f=4$) and 350 K (for $f=2$) (ref. 10). It is generally believed that the high early surface temperatures on Venus triggered the runaway greenhouse effect which finally resulted in the present-day massive atmosphere and very high surface temperatures (~750 K). Our results suggest, therefore, that 10^{13} kg of NH_3 in the evolving atmosphere of the Earth could produce surface temperatures too high for the subsequent evolution that is known to have occurred. The question of the possibility of a climate catastrophe has been discussed recently[28,30]. We suggest that the geological data[23,31] do not support any scenario which has either very high early surface temperatures or very large mixing ratios of ammonia. Note, however, that work on oxygen isotope levels in certain cherts suggests higher surface temperatures in the Precambrian[32]. We consider that surface temperature data are a valuable additional source of information. If the primitive atmosphere[28] contained even larger amounts of NH_3 (say through a combination of catalytic fixation and impact degassing of CI type material), the known surface temperature evolution would seem to be impossible. For instance, we have computed the additional greenhouse increment for 10^{15} kg NH_3 in the 4,250 Myr BP atmosphere in Table 1. In this case the value of $\Delta T = 108.3$ K gives a global average temperature of 418.3 K.

The present results suggest that a source of abiological ammonia by fixation of atmospheric N_2 in the presence of TiO_2 may provide enough reduced gas for local conditions (as dissolved NH_3) to be hospitable for the origin and subsequent evolution of life. However, the strong dependence of global surface temperatures on the partial pressure of ammonia indicates that the global mixing ratio is unlikely ever to have been above 1.5×10^{-5} by volume. This mechanism of NH_3 production may have constituted the major source of NH_3 in the prebiotic world, although photochemical destruction clearly restrained the build-up of ammonia levels in the primitive atmosphere.

We thank G. N. Schrauzer for unpublished data.

Does the whole of the Earth's core convect?

K. A. Whaler

Bullard Laboratories, Department of earth Sciences, University of Cambridge, Madingley Road, Cambridge CB3 0EZ, UK

Higgins and Kennedy[1] used data on the behaviour of iron at high temperatures and pressures to infer that the top of the Earth's liquid core is stably stratified. Attempts to confirm this result both thermodynamically[2] and using seismological data[3] have been inconclusive. I present here geomagnetic results which may resolve the controversy. If a stratified region exists there will be no upwelling or downwelling of core fluid at the core–mantle boundary (CMB), so there will be no horizontal divergence of velocity v, that is $\nabla_H\cdot\mathbf{v} = 0$, where

$$\nabla_H = \nabla - \hat{\mathbf{r}}(\hat{\mathbf{r}}\cdot\nabla)$$

$\hat{\mathbf{r}}$ denotes the unit radial vector. This hypothesis can be tested directly, using geomagnetic data, at a few isolated points on the CMB, and local averages of $\nabla_H\cdot\mathbf{v}$ can be examined over the rest of the surface. A statistical treatment of the results strongly suggests that $\nabla_H\cdot\mathbf{v} = 0$, which is a consequence of a stably stratified layer.

The radial induction equation at the CMB, where $\mathbf{v}\cdot\hat{\mathbf{r}} = 0$, is, on the decade time scale[4,5],

$$\dot{B}_r + \mathbf{v}\cdot\nabla_H B_r + B_r\nabla_H\cdot\mathbf{v} = 0 \tag{1}$$

where a dot denotes time differentiation and the subscript r the radial component. This equation cannot be used to calculate the horizontal divergence of velocity directly because of a fundamental ambiguity[4,5]. However, at local extrema of B_r (points at which $\nabla_H B_r = 0$), the second term of equation (1) vanishes, eliminating the unknown **v**. If the horizontal velocity divergence is zero, these extrema must be points at which $\dot{B}_r$ is zero. Roberts and Scott[4] have observed that this condition would hold if the velocity were purely toroidal.

Table 1 Secular variation and horizontal divergence at extrema

The analysis was carried out for the International Geomagnetic Reference Field (IGRF) model[6] of 1965.0, a set of surface spherical harmonic coefficients up to eighth degree and order. The radial component of the field at the CMB ($r = 3{,}485$ km) is shown in Fig. 1. Solid contours indicate positive and zero values and dotted contours are negative, the contour interval is 1 G. The dashed lines are contours of zero $\dot{B}_r$, and in general they pass remarkably close to the extrema of B_r. I have found 19 extrema, marked by crosses in Fig. 1, whose secular variation and horizontal velocity divergence are given in Table 1. It is impossible to construct satisfactory error bounds either for the positions of the extrema or the zero $\dot{B}_r$ contours, so, to check that these numbers are significant, I have compared the mean and standard deviation of these $\dot{B}_r$ values with those from sets of 19 geographically randomly distributed points (see Table 2). None of these sets contained points with an angular separation of less than 15°. Clearly, the random points are more variable: none of the 24 sets had a smaller standard deviation than that of the extremal points. Taking all the random points together (mean 0.26, standard deviation 2.05), I used a one-tailed *F*-test on the ratio of the variances of the random and extremal points. The null hypothesis of the variances being equal can be rejected

* The mean is inconsistent with zero at 95% level (using a 2-tailed Student's *t*-test).

† Extremal set; the rest are randomly generated.

0028–0836/80/410528—03$01.00

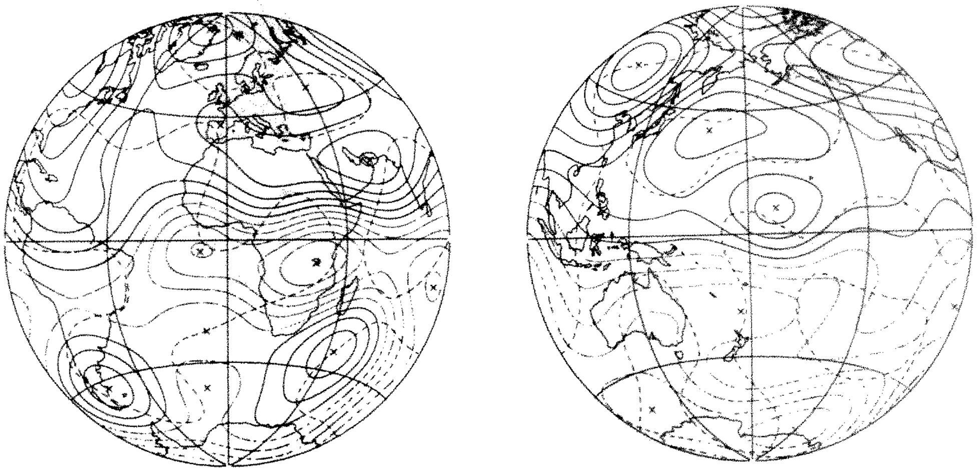

Fig. 1 Radial component of main field for 1965.0 at CMB on a Lambert equal area projection are positive and zero values, dotted contours negative. Dashed lines are contours of zero radial secular variation. Local extrema of the radial main field component are marked by crosses.

at the 99% level. Looking at the means of the individual sets, five have a smaller mean than that of the extremal points, but two others (marked with an asterisk in Table 2) are inconsistent with zero at the 95% level (using a two-tailed Student's *t*-test). Thus the values of $\dot{B}_r$ (and hence $\nabla_H\cdot\mathbf{v}$) at the extrema are significant—they are consistent with zero and less variable than would be expected from purely random sampling.

Backus (personal communication) suggested that $\nabla_H\cdot\mathbf{v}$ over the rest of the core could be estimated by integrating equation (1). The most useful form is shown to be, after some manipulation,

$$\iint_{S_0} \dot{B}_r\,\mathrm{d}S + B_r \iint_{S_0} \nabla_H\cdot\mathbf{v}\,\mathrm{d}S = 0 \qquad (2)$$

where the surface S_0 is bounded by a contour of B_r. Thus an additional necessary (but not sufficient) condition is that integrals of $\dot{B}_r$ over any surface bounded by a contour of B_r must vanish if $\nabla_H\cdot\mathbf{v} = 0$. I have computed surface integrals for the 1965.0 IGRF with 10% accuracy; the corresponding values of $|\iint \nabla_H\cdot\mathbf{v}\mathrm{d}S|/\iint \mathrm{d}S$ are presented in Table 3. Each surface of integration encompasses 1 G variations in the main field (2 G between +1 and −1 G), so the surfaces of integration are independent and together cover the whole core. Again the effect of errors in the spherical harmonic coefficients cannot easily be assessed, so the results were compared with sets of random integrals of $\nabla_H\cdot\mathbf{v}$. The random integrals were generated by rotating the secular variation field, keeping the main field fixed, and then integrating $\dot{B}_r$ over the same surfaces. This preserved the frequency content of the secular variation field.

The absolute values of the integrals of $\nabla_H\cdot\mathbf{v}$ per unit surface area for the rotated secular variation fields are also given in Table 3. The two rotations were through 180° in longitude (the transformation $(\theta, \phi) \rightarrow (\theta, 180° + \phi)$) and North to South Pole inversion $((\theta, \phi) \rightarrow (180° - \theta, 180° - \phi))$. Of both sets of random integrals 60% are larger than for the unrotated $\dot{B}_r$ field, and the mean integral of $\nabla_H\cdot\mathbf{v}$ per unit area, regardless of sign, is 62.3 and 38.8 after rotation, but 30.4 for the original integrals. These results suggest that the average horizontal divergence is less than for a random secular variation field.

The results presented here should be relatively insensitive to errors in the IGRF because a statistical treatment has been adopted, but there are problems associated with the downward continuation of the surface fields. The short-wavelength crustal component of the main field and errors in the secular variation are amplified by extrapolation to radii below the surface. Most secular variation models are dominated by small-scale instabilities at the CMB. A fuller report incorporating techniques for reducing these problems will be given elsewhere[7].

Assuming $\nabla_H\cdot\mathbf{v} = 0$ everywhere, the velocity component perpendicular to contours of B_r can be found everywhere on the CMB. An upper limit for the vertical growth rate of velocity, $\partial v_r/\partial r$, at the CMB is $1.44\times10^{-10}\,\mathrm{s}^{-1}$ (averaging $|\nabla_H\cdot\mathbf{v}|$ from Table 1). Benton and Muth[8] recently obtained $1.23\times10^{-10}\,\mathrm{s}^{-1}$ and $0.95\times10^{-10}\,\mathrm{s}^{-1}$ using independent methods. Benton[9] has developed a method similar to part of that described here. The data say nothing about the region below the CMB and convection may still occur deeper down. An alternative explanation of this result is that the core fluid flow is dominated by rotation (geostrophic) and is uninfluenced by strong magnetic fields.

Table 3 Integrals of $\nabla_H\cdot\mathbf{v}$ over surfaces bounded by contours of B_r for the original and rotated $\dot{B}_r$ field

Accumulation of calcic plagioclase in ocean-ridge tholeiite: an indication of spreading rate?

M. F. J. Flower

Department of Geological Sciences, University of Illinois, Chicago, Illinois 60680

Basaltic magma generated at the Mid-Atlantic Ridge (MAR) appears on eruption to be characterized by the widespread accumulation of calcic plagioclase (An_{70-90}) independently from olivine and clinopyroxene[1–5]. Plagioclase accumulation is curiously absent from basalt formed at faster-spreading ridge axes such as the Eact Pacific Rise (EPR)[6–11], and it is interesting to speculate about the possible relationship of this phenomenon to spreading rate. Recent experiments[12] and studies of thermal regime at ocean-ridge spreading axes as a function of spreading rate[13,14] suggest an attractively simple solution to the problem, and point the way to a useful genetic spreading rate distinction for ophiolite rocks of unknown provenance.

The major-element chemical variation of basalts sampled from the Atlantic and Pacific Oceans is depicted schematically in Fig. 1 showing principal mechanisms of post-genetic fractionation identified from least-squares analysis of rock and glass data (1–4). Trends 1–4 are all encountered in Atlantic basalts, but trend 3 (representing cotectic fractionation of plagioclase + clinopyroxene ± olivine) is the prevalent, if not exclusive, trend in Pacific basalts[7–10], with only one recently reported example of trend 1 (ref. 11). Trends 1 and 2 are rarely encountered in Atlantic basalts, but trend 4 is common. However, it is noticeably absent from the Pacific. This trend reflects accumulation of calcic plagioclase in both primitive (MgO-rich) and evolved (MgO-poor) liquids, and is interesting in view of experimental indications[15–18] that plagioclase is at no pressure the sole anhydrous liquidus phase for tholeiitic basalt. Appeal to hydrous melting and high oxygen fugacity as a means to enrich primary magma in normative plagioclase[2–4,15] is probably not justified in view of the low volatile contents measured in ocean-ridge basalts[19,20] and ubiquitous FeO-enrichment trends in MORB glass[21], and we are led to interpret it as an effect of differential phenocryst distribution under anhydrous conditions.

Density relations at one atmosphere are quite complex. Evolved, FeO-rich, basaltic liquid is more dense than MgO-rich, primitive liquid[22] while CaO-rich plagioclase, typically crystallizing from primitive magma, is denser than NaO-rich plagioclase characteristic of evolved magma[12]. In general, however, most plagioclase varieties will be denser than primitive or moderately primitive magmas at pressures less than about 1 kbar (ref. 12). Slow cooling and crystallization in shallow reservoirs would allow plagioclase to accumulate along with denser mafic phases by gravitative separation from the liquid phase. Fujii and Kushiro[12] demonstrate that with increasing pressure

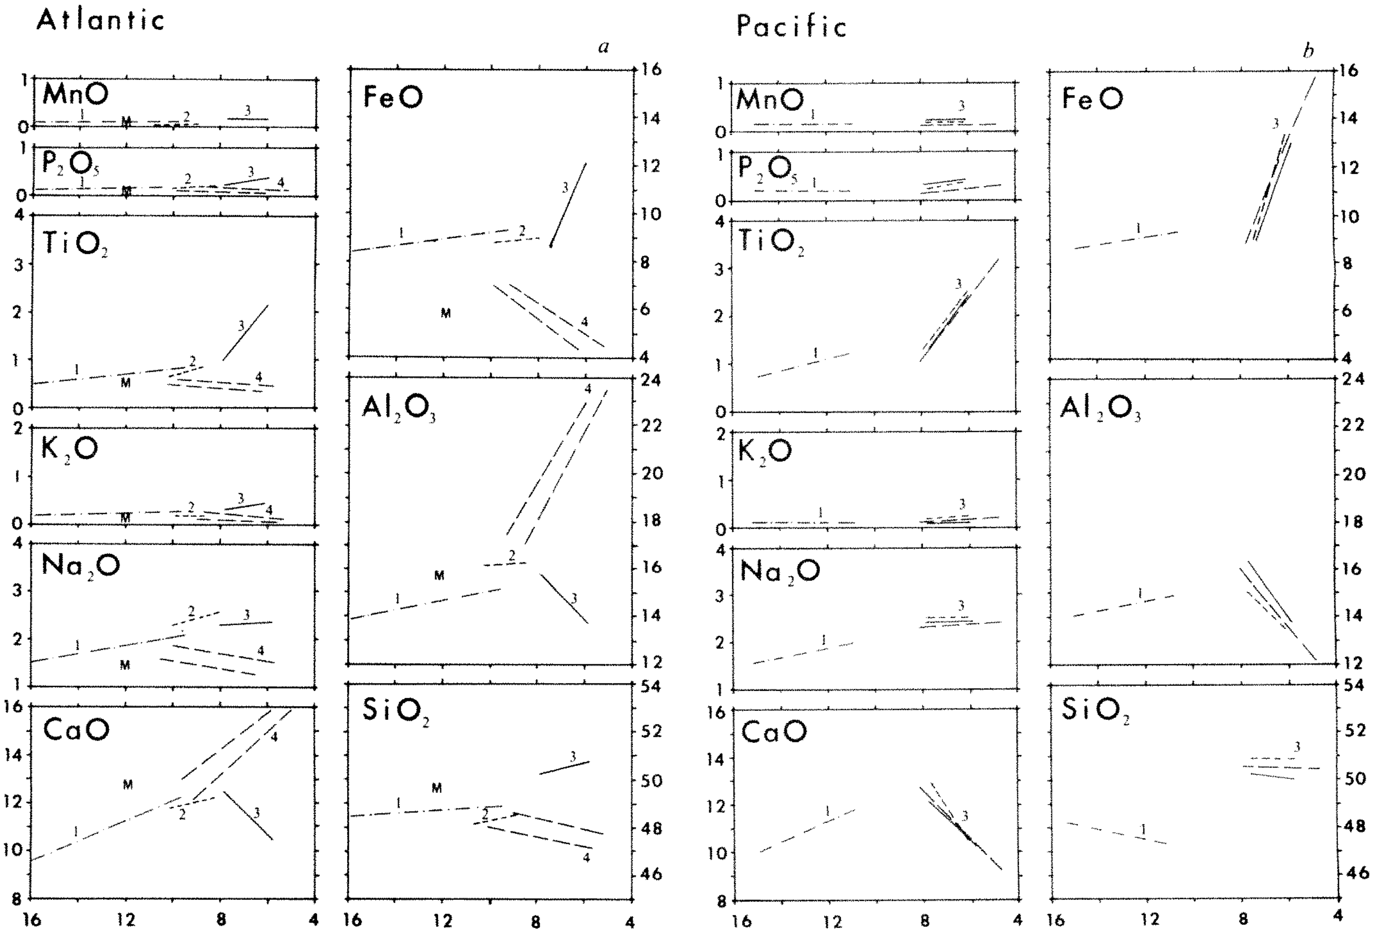

Fig. 1 MgO variation diagrams to illustrate ocean-ridge basalt fractionation, from data cited in *DSDP Initial Report* Vols **34, 37, 45, 46, 51–53, 64** and **65**, and in refs 1–11, 21, 30. Trend lines as follows: (1) olivine control by fractionation or accumulation; (2) olivine + plagioclase fractionation; (3) plagioclase + clinopyroxene ± olivine fractionation; (4) accumulation of plagioclase; (M) accumulation of plagioclase + clinopyroxene + olivine. All types appear in Atlantic basalts; type 4 is rare or non-existent in Pacific basalts.

0028–0836/80/410530—03$01.00

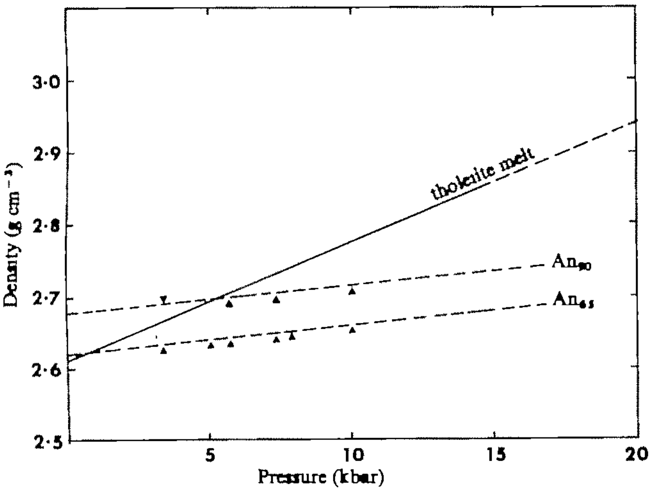

Fig. 2 Density versus pressure relations for Kilauea 1921 olivine tholeiite melt and plagioclase feldspar (after Fujii and Kushiro[12]). Solid lines indicate melt density and broken lines plagioclase density at near-liquidus temperatures. Triangle apices show direction of plagioclase movement.

there is a tendency for plagioclase to float in MgO-rich basaltic liquid, the extent of this tendency depending on plagioclase anorthite content and a significant increase in melt density with pressure. Fujii and Kushiro show that the melt density increase transgresses that of plagioclase (An_{90}) at about 6 kbar (Fig. 2), indicating that pressure is the main requirement for plagioclase flotation. These relations may be confirmed by molar volume calculations[23] and directly through experiment[12].

By implication, therefore, the demonstration of plagioclase flotation independently from mafic phases in erupted basalt may reflect pressure-characteristic fractionation in ocean-ridge magma supply systems. The type and extent of fractionation resulting from the cooling and crystallization of mantle-released magma is determined by the interrelation in *P–T* space of basalt liquidi, ocean-ridge geotherm and magmatic ascent path(s). Experimental evidence[16] and the discovery of both spinel- and plagioclase-lherzolite 'fossil' melt residues[24,25] suggests primary ocean-ridge tholeiite is generated by fairly advanced (15–25%) partial melting, at consistently low water and oxygen fugacities, near the solidus intersection of the plagioclase/spinel-lherzolite transition, that is, at about 1,300 °C and 8–10 kbar pressure. These conditions imply primary liquid compositions with 10–12 weight % MgO, consistent with requirements (for example, olivine compositions of ~ Fo_{90}) for equilibration with common residue lherzolite compositions[26]. More MgO-rich primary compositions[27] would show multiple saturation at about 15 kbar, so that a 'pivotal' region of 10–15 kbar (30–45 km depth) may be defined as a constraint to average ridge axis geotherm configurations (see ref. 28).

Sleep[14] computed isotherm distributions for the upper 10 km of ridge axes in relation to spreading rates and was able to define the relative stability of magma reservoirs. According to Sleep's model, basalt supraliquidus temperatures become increasingly localized along axial geotherms as spreading rate declines. At very slow rates (<1 cm per yr), high-level magma storage appears unlikely and diapiric solid intrusion to the sea floor may occur. These considerations are combined schematically in Fig. 3, and together allow us to postulate:

(1) Two or more stages of crystallization (for example, at 15–25 km and <5 km depth, but depending on model parameters) for magma ascending at slow-spreading (<about 5 cm per yr) axes; and

(2) Exclusively low pressure (for example, < about 3 km depth) crystallization at fast-spreading (> about 5 cm per yr) axes, with direct ascent of superheated primitive magma into shallow axial chambers; as general conditions for the steady-state geotherms depicted.

Although melting and magma uprise are probably episodic (constraints and limitations of this model are discussed in ref. 29), an important qualitative deduction can be made from Fig. 3: that polybaric fractionation, a regime promoting the accumulation of plagioclase in magma, is far more likely at slow-spreading than fast-spreading ridge axes. Further support for the influence of spreading rate on fractionation is provided by the widespread development of phenocryst reaction morphologies in Atlantic, but not in Pacific, basalts[6–10,30–33]. Resorption and oscillatory zoning of plagioclase and clinopyroxene phenocrysts are often attributed to minor variations in P_{H_2O} and/or magma mixing[34], but are equally explicable as due to partial polybaric re-equilibration of higher-pressure liquidus assemblages in cogenetic liquid, during its storage at low pressure.

'Fast-spreading' basalts are invariably aphyric or only sparsely phyric[7–10]. There is no reported occurrence of phenocryst reaction of the type observed in Atlantic basalts, or of plagioclase accumulation. Where present, phenocrysts appear to represent low pressure liquidus crystallization products[7–10]. Interestingly, basaltic crust generated at 'intermediate' spreading rates (for example, at the Gorda Rise, Costa Rica Rift and Gulf of California) shows incipient development of the 'slow-spreading' petrographic tendencies[6]. Finally, intra-flow variation due to plagioclase accumulation during post-eruptive phenocryst movement (flow differentiation) is not significant in comparison to that associated with pre-eruptive fractional crystallization[35], and in any case could not be spreading rate-dependent.

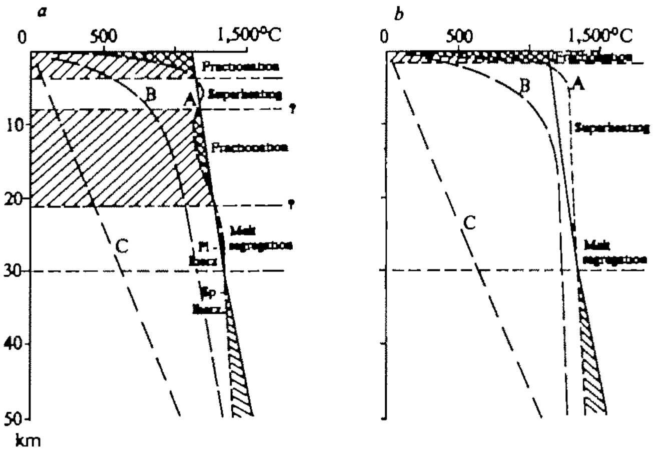

Fig. 3 Thermal gradients interpolated from Sleep's[14] computed isotherm distribution for *a*, a slow-spreading (1 cm per yr) ocean-ridge and *b*, a fast-spreading (5 cm per yr) ridge, and from experimental data for high pressure 4-phase saturation in primitive tholeiite (ref. 16); *a*, at spreading axis, *b*, at 30 km from axis, and *c*, 'average' ocean crust. Schematic depth intervals for fractionation, superheating and melt segregation reflect idealized steady-state spreading. Pl. lherz., plagioclase-lherzolite; Sp. lherz., spinel-lherzolite.

To summarize, I interpret the accumulation of plagioclase in ocean-ridge tholeiite as a comparatively high pressure effect. It is characteristic of slow-spreading axes such as the MAR for which thermal models[13,14] and seismic data[36,37] imply transient, polybaric, fractionation systems, while it is incipient only, or absent, at faster-spreading axes. The oft-cited general enrichment of FeO*, TiO_2 and lithophile elements at the latter (for example ref. 38), attributed to iterative fractionation processes under low f_{O_2} conditions in steady-state magma chambers[39,40], may be in part illusory, and result simply from relative dilution of these components by the accumulated plagioclase in Atlantic basalt. As further confirmation, no systematic chemical distinction of basaltic glass (that is liquid fraction) can be made between fast and slow-spreading axes[21].

Rare earth element and Sr data should be sensitive to plagioclase accumulation. However their interpretation has to consider the combined potential effects of plagioclase and apatite (?) buffering in the melt residue, and removal of plagioclase during fractional crystallization prior to accumulation. It should also be noted that Eu anomalies are comparatively slight for CaO-rich plagioclase in relation to basalt liquid at low f_{O_2} (refs 41, 42). DSDP/IPOD basalts[43-51] show correspondence between coarsely plagioclase-phyric lithologies and small (but significant) positive Eu anomalies, and decreased Rb/Sr, Zr/Sr, Ti/Sr (etc.) ratios as compared to glass or aphyric types.

Evidence for phenocryst-liquid reaction and plagioclase accumulation may be a sensitive indicator of thermal and kinematic conditions at dilating plate margins, and provide important information on the nature of magma supply at ocean ridges. Such petrochemical spreading rate discriminants may be applicable to obducted ocean crust whose conditions of formation at extinct accretionary plate margins are not easily inferred from other criteria.

I thank Bill Melson, Paul Robinson, Hans Schmincke and Tom Wright for useful discussions.

Behaviour of phosphate in estuarine water

J. David Smith & Andrew R. Longmore

Marine Chemistry Laboratory, School of Chemistry,
University of Melbourne, Parkville, Victoria 3052, Australia

The phosphate load in many rivers has been increased through soil disturbance and discharge of sewage and other wastes. Understanding how much phosphate may be removed from the waters of rivers and estuaries to the sediment would aid waste disposal planning. Phosphate carried through estuaries to coastal waters can increase growth of phytoplankton and macroalgae, with effects on fisheries and fouling of structures and beaches. Removal of dissolved phosphate to the sediment in estuaries has been predicted from indirect evidence[1–3], but measurements of dissolved phosphate in estuaries have shown various patterns of behaviour[4–7]. A constant level of dissolved phosphate over a wide salinity range, observed in some estuaries[6,7], has been attributed to buffering of the phosphate by particulate matter. This implies the release of phosphate from particulate matter in some conditions. Seawater held in contact with large concentrations of sediment in laboratory conditions tends to a steady-state level of dissolved phosphate in the range 3–28 μg P l^{-1} (refs 8–11). Our laboratory studies, using a simple estuarine mixing model system, show that inorganic removal of phosphate is likely to be less than 10% in estuaries fed by rivers of iron content near the world average[12].

Phosphate in waters of the Yarra River estuary (Australia) shows large variations related to river flow (Fig. 1). At low flow (21 February 1977) filtered river water contained 185 μg P l^{-1}, and adjacent seawater in Port Phillip Bay[13] contained 90 μg P l^{-1}, with a major input of phosphate part way along the estuary. After a period of high flow (24 June 1977) phosphate in the filtered river water was 32 μg P l^{-1}, with much of the phosphate in the estuary then being supplied from the seawater. This variability of phosphate distribution in the Yarra estuary made interpretation in terms of phosphate behaviour difficult, and a series of laboratory studies were undertaken to elucidate the effects of some of the non-biological factors.

Reactions in estuaries are strongly influenced by interactions of dissolved species with surfaces of suspended particles, and by aggregation of fine particles as salinity increases. Both types of interaction have the effect of converting 'dissolved' species into 'particulate' form, where the differentiation is by whether or not the species passes through a chosen filter. The ionic strength and *p*H of estuarine waters increase with increasing salinity, and a

Table 1 Starting solutions used in estuarine mixing experiments

No.	Humic acid (mg l^{-1})	Iron (μg Fe l^{-1})	Phosphate (μg P l^{-1})
1	0	0	185
2	9.0	0	184
3	1.2	100	160
4 (*a*)	0	750	124
5 (*b*)	0	750	42
6 (*c*)	9.0	750	174
7 (*d*)	0	750	144

Each solution initially contained 200 μg P l^{-1} added as KH_2PO_4. The results show the concentration of phosphate remaining in solutions that had been aged overnight, then filtered. *a*, P added after Fe. *b*, P added before Fe. *c*, P added after humic acid and Fe. *d*, Fe added 5 days before P. Results of adding seawater to unfiltered solutions *a*, *b* and *c* are shown in Fig. 3.

0028-0836/80/410532—03$01.00

complex sequence of reactions ensues. For this reason we designed a laboratory system to simulate the progressive mixing of river water and seawater, as it occurs in an estuary, rather than using the alternative of batch mixing. The Yarra estuary is stratified[14] with mixing occurring at different rates in the horizontal and vertical directions. A time of 1–2 h for doubling of the salinity was estimated for the horizontal direction, and this was later confirmed by J. Hinwood (personal communication). For estuaries that are much larger, especially if they are also well mixed, the half life for salinity change may be longer by orders of magnitude.

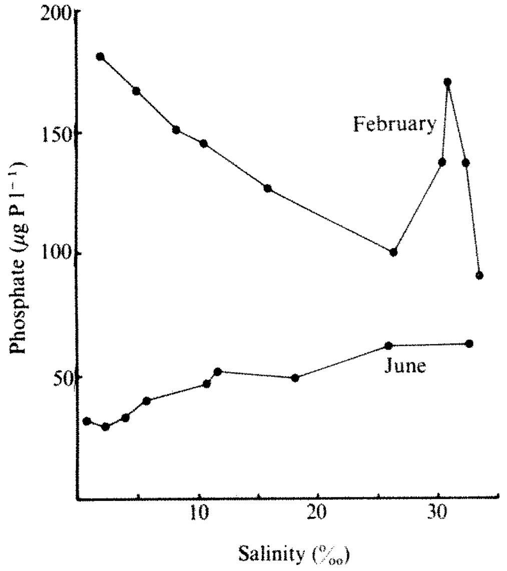

Fig. 1 Variation of dissolved phosphate with salinity in waters of the Yarra River estuary on two occasions in 1977.

In our laboratory model, seawater was pumped at a steady rate into a vessel containing river water, and the mixture pumped out at the same rate to maintain a constant volume. The solution was held at 15 ± 0.1 °C, and stirred at a constant rate to ensure rapid mixing and maintain particulate matter in suspension. The salinity approached that of the seawater exponentially, with a half life for salinity change governed by the rate of flow of the peristaltic pump used and the initial volume of river water. Adding seawater at 3.4 ml min^{-1} to 500 ml of river water gave a half life for salinity of about 90 min. Samples of the outflow were collected for analysis over a period of 5 h. Phosphate was determined colorimetrically[15] on 10-ml samples collected in a graduated syringe and immediately filtered through 0.2-μm pore size Nuclepore filters. All acid-soluble phosphates, including dissolved and colloidal forms, would be included using this method. Iron was determined colorimetrically using ferrozine[16] on filtered samples buffered at pH 5. Humic acid was determined from absorbance at 365 nm, calibrated using humic acid extracted from a large volume of Yarra river water. Salinity was determined to ±0.1‰ from refractive index.

In a laboratory experiment, estuarine mixing was simulated by adding seawater to unfiltered Yarra river water. The seawater from Bass Strait (S = 35.0‰, pH 8.09) contained 4 μg P l^{-1} which was unchanged by filtration. River water collected above seawater influence, contained 26 mg l^{-1} suspended matter and 1.9 mg l^{-1} humic acid and was pH 7.25. The filtered river water contained 99 μg Fe l^{-1} and 124 μg P l^{-1}, compared with 1,800 μg Fe l^{-1} and 214 μg P l^{-1} in the acidified unfiltered water. Thus in the river water sample used, 94.5% of the iron and 42% of the phosphate was associated with the particulate matter. Behaviour of the three components measured during mixing was non-conservative, with iron removal 70% (similar to that reported for other rivers[12,17,18]), humic acid removal 23%, and phosphate removal 6%. The salinity of maximum removal was different for each component (Fig. 2).

A separate series of experiments using synthetic starting solutions allowed the effects of iron and humic acid to be differentiated. When $FeCl_3$ was added to water, the level of Fe detectable after filtration fell very rapidly to less than 5 μg l^{-1}. Iron was stabilized in 'solution' by adding humic acid[19]. We found that 1.2 mg of humic acid per 100 μg of Fe was effective, using a filtered solution of 1.2 mg ml^{-1} Aldrich commercial humic acid in 0.1 M tris(hydroxymethyl)methylamine. The starting solutions listed in Table 1 were allowed to stabilize overnight before use, and the amount of phosphate in a small sample of filtrate was determined immediately before the start of each mixing experiment. The addition of iron after the phosphate caused much greater phosphate removal than occurred when the iron was added before the phosphate. When seawater was added to the unfiltered starting solutions in the estuarine mixing model, dissolved phosphate was essentially conservative in all cases except in the presence of high levels of iron and humic acid. Starting with 9 mg HA, 750 mg Fe and 200μg P l^{-1}, a maximum of 44% of the phosphate was removed from solution (Fig. 3).

The lack of interaction of iron with humic acid is expected as both are anionic. The indifference of iron to dissolved phosphate during estuarine mixing is related to the low concentration of iron in true solution in ionic form, and the chemical stability of hydrated iron oxide colloidal particles after they are formed. When associated with humic acids, iron is present both weakly bound on external surfaces, and as hydrated oxides[20]. The

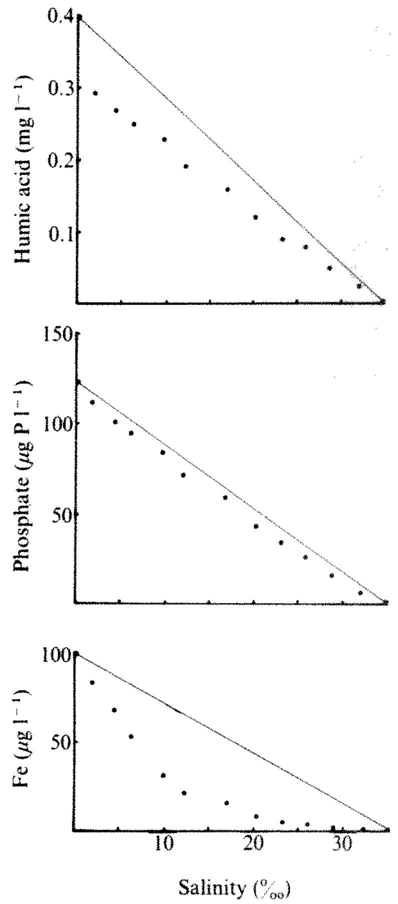

Fig. 2 Changes in concentration of filterable humic acid, phosphate and iron, when seawater was added to unfiltered Yarra River water in a laboratory model system.

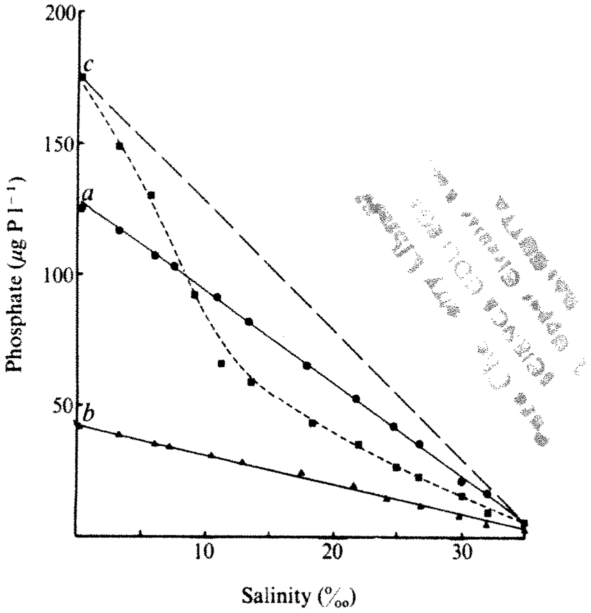

Fig. 3 Concentrations of filterable phosphate observed during addition of seawater to different synthetic solutions in a laboratory model system. Initial solutions were prepared as follows: *a*, phosphate added after iron; *b*, phosphate added before iron; *c*, phosphate added after humic acid and iron. The initial solutions were stirred overnight then used unfiltered.

weakly bound iron seems able to interact with dissolved phosphate. The presence of cations of Na, K, Ca and Mg, which are able to complex phosphate, is expected to increase the stability of dissolved phosphate in real river waters compared with the synthetic starting solutions[21].

A consequence of the observed behaviour of phosphate is that the proportion of phosphate removed from solution in river water, before it enters the sea, will be largely controlled by the sequence and concentrations of the additions of iron, humic acid and phosphate to the river. In rivers exceptionally high in iron and humic acid, up to about half of the dissolved phosphate may be removed by inorganic processes in the estuary. For rivers near the world average concentration of iron[12], dissolved phosphate is likely to show conservative chemical behaviour in the estuary, or removal to only a small degree.

We thank the ARGC and VIMS for financial support.

Changes in spruce composition following burial in lake sediments for 10,000 yr

Philip A. Meyers, Mary J. Leenheer
& Karen M. Erstfeld

Department of Atmospheric and Oceanic Science, The University of Michigan, Ann Arbor, Michigan 48109

Richard A. Bourbonniere

National Water Research Institute, Canada Centre for Inland Waters, Burlington, Ontario, Canada L7R 4A6

Organic matter in lake sediments is a mixture of biological materials from a number of modern sources plus variable amounts of recycled detrital material. Hence, it is usually difficult to distinguish input variations over time from the diagenesis of organic matter. Comparison of old material of known biological origin with younger material helps resolve this problem. We have compared the compositions of wood and needles from a modern white spruce (*Picea glauca*) with those from a white spruce buried for 10,000 yr in a lake bottom. Although the tissues are structurally well preserved, some chemical changes are evident in the old samples. Total fatty acid concentrations decrease by over 90%. Sterol and hydrocarbon concentrations are similar in the modern and 10,000-yr-old wood, but the concentration of sterols is lower in the old needles. Cellulose components in the wood have decreased relative to lignin components, although both types of materials remain in high concentration in comparison to other organic components.

The types of chemical alterations which biological materials experience during early diagenesis in geological settings are important to biogeochemistry. A particularly interesting approach which has been used to describe some of these changes has involved chemical analysis of fossil materials, including bones[1], hair[2], corals[3], and marine plankton[4,5]. In addition, fossilized fruit[6], leaves[7] and wood[8,9] have been studied.

We collected samples of wood and needles from a living white spruce (*P. glauca*) at The University of Michigan Matthaei Botanical Gardens near Ann Arbor. Similar samples were obtained from a tree which had been drowned and buried still erect in a lake bottom 10,000 yr ago. This lake was formed by glacial damming near present-day Marquette, Michigan, and was then quickly filled with sediment[10]. Lipid components of wood and needle samples were extracted in a Soxhlet apparatus with benzene–methanol for 48 h and by alkaline hydrolysis of the extracted samples in methanolic 0.5M KOH in benzene. The two extracts are analogous to the unbound and bound lipids released from sediments by a similar treatment[11]. Each extract was fractionated by thin-layer and column chromatography into fatty acid, sterol, and aliphatic hydrocarbon fractions which were analysed by gas chromatography. Cellulose and lignin components of the modern and ancient wood samples were isolated by hydrolysis with 5M NaOH at 170 °C for 12 h followed by extraction of the degradation products with ethyl acetate. These were analysed as their trimethylsilyl derivatives by GC and GC-MS.

As shown in Table 1, the concentrations of all of the needle components and some of the wood components are lower in the 10,000-yr-old samples than in the modern ones. If the biochemical processes of the white spruce have not changed over the past 10,000 yr, then these differences are due to alterations which have occurred in the older samples during burial in the water-saturated sediment.

Fatty acid concentrations show the greatest differences, and these reflect degradation of acids originally present in the wood

0028–0836/80/410534—03$01.00

and needles. The unbound fractions have greater decreases in concentration than do the bound fractions. Because the unbound acids are extracted readily with solvent, it is probable they exist in forms that are vulnerable to both solution and microbial attack in an aqueous environment such as a lake sediment. There are some differences between the distributions in the wood and needle samples. For example, *n*-tetradecanoic acid is abundant in both the modern and old needles, but not in either wood sample. Also, *n*-docosanoic and *n*-tetracosanoic acids are important components of the unbound acids in the needles, but not in the wood. Another major difference is that the bound acid fraction is an order of magnitude more abundant in the needle samples.

Some of the fatty acid changes are shown in Fig. 1. These compositions are of wood samples; comparable changes were observed in the needles. Relative proportions of unsaturated acids are less in the older wood, whereas the contributions of *anteiso* methyl-branched acids indicative of microbial processes increases. Longer-chain *n*-alkanoic acids seem to be degraded less in the bound acids. Similar differences have been found in fatty acids extracted from modern and 12,000-yr-old Lake Huron sediments[12] and evidently are due to diagenesis rather than changes in input.

Unbound sterol concentrations of the needles indicate a time-related loss of the same magnitude as found in the fatty acids. However, the bound sterol concentration increases from essentially zero to 55 $\mu g\, g^{-1}$, suggesting conversion of some unbound sterols to bound forms. A similar conversion has been reported in young sediments[13,14] and also seems to occur in the wood samples. In the wood, this is accompanied by a small increase in the concentration of unbound sterols. Because diagenetic formation of sterols from other wood components is unlikely, the apparent increase in concentration suggests preferential losses of proteinaceous and saccharide materials, with the result that sterols comprise a larger portion of the old wood. Sterols are evidently only mildly reactive in wood. This also appears to be true in sediments[13–15].

Although at lower concentrations than the sterols, aliphatic hydrocarbons behave similarly. The concentration of unbound hydrocarbons is lower in the old needles than in the new, but higher in the old wood than in the modern sample. Unlike the sterols, no conversion of hydrocarbons from the unbound form to the bound form is evident. In view of the lack of reactive functional groups in saturated hydrocarbons, this is not surprising. Normal alkanes from C_{16} to C_{37} are present in these samples, and no major compositional changes are found between the 10,000-yr-old and modern samples.

The changes in the lipid components of the needles suggest that the unbound lipids are easily removed or degraded over geologically short periods of time in sediments. Much of this material may exist as a waxy coating on the needles which is exposed to microbial degradation, chemical weathering and dissolution. Unbound lipids in wood are internal structural components and therefore not as available to similar attack as are the needle-coating lipids. Even so, wood fatty acids are destroyed or converted to non-acid forms relatively quickly. Evidently, preservation of fatty acids in sediments requires special circumstances, such as anoxic conditions and rapid burial.

Table 1 Extractable components of modern and 10,000-year-old wood and needles from the white spruce *Picea glauca*

	Wood			Needles		
Component	Modern	Old	Δ	Modern	Old	Δ
Fatty acids						
unbound	1,414	77	−1,337	2,785	114	−2,671
bound	27	20	−7	362	237	−125
total	1,441	97	−1,344	3,147	351	−2,796
Sterols						
unbound	311	339	+28	2,159	107	−2,052
bound	2	11	+9	0	55	+55
total	313	350	+37	2,159	162	−1,997
Hydrocarbons						
unbound	27	36	+9	146	54	−92
bound	1	1	0	1	1	0
total	28	37	+9	147	55	−92
Cellulose plus lignin	157	192	+35			

Concentrations of fatty acids, sterols and hydrocarbons are given in μg per g dry wood, cellulose plus lignin components are in mg per g. Δ, Difference between modern and old concentrations.

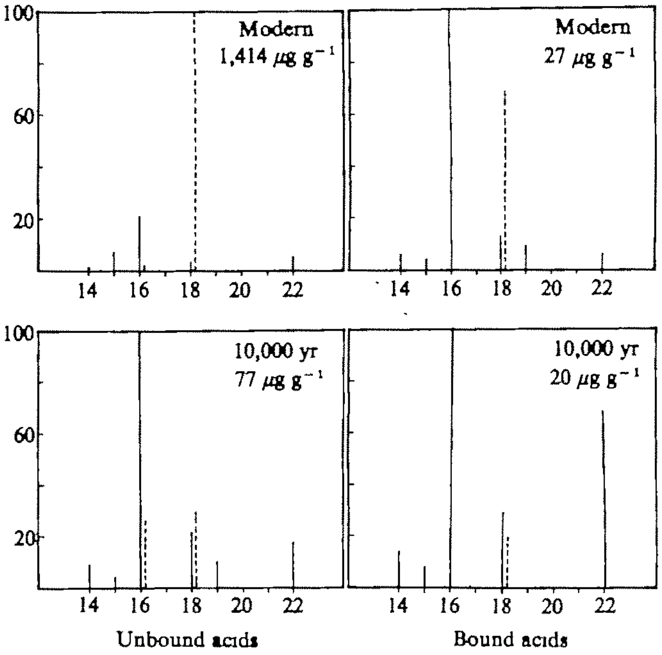

Fig. 1 Comparison of fatty acids extracted from modern and 10,000-yr-old spruce wood. Unbound acids released by Soxhlet extraction; bound acids by alkaline hydrolysis of extracted wood. Compositions are relative to major acid component (100%). Acids are displayed by number of carbon atoms. Solid lines represent *n*-alkanoic acids; dashed lines *n*-alkenoic acids, dotted lines *anteiso* acids.

The cellulose plus lignin component of the old wood is at a higher concentration than in the modern wood. As suggested in the case of wood sterols and hydrocarbons, this indicates less alteration of these materials relative to other, more labile components. Lactic acid is the most abundant compound found in these samples. Oxalic and succinic acids are present as hydrolysis products of cellulose[16]. Their proportions relative to each other are the same in both samples. Vanillic acid and ferulic acid are also found and are derived from lignin[16,17]. The contribution of cellulose components, represented by oxalic and succinic acids, decreases relative to that of lignin components, represented by vanillic and ferulic acids, in the old wood. The ratio of these components changes from 2.2 in the modern wood to 1.2 in the old, indicating a selective loss of cellulose compared to lignin over this 10,000-yr period of burial.

These data give relative rates of degradation of some types of biological compounds buried in lake sediments for short periods of geological time. In woody tissue, the order of alteration is fatty acids $\gg$ sterols $>$ aliphatic hydrocarbons $>$ cellulose $>$ lignin. In spruce needles, the order is fatty acids $=$ sterols $\gg$ aliphatic hydrocarbons. These relative rates can be useful for understanding the cycling of organic matter in young subaqueous sediments. Furthermore, this study describes some woody tissue changes which occur during the early stages of coalification.

We thank Dr W. J. Merry for buried spruce samples, and we acknowledge support from the donors of the Petroleum Research Fund administered by the American Chemical Society and from the NSF (grant EAR 7822432).

Evidence for diploidy and mating in trypanosomes

A. Tait

Department of Genetics, University of Edinburgh, West Mains Road,
Edinburgh EH9 3JN, UK

The question of whether any sexual process takes place at some stage of the life cycle of the trypanosome has often been raised[1,2] and crosses between different drug-resistant strains[3,4] have provided no convincing answer. Multinucleate forms of trypanosomes have been observed by electron microscopy[5,6] but their significance and origin remain obscure. As part of a study aimed at examining the speciation and genetics of the *Trypanosoma brucei* complex of trypanosomes, a series of isolates from a population of *T.b. brucei* have been screened for electrophoretic variation in 19 enzymes. The results of this survey, reported here, provide strong evidence that trypanosomes are diploid and undergo random mating and recombination.

The population used consisted of 17 stocks of *T.b. brucei*, collected in 1969–70 from Lugala, Uganda, by members of the East African Trypanosomiasis Research Organisation (EATRO). Fifteen of the stocks were obtained by injection of infected tsetse salivary glands into mice and subsequent storage of infected blood in liquid nitrogen. The remaining two stocks were obtained by injection of infected blood from wild game into mice, followed by storage in liquid nitrogen. Samples of these stocks were transferred to the Centre for Tropical Veterinary Medicine in Edinburgh. This material was made available by Dr A. Gray and preparations of trypanosomes were obtained by infecting laboratory mice with these stocks, followed by DEAE-cellulose chromatography[7] of infected blood. Extracts from such purified preparations were then subjected to starch gel electrophoresis and the gels specifically stained for the 19 enzymes listed in Table 1.

Electrophoretic variation was observed in eight of the enzymes, which can be subdivided on the basis of the type of variant banding pattern obtained on gels (Table 1). In type I, with, for example, isocitrate dehydrogenase, some stocks produce a single band of enzyme activity at one position on the gel (1CD-1), others produce a single band at a second position (1CD-2), and a third group of stocks produce three bands, two of which correspond to 1CD-1 and 1CD-2, respectively, the third (of double intensity) lying midway between 1CD-1 and 1CD-2 (Fig. 1*a*). In type II, with, for example, alkaline phosphatase, individual stocks may produce single bands at one of two alternative positions (AP-1 or AP-2), whereas other stocks produce two bands at positions corresponding to AP1-1 and AP-2 (Fig. 1*a*). Of the eight polymorphic enzymes found, three are of type I and five of type II (Table 1). Furthermore, four of the type II enzymes show more than two possible positions at which the bands may appear. The variants observed for the eight polymorphic enzymes are shown in Fig. 1*a* and *b*, together with the nomenclature used for their designation. With all these enzymes multiple-banded types were observed, triple banded in the case of type I and double banded in the case of type II.

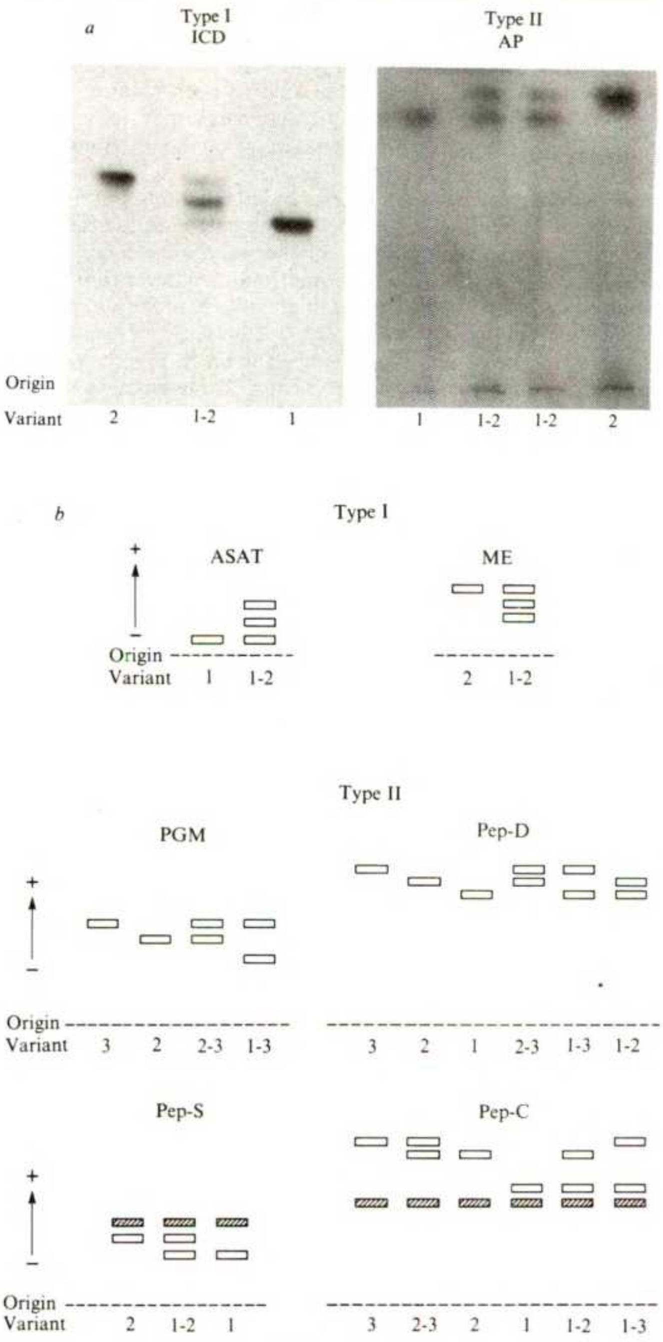

Fig. 1 Electrophoretic enzyme variation in isolates of *T.b. brucei*. *a*, Photographs of starch gel electrophoresis slabs stained for isocitrate dehydrogenase (ICD) and alkaline phosphatase (AP). Samples were run in 9% hydrolysed starch gels in 0.026 M Tris, 0.0033 M citric acid, *p*H 8.6, at 270 V for 3 h. The electrode buffer was 0.66 M Tris, 0.083 M citric acid, *p*H 8.6, and the enzyme activities were stained using published methods[16]. *b*, Diagrams of starch gel electrophoresis slabs stained for aspartate amino transferase (ASAT), malic enzyme (ME), phosphoglucomutase (PGM), peptidase-S (Pep-S), peptidase-C (Pep-C) and peptidase-D (Pep-D). The peptidases are designated on the basis of their di- and tripeptide specificities using the nomenclature described by Harris and Hopkinson[16]; the cross-hatched bands shown on Pep-S and Pep-C gels represent the two invariant peptidases (Pep-A and Pep-B, see Table 1) which overlap in their substrate specificities. Details of the electrophoretic conditions and activity stains will be published elsewhere. The variant bands observed are designated by numbers in order of increasing mobility.

					2	3	(4.7)

Genotypes are designated as described in Fig. 1*a*,*b*. Expected genotype numbers were calculated from the observed allele frequencies assuming that the population was in Hardy–Weinberg equilibrium.

Hybrid banding patterns such as those seen in types I and II enzymes would be expected in a diploid organism in which some individuals are heterozygous for allelic variants of dimeric (in the case of type I) and monomeric (in the case of type II) enzymes. Similar patterns of multiple banding have been shown for many enzymes in, for example, humans[8], *Drosophila*[9] and mice[10], and have been demonstrated to be due to individuals heterozygous for the different alleles. Thus, the observation of both single-banded and hybrid-banded electrophoretic enzyme patterns suggests, by analogy with other organisms, that trypanosomes are diploid and that mating has taken place to generate the 'heterozygous' patterns. Godfrey and co-workers have reported variation in enzyme electrophoretic mobility in several different species and subspecies of trypanosomes[11–13] and with five of the enzymes 'hybrid' band patterns have been reported[14,15] in stocks of the *T. brucei* complex. These results would also support the interpretation of the observations presented here.

An alternative explanation, in the case of the type II enzymes, might be based on the assumption that the two-banded patterns are not due to heterozygotes, but to mixtures of two different clones. It is unlikely, however, that the stocks used in this study were, in fact, such mixtures. Four stocks exhibiting multiple band patterns were cloned by infecting mice with single trypanosomes and the resulting clones examined by starch gel electrophoresis. All four cloned stocks again showed multiple-banded patterns for all eight polymorphic enzymes. Thus, none of the multiple-banded patterns shown by these stocks could have been due to mixtures of clones. Moreover, in the case of the type I enzymes which show three bands of activity, the band of intermediate mobility was only observed in conjunction with the two other bands; nor were there any stocks showing mixtures of the latter without the intermediate band. It is, therefore, assumed that most of the stocks showing multiple-banded patterns were heterozygotes. Based on this assumption, the allele frequencies for these enzyme variants and from them the expected genotype frequencies can be calculated, assuming that the population is in Hardy–Weinberg equilibrium. The observed and predicted genotype proportions are presented in Table 2 for the eight enzymes studied. Clearly, expected and observed proportions are in good agreement and the goodness of fit has been examined using the χ^2 test. The values obtained show that the observed proportions of genotypes do not differ significantly at the 5% level from those predicted by the Hardy–Weinberg equilibrium. This finding, together with the similarity of the banding patterns to those observed with known heterozygotes in other organisms and their occurrence in all variant enzymes examined, provides strong evidence that these trypanosome strains are diploid and undergo random mating.

The data also provide evidence for the occurrence of genetic recombination between genes at different enzyme-determining loci. Classification of the stocks with regard to variants of any two enzymes simultaneously shows (Table 3) that 50 out of a possible total of 90 recombinant types occur, even with the small number of stocks studied. As the number of isolates is small, comparisons have only been made between pairs of enzymes showing two alleles. This strongly suggests that recombination has occurred between the loci specifying these enzymes, as the frequency of possible combinations of variants generated by

mutation in the absence of recombination would be expected to be very low.

The present findings provide strong evidence for diploidy, random mating and recombination between different loci in this population of trypanosomes. Conclusive proof that these organisms are diploid and undergo mating would require the demonstration of heterozygotes produced by hybridization of cells showing different variants of the same enzyme. Experiments are under way (using a range of genetic markers) to demonstrate such hybridization.

This work was supported by a Wellcome Trust Fellowship in Tropical Medicine. I thank Drs A. Gray and T. Jones for making available the trypanosome stocks used in this work, Professor G. H. Beale for helpful discussions and J. Wallace for technical assistance.

Changing proteins on the surface of a parasitic nematode

Mario Philipp, R. M. E. Parkhouse* & Bridget M. Ogilvie

Divisions of Parasitology and Immunology*, National Institute for Medical Research, Mill Hill, London NW7 1AA, UK

Most of the organisms of the phylum Nematoda are free living, but some are animal or plant parasites of major importance to man. During their life cycle all nematodes undergo a series of moults in which they shed an external cuticle, consisting of an outermost membrane-like layer of unknown composition and a series of fibrillar layers similar to collagens[1–4]. Because of this structure, the cuticle has been viewed as an acellular exoskeleton[1] with rather inert molecular components. However, observations have shown that it contains enzymes and sometimes haemoglobin[3,4], and that nutrients are absorbed through it in the infective lárvae and adult stages of *Brugia pahangi*[5]. It is bound by complement and antibody, resulting in the adherence of leukocytes[6], and antibody-dependent cell-mediated reactions damage the cuticule of newborn larvae of *Trichinella spiralis*[7–9] and the microfilariae of *Dipetalonema viteae* and *Litomosoides carinii*[10,11]. We report here that the surface of the cuticle of the parasitic nematode *Trichinella spiralis* expresses protein molecules which change qualitatively following the moulting process, and quantitatively during growth of the worms within one stage. Also, surface proteins are released *in vitro* at a rate which depends on the conditions of culture of the worms.

If the cuticle is functional it should have a more dynamic molecular structure than has so far been described. As parasitic nematodes are exposed to very different host environments during their life cycle, we chose to study surface components of one of them—*T. spiralis*.

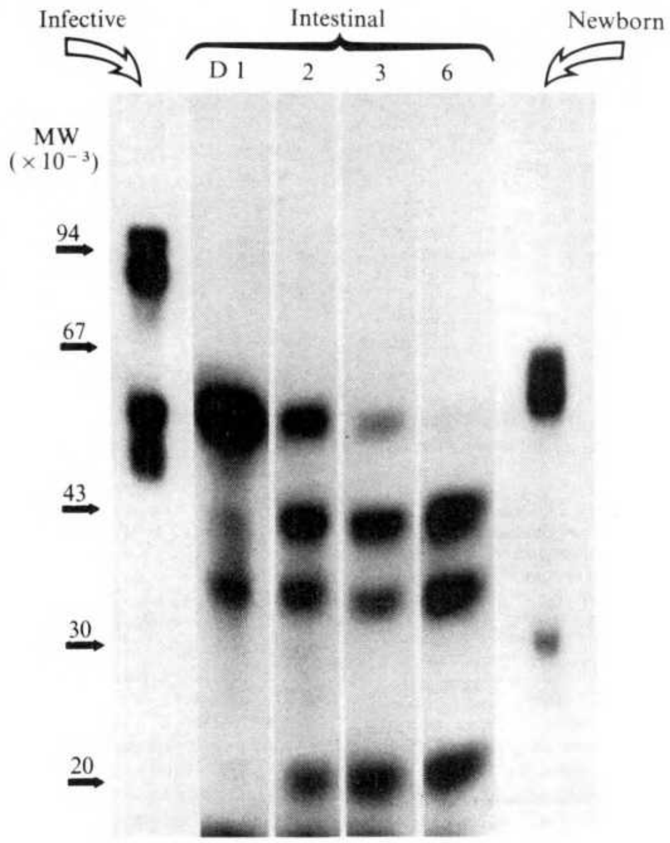

Fig. 1 Radiolabelled surface proteins of the three stages of *T. spiralis*: infective larvae, intestinal worms (removed from small intestines at days 1, 2, 3 and 6 after oral infection), and newborn larvae. About 10^4 infective larvae, 10^4 intestinal worms and 10^5 newborn larvae were washed 10 times in phosphate-buffered saline (PBS) by low-speed centrifugation. To 0.1–0.5 ml of PBS containing the worms and 0.1–1 mCi $Na^{125}I$, chloramine T was added to a final concentration of 0.050 mg ml^{-1}. The mixture was left to react at room temperature for 3 min after which tyrosine was added to react with the uncombined iodine. As judged by mobility, the worms were 90–100% viable after labelling. The worms were washed repeatedly in PBS and then lysed in Tris-P buffer (10 mM Tris-HCl, *p*H 8.3, 50 μg ml^{-1} *L*-1-tosylamide-2-phenylethylchloromethyl ketone, 25 μg ml^{-1} *N*-α-*p*-tosyl-L-lysine-chloromethyl ketone-HCl, 1 mM phenylmethyl sulphonyl fluoride and 2% Na deoxycholate). Intestinal worms and infective larvae were disrupted by homogenization in a glass–glass homogenizer, whereas sonication was used with newborn larvae. The lysates were centrifuged for 30 min at 11,000*g* and the supernatant, containing 90–95% of the total radioactivity (70–80% acid precipitable) was analysed by SDS-polyacrylamide gel electrophoresis (SDS-PAGE). Slab gels containing 7.5% acrylamide were used. The samples were boiled for 5 min in a buffer solution containing 8.3 mg ml^{-1} β-mercaptoethanol and 17.0 mg ml^{-1} SDS. The radiolabelled material has been shown to be located on the worms surface by: (1) Autoradiographs of sections of radiolabelled worms. (2) Absorption of antibodies to the labelled proteins by whole intact worms. (3) Alteration of the rate of turnover of the radiolabelled proteins by neutrophil attachment to the worms' surface (this letter). The SDS-PAGE pattern of the infective larvae was neither altered when the worms were radiolabelled 72 h after the pepsin digestion of rat muscle, nor when radiolabelled worms were incubated with pepsin in similar conditions to the ones used in the digestion process, before homogenization.

0028-0836/80/410538—03$01.00

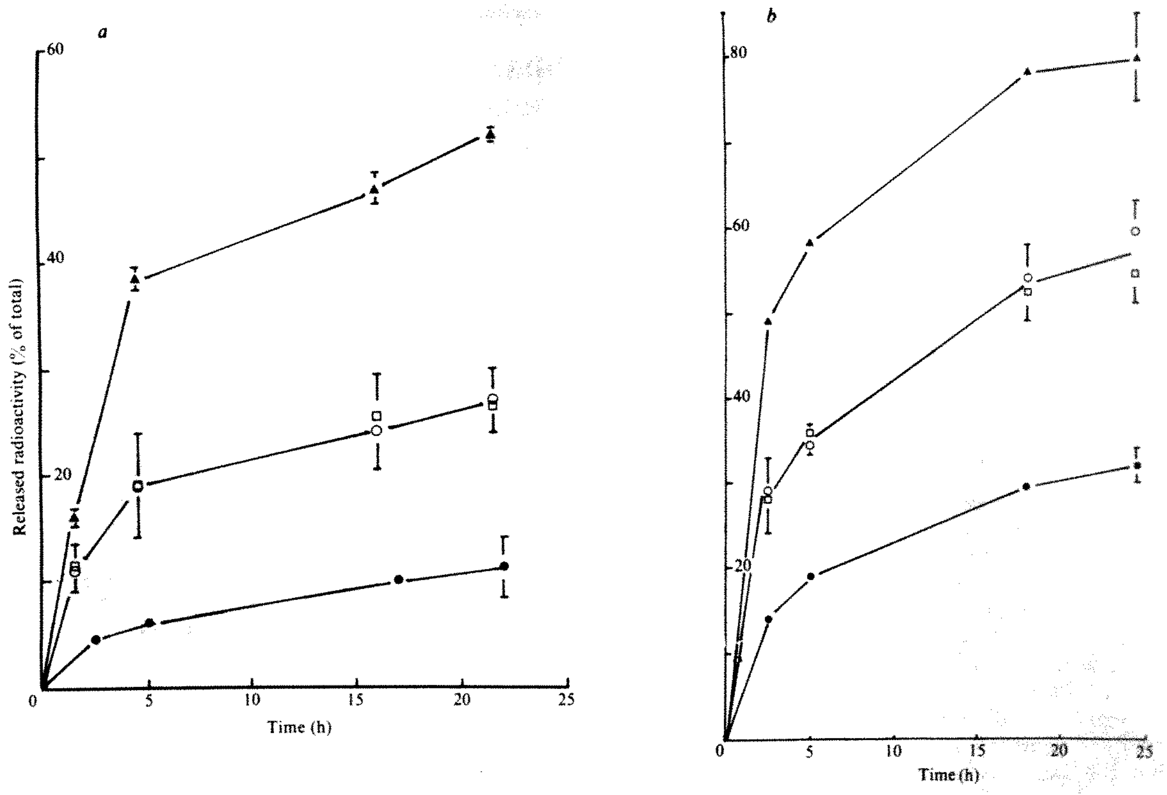

Fig. 2 Release of radiolabelled proteins from the surface of *a*, infective larvae and *b*, intestinal worms (day 2) cultured in RPMI (●), normal rat serum (□), immune rat sera (○), in RPMI and immune rat sera plus rat neutrophils (▲). RPMI 1640 (Gibco) was buffered with $NaHCO_3$ and 20 mM HEPES to *p*H 7.2, and 1×10^5 units ml^{-1} penicillin, 100 μg ml^{-1} streptomycin and 1% glucose were added. About 10 living radiolabelled worms were incubated in 0.4 ml of the above media at 37 °C. Aliquots (5 μl) were taken at intervals and from the measured radioactivity the average released amount was calculated and expressed as per cent of the initial radioactivity of the worms. All data points were determined in triplicate. Error bars represent maximum dispersion of average data points corresponding to duplicate experiments run on two different occasions. Normal rat sera were collected from Sprague–Dawley rats and kept at −20 °C until used. Immune rat sera were taken from Sprague–Dawley rats 21 days after oral infection with 4,000 infective larvae of *T. spiralis* and kept at −20 °C until used. Neutrophils were obtained by peritoneal lavage of Sprague–Dawley rats 4 h after they had been given a peritoneal injection of 10 ml of 1% glycogen (Sigma) in PBS. This yielded about 80% neutrophils. About 2×10^7 cells were used in each experiment.

The life cycle of *T. spiralis* can be reproduced in the laboratory using rodent hosts[12]. The infective larvae, which are found in the striated muscle of vertebrate hosts, can be recovered by enzymatic digestion of the muscular tissue[12]. When such muscle is ingested by another animal, the infective larvae undergo a very rapid series of moults that are completed within 24 h, and the worms become adapted to the small intestine of the host. The intestinal stage worms grow and become sexually mature during the first 5 days after oral infection, and can be recovered from the intestine between days 1 and 6 (ref. 12). The newborn larvae, which are shed from the mature female worms after mating can be recovered by maintaining the 6-day-old intestinal stages *in vitro* overnight[12]. In *in vivo* conditions the newborn larvae make their way through the wall of the small intestine and migrate to striated muscle cells of the new host, thus completing the life cycle.

Infective larvae, intestinal worms and newborn larvae were surface-labelled with ^{125}I-labelled iodine, as described in Fig. 1 legend. The radiolabelled surface components of each stage, including four different phases in the maturation of the intestinal stage, were analysed by electrophoresis on SDS-polyacrylamide slab gels. An autoradiograph of such a slab gel is shown in Fig. 1. All samples are reduced with β-mercaptoethanol.

The infective larvae expressed four main surface proteins of apparent molecular weights (MWs) 47,000, 55,000, 90,000 and 105,000. The intestinal stage presented a qualitatively different pattern of surface proteins. At day 1 after oral infection extracts of labelled worms gave one predominant band of MW 56,000 on the gels. However, unlike the molecule of MW 55,000 seen on infective larvae, this component did not bind to lentil lectin (data not shown). A second fainter band ran at MW ~33,000 (Fig. 1, D1) and traces of radiolabelled protein could be detected at MWs ~40,000 and 20,000 in extracts of 1-day-old intestinal worms.

During maturation of the intestinal worms—days 1 to 6 after infection—an inversion in the relative intensity of the bands took place. Thus, the intensity of the 56,000 MW band decreased, and the 40,000- and 20,000-MW bands became gradually more intense. A slight intensification of the 33,000-MW band could also be seen.

The surface protein pattern of the newborn larvae was qualitatively different compared with the other two stages. There were two bands running at approximate MWs of 58,000 and 64,000, and a pair of comparatively faint bands of MWs 28,000 and 30,000. Thus, whereas the surface proteins changed qualitatively in the transition between any pair of different stages, only quantitative changes took place when the intestinal worms passed through the different phases in their maturation.

Further evidence for a dynamic cuticle came from experiments which showed that the radiolabelled surface proteins of the infective larvae and the intestinal worms may be released by the worms *in vitro*. Worms of either stage were radiolabelled with ^{125}I, as described in Fig. 1 legend, and incubated at 37 °C in four different culture conditions: RPMI, normal rat serum, immune rat serum and immune rat serum plus rat neutrophils. Samples of the culture fluid were taken at intervals and the released radioactivity was expressed as a percentage of the total radioactivity present on the worm's surface at time zero. A plot of the released radioactivity against time for both the infective larvae and intestinal worms is shown in Fig. 2*a* and *b* respectively. Radiolabelled material was released in all four culture conditions. The rate of release was slowest in RPMI. In this medium the infective larvae released the 55,000-MW protein first and then the 105,000-MW component. The other two surface components were not released even after 48 h in culture. The intestinal worms released all four of their radiolabelled surface components in RPMI. The release of proteins was twice as fast when the worms were left in normal rat sera or sera from immune rats (previously infected with *T. spiralis*). This phenomenon cannot be explained in terms of different viability of the worms as they started to die only after 48 h in culture either in RPMI or in rat sera with or without antibody. Antibodies did not seem to affect the rate of protein release although they could be shown to bind to the radiolabelled proteins, in as much as these co-precipitated with immune rat sera and an anti-rat immunoglobulin antiserum.

A marked increase in the rate of release was achieved by co-culturing the worms with rat neutrophils (5×10^7 cells per ml) in the presence of immune rat sera (Fig. 2). Neutrophils adhered to the surface of both the infective larvae and the intestinal worms and began to dissociate from the worms' surface after 3–4 h in culture. Similarly, enhanced release of surface molecules was obtained when the labelled worms were cultured with normal serum and neutrophils (data not shown). These results indicate that the radiolabelled proteins are located on the surface of the cuticle, possibly on the outermost membrane-like layer, as neutrophils can be shown to remove this layer by about 4 h in culture (M. Jungery, personal communication). Furthermore, antibodies which precipitated the radiolabelled proteins also bound to intact worms, and autoradiographs of sections of radiolabelled worms showed that the label was on the cuticle and not on internal organs of the worm (M.P., R.M.E.P. and B.M.O., unpublished observations). The label was not concentrated in any particular region of the cuticle. However, release of protein material from the region of the bacillary pores cannot be ruled out nor confirmed with our present data.

In conclusion, our results indicate that the cuticle of *T. spiralis* is a dynamic organ, the surface of which shows dramatic changes at the molecular level during the moulting process and more gradual modifications during growth within one stage. The qualitative modifications of the surface proteins during a change in stage and antigenic evidence imply that these molecules are stage-specific. The surface proteins are strikingly few in number and are released into the medium when *T. spiralis* is maintained *in vitro*. This suggests that the secretions and excretions of nematodes include proteins shed from the cuticle.

Sharing of an idiotypic marker by monoclonal antibodies specific for distinct regions of hen lysozyme

Dennis W. Metzger, Alexander Miller & Eli E. Sercarz

Department of Microbiology, University of California, Los Angeles, California 90024

Idiotypes have been defined serologically as variable-region markers present on unique subsets of antibody molecules. Most studies involving myeloma proteins and antibody responses in inbred mice have indicated that idiotypy is closely related to antigenic specificity. However, indirect evidence[1-7] suggests that idiotypy can sometimes be dissociated from specificity. In the response to the small monomeric protein, hen egg-white lysozyme (HEL), previous results[8,9] demonstrated that 70–95% of the anti-HEL antibody found in sera of primed and boosted mice is specific for a particular region of HEL and bears a predominant idiotype (IdX-HEL). In this report, hybridoma anti-HEL antibodies tested with well-characterized peptide fragments of HEL show that the IdX-HEL marker can be found on antibodies of completely distinct antigen specificities. Thus, a mode of recognition other than antigenic recognition probably plays a major role in the immune response to HEL.

Hybridoma anti-HEL antibodies were obtained by fusing HEL-primed A/J spleen cells with the nonsecreting BALB/c myeloma cell line, S194/5.XXO.BU.1 (Salk Institute). The growing hybrids were cloned by limiting dilution and monoclonality was confirmed by isoelectric focusing of several individual subclones, all of which for a particular hybridoma were indistinguishable with regard to spectrotype. The activity of the monoclonal antibodies was determined in a solid-phase radioimmunoassay[10] by direct binding to HEL and, in addition, this assay was used with peptide fragments that define discrete segments of the HEL molecule (N–C peptide amino acids 1–17, Cys 6–Cys 127, 120–129; mixed disulphide L_{II} peptide amino acids 13–105; and mixed disulphide L_{III} peptide amino acids 106–129) to assess specificity. The N–C peptide overlaps with L_{II} for a small sequence of five amino acids (13–17); L_{II} and L_{III} are non-overlapping peptides. Bovine ribonuclease, a protein of similar size and charge to HEL, was used to assess background levels of binding. As seen in Table 1, the anti-HEL hybridoma antibody, 6D7, recognizes the L_{II} but not the N–C peptide. Conversely, the hybridoma antibody, 5E4, recognizes HEL and the N–C peptide. In other experiments (not shown) the peptides

Table 1 Specificity of hybridoma antibodies 6D7 and 5E4

	Antigen on plate: radioactivity bound (c.p.m. $\times 10^{-3}$)			
Hybridoma	HEL	Ribonuclease	N–C	L_{II}
6D7	19.7	1.8	1.9	13.2
5E4	17.9	0.7	13.9	0.8

Specificity was assessed in a solid-phase radioimmunoassay in which the wells of microtitre plates (Cooke) were coated with 100 µl of 0.5 mg ml^{-1} antigen at 4 °C overnight. The plates were then flooded with a solution of 1% bovine serum albumin in phosphate-buffered saline (1% BSA–PBS) at room temperature for 1 h to saturate the protein-binding capacity of the wells. Next, the hybridoma supernatants (25 µl) were added to the wells at room temperature for 2 h. Binding was assessed using 50 µl of affinity-purified ^{125}I-goat anti-mouse Ig (10^5 c.p.m. per well) at room temperature for 1 h. Between each specific addition, the plates were washed extensively with 1% BSA–PBS. 6D7 is an IgG2bκ monoclonal antibody and 5E4 is an IgGlκ monoclonal antibody as determined by the solid-phase radioimmunassay using rabbit anti-subclass antisera (provided by Drs J. Teale and N. Klinman, Scripps Clinic and Research Foundation) to assess binding to HEL. The results are expressed as c.p.m. bound per well.

Table 2 Competitive inhibition of the binding of hybridoma antibodies 6D7 and 5E4

Inhibitor	Amount of inhibitor (μg)	Inhibition of 6D7 binding (%)		Inhibition of 5E4 binding (%)	
		HEL plate	L_{II} plate	HEL plate	N–C plate
HEL	0.001	16	24	5	0
	0.1	88	78	45	94
	10	92	88	94	92
Ribonuclease	10	0	0	0	0
L_{II}	10	58	90	0	0
N–C	10	0	0	33	72

Inhibition studies were performed using the solid phase radioimmunoassay and a dilution of hybridoma supernatant capable of 40–50% maximal binding to the insolubilized antigen. The supernatants (25 μl) were preincubated with 25 μl of 1% BSA–PBS to determine control binding or with 25 μl soluble inhibitor at 37 °C for 30 min and then at 4 °C overnight. The mixtures were incubated at room temperature for 2 h in wells coated with the target antigen after which the wells were washed and incubated at room temperature for 1 h with 75 μl of ^{125}I-goat anti-mouse Ig (10^5 c.p.m. per well). As much as 1 μg of L_{II} or N–C did not cause significant inhibition of binding of 6D7 or 5E4, respectively.

were coupled to keyhole limpet haemocyanin (KLH) to increase the sensitivity of detection and significant binding to L_{III}–KLH over background was observed with 5E4 but not 6D7. Thus, 5E4 appears to have specificity for a determinant in the C-terminal portion of HEL (amino acids 120–129) whereas 6D7 is specific for an epitope within the middle region of HEL (amino acids 17–105).

These non-overlapping specificities were confirmed by competitive inhibition of the radioimmunoassay in which the hybridoma antibodies were pre-incubated with the soluble peptides and then assayed for binding to insolubilized HEL and its fragments. As seen in Table 2, L_{II} but not N–C competed effectively for the binding of 6D7 to HEL (and L_{II}). On the other hand, N–C but not L_{II} inhibited the binding of 5E4 to HEL (and N–C). Thus, 5E4 and 6D7 recognize distinct epitypes on the HEL molecule. The need to use the peptides in large amounts relative to HEL for inhibition suggests that the antibodies have greater affinity for the native, conformationally restricted, HEL molecule than for the peptides.

The idiotypy of the two monoclonal antibodies was investigated next. It has been found[8] that anti-IdX-HEL antiserum appears to define an idiotypic marker which resides close to the antigen-combining site and is present on the majority of secondary response anti-HEL antibody. Thus, anti-IdX-HEL antiserum, unlike polyvalent anti-Ig, interferes with the binding of HEL to its antibody in a standard Farr-type assay. The presence of IdX-HEL on 5E4 and 6D7 was assessed in a similar manner using a guinea pig anti-IdX-HEL antiserum raised against a third hybridoma anti-HEL, AD2. AD2, although not showing detectable binding to peptide fragments, does exhibit a relatively rare pattern of cross-reactions different from either 5E4 or 6D7 when tested with a panel of related lysozymes. The anti-IdX-HEL antiserum induced with AD2 appears to be similar to anti-idiotype raised against serum anti-HEL in that it interferes with the binding of HEL to most of the secondary anti-HEL serum antibody of B10.A mice. As shown previously[9], such antibody is specific primarily for the N–C peptide. The anti-IdX-HEL antiserum against AD2 does not affect the binding of an essentially non-HEL cross-reactive lysozyme, human lysozyme, to its antibody (D. W. M., unpublished observations). As seen in Fig. 1, the recognition of HEL by 5E4 or 6D7 was in both cases almost completely inhibited by the anti-IdX-HEL antiserum, presumably by interaction with variable region residues not directly within, but close to, the antigen-combining site. In contrast, an anti-HEL hybridoma antibody, 2G3, which appears to lack the IdX-HEL marker, was almost unaffected by anti-idiotype treatment. We have also found that the individual hybridoma product, 6D7 (as well as 5E4), can remove all the activity from an anti-idiotypic antiserum raised against conventional serum anti-HEL antibody[11]. Thus, two monoclonal antibodies that clearly differ in peptide specificity for a multideterminant antigen can both bear the IdX-HEL marker.

Earlier studies from our laboratory demonstrated that the majority of serum antibody produced in secondary responses of mice shared two properties: specificity for the N–C portion of HEL and presence of a common idiotype, IdX-HEL[8,9]. The small amount of L_{II}-specific antibody that was detectable appeared to lack the IdX-HEL marker. Nevertheless, using hybridoma technology we have been able to detect L_{II}-specific, idiotype-positive antibodies.

In previous work[11,12] we found that anti-HEL antibodies displaying the IdX-HEL marker replace an IdX-negative anti-HEL population appearing early after immunization. This replacement, along with the results in this report, indicates that idiotype selection *per se* plays a pivotal role in the predominance of the IdX-HEL marker during the secondary anti-HEL response. This selection is presumably mediated by an idiotype-specific T cell (IdXTh); in recent work it has been demonstrated that such IdXTh cells are necessary to complement antigen-specific T cells (AgTh) for the optimal induction of an *in vitro* anti-HEL response[13]. The activation of AgTh cells of a particular specificity under the influence of the major histocompatibility complex, in concert with antigen-bridging constraints in T–B collaboration, can explain the prevalent epitypic specificity of the B cell response. This combination of potent idiotypic selection by IdXTh cells and specificity selection by AgTh cells would rationalize the common finding of convergence between idiotypy and antigen specificity. Occasional utilization of less common T-helper cell clones could allow idiotypy to be associated with antibody of different specificity, as we have noted here and as observed in the seminal findings of Oudin and his colleagues[1,2].

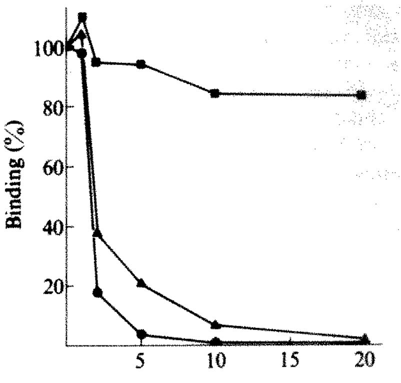

Fig. 1 Inhibition of hybridoma anti-HEL binding to ^{125}I-HEL by anti-idiotype. Anti-IdX-HEL was raised in guinea pigs using affinity-purified monoclonal anti-HEL antibody that was obtained by fusing immune B10.A lymph node cells with the BALB/c myeloma, P3x63Ag8. The resulting antiserum was repeatedly passed over normal (B10.AxBALB/c)F_1 Ig columns. Inhibition curves with anti-IdX-HEL were obtained by adding increasing amounts of anti-idiotype to tubes containing a dilution of hybridoma anti-HEL capable of binding 40–50% of 10ng ^{125}I-HEL. Following incubation, the Ig fraction in each tube was precipitated with 18% (w/v) Na_2SO_4, the precipitates were washed extensively, and the amount of bound ^{125}I-HEL was determined using a Nuclear Chicago γ-counter. Data are presented as the per cent of binding obtained in the absence of anti-idiotype. All values have been corrected for background binding in tubes containing anti-IdX-HEL and ^{125}I-HEL alone. ■ hybridoma antibody 2G3; ▲ hybridoma antibody 6D7; ● hybridoma antibody 5E4.

Effect of cyclosporin A on T-dependent and T-independent immunoglobulin synthesis *in vitro*

T. Paavonen & P. Häyry

Transplantation Laboratory, Fourth Department of Surgery, University of Helsinki, Haartmaninkatu 3, SF 00290 Helsinki 29, Finland

An immunosuppressive cyclic polypeptide, cyclosporin A (CyA), isolated originally from two species of fungi[1], prolongs organ allograft survival in several species[2–7]. However, virtually nothing is known about the pharmacokinetics of this substance and its mode of action in man. We have quantified the impact of CyA on T-dependent and T-independent immunoglobulin (Ig) synthesis of human blood leukocytes *in vitro*, and on the proliferating capacity of the interacting lymphoid cell populations—T cells, B cells, Tμ and Tγ cells. CyA inhibited all responses at approximately equal concentrations. The blast cells rather than resting lymphocytes and/or Ig-synthesizing plasma cells were incapacitated by the drug. As the phagocytosis of accessory macrophages was inhibited only at a 100–1,000-fold higher drug concentration, we conclude that CyA has a relatively specific direct effect on human T and B blast cells *in vitro*.

Pokeweed mitogen (PWM) induces a T-dependent Ig-synthesis in human lymphocytes *in vitro*[8], whereas *Staphylococcus aureus* bacteria act in similar conditions as T-independent mitogens[9]. Present fractionation methods enable adequate separation of the participating lymphoid cell populations and the evaluation of the effect of the drug on the different populations separately.

Human mononuclear leukocytes were isolated via Ficoll–Isopaque (FIP, Pharmacia) density centrifugation[10], treated with iron powder plus magnet[11], washed and plated for culture. Microculture conditions in Falcon Microtest II tissue culture plates with 3×10^5 responder cells and 200-μl volume were used. Pokeweed mitogen (50 μg ml^{-1}, Gibco), or heat-killed, formalin-fixed *S. aureus* Cowan I bacteria[9] at a concentration of 100×10^6 organisms ml^{-1}, were used as mitogens. CyA, which is insoluble in water, was first dissolved in absolute ethanol and added to cultures at indicated final concentrations. All cultures containing CyA contained an equal amount (0.13%) of ethanol, and for controls corresponding stimulations in the absence and in the presence of ethanol were used. The proliferative activity in cultures was measured by 6-h tritiated thymidine (^{3}H-TdR) uptake (2 μCi ml^{-1}, specific activity 6.7 Ci mmol^{-1}; NEN) on the fourth culture day, when the peak proliferative response took place. To quantify the viable cell number, the blastogenic response and the rate of intracellular Ig synthesis, 10^4 chicken red blood cells (ChRBC) were added per culture well before terminating the cultures. The cell viability and the blastogenic response were assessed from May–Grünwald–Giemsa-stained cytocentrifuged cell smears[11]. The degree of intracellular Ig synthesis was analysed from similar smears with fluorescein isothiocyanate-conjugated, 1:30 diluted, polyvalent anti-human Ig (anti-IgM, -IgA, and -IgG; Dakopatts) using standard fluorescence technology. The results were expressed as number of blast cells, lymphocytes or cells containing intracellular Ig per 100 (autofluorescent) ChRBC. The release of Ig was quantified by indirect protein A (Pharmacia) plaque assay on the sixth culture day[12], and expressed as plaque-forming cells (PFC) per 10^5 cultured cells.

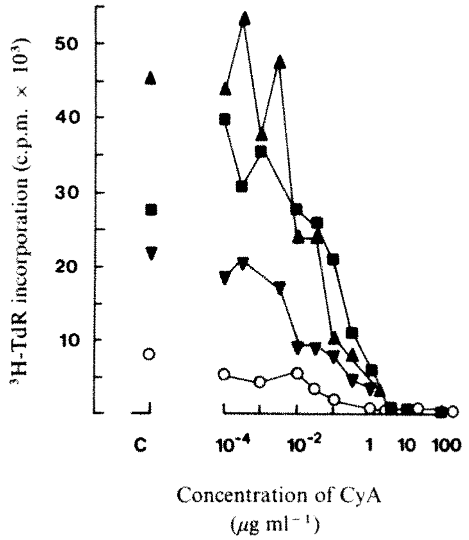

Fig. 1 Effect of increasing concentrations of CyA on the proliferative response of T- (■), Tμ- (▼), Tγ- (▲), and B-enriched (○) blood white cell populations to PWM. C indicates PWM-stimulated control cultures in the presence of 0.13% of ethanol. Mean incorporation in controls containing no mitogen was approximately 1–3 × 10^2 c.p.m.

Fractionation of T and B cells and the Tμ and Tγ subsets of T cells was modified from Moretta *et al.*[13]: FIP-isolated iron powder-treated blood mononuclear cells were rosetted with 2-aminoethyl-isothiouronium bromide-hydrobromide-treated sheep red cells[14] and centrifuged over FIP. The interphase (B-enriched) fraction contained >95% lymphocytes and 1–2% of monocytes. Approximately 80% of the lymphocytes expressed surface Ig. The red cells from the bottom (T-enriched) fraction were lysed[11] and the white cells were rosetted with IgG-coated erythrocytes as described[13]. After another centrifugation over FIP, the Tμ-enriched fraction was collected from the interphase while the bottom fraction was enriched for Tγ. In three separate experiments we found that the B cells, without recombination with T cells, were entirely unable to synthesize Ig after stimulation with PWM. When the B cells were recombined with T cells, the response was reconstituted. Recombination with Tμ cells induced an even higher Ig response, whereas recombination with the Tγ-enriched population was distinctly inferior in helper capacity. This indicates enrichment of helper cells in the former and either lack of helper cells and/or enrichment of suppressor cells in the latter T-cell fraction.

Mononuclear phagocytes were enriched via fractionation over a discontinuous Percoll gradient. Percoll (Pharmacia) was mixed with 10% fetal calf serum (FCS) containing RPMI-1640 medium (Gibco) at the following concentrations (%): 37.5, 40.0, 42.5, 45.0 and 47.5, and layered in five layers. 100×10^6 FIP-isolated blood leukocytes were layered in the RPMI-FCS medium on the top layer, the tubes were centrifuged for 45 min at 267*g* and the fractions from the five interphases were recovered. Mononuclear phagocytes were distributed primarily at the first interphase, where 90–95% of all leukocytes were monocytes according to morphological criteria.

In four experiments we stimulated the blood leukocytes with PWM or *S. aureus* bacteria, and quantified the rate of ^{3}H-TdR incorporation, intracellular Ig synthesis and release of Ig into culture medium (Table 1). CyA suppressed all responses at

‡ Number of ingested staphylococci per cell after culture of the blood monocytes for 48 h in the presence of various concentration of CyA. Mean numbers of triplicate determinations ±s.d. Exposure time of staphylococci, 30 min; CyA present in the culture medium also during phagocytosis.

equal concentrations, regardless of whether PWM or staphylococci were used as mitogen.

Blood leukocytes were then enriched for T and B cells, and the T cells further to Tμ and Tγ cells. The effect of the drug was assessed separately on the proliferative response of the different cell populations. In all three experiments the drug suppressed at equal concentrations the proliferative response of T, Tμ and Tγ and B-enriched cell populations to PWM (Fig. 1). Whereas a distinct suppression of the blastogenic response (Table 2) was observed already at a concentration of 10^{-3}–10^{-2} μg ml^{-1}, the viability of resting lymphocytes was not decreased until a concentration of 1–10 μg ml^{-1} was reached.

Because both mitogens are monocyte-dependent, a possibility still existed that CyA affects through the accessory cells, that is, through the monocytes present in the culture. Blood monocyte-enriched population was therefore cultured for 48 h in the presence of different concentrations of CyA, and 200 × 10^6 staphylococci were added per culture. After an additional 30-min incubation, coverslips were removed from the bottom of the culture vessels, washed, stained and the average number of intracellular staphylococci was quantified (Table 3). Prior culture with CyA has virtually no effect on the phagocytic activity of blood monocytes up to a concentration of 1 μg ml^{-1}. At 10 μg ml^{-1}, the rate of phagocytosis was reduced by ~50%.

Altogether, CyA suppressed at equal concentrations both T-dependent and T-independent Ig production. The distinctly inhibitory concentration *in vitro*, 1 × 10^{-1} μg ml^{-1}, was somewhat smaller than the expected maintenance concentration in the blood after peroral administration at the recommended dose of 17 mg per kg per day (ref. 7). Moreover, all participating populations of lymphoid cells—T helper cells, T suppressor cells and B cells—were equally sensitive to this drug, and the drug suppressed far better the blastogenic response than killed resting lymphocytes in cultures. Because blood monocyte phagocytosis was not affected by previous culture with CyA, we consider it unlikely that the drug effect is mediated through the accessory mononuclear phagocytes[15,16].

Although species differences may exist, our results contradict the finding of White *et al.*[17] on porcine lymphocytes that T cells are more sensitive than B cells to CyA *in vitro* and those of Gordon *et al.*[18] who demonstrated that colony formation by transformed human 'B lymphocytes' is marginally less sensitive to CyA than colony formation by (a fraction of) T lymphocytes. However, our results are compatible with these of Borel *et al.*[2]

who demonstrated that haemagglutinating antibody response in the mouse was suppressed at approximately equal doses compared to skin graft rejection, and with the observation of Allison *et al.* (unpublished, cited in ref. 4) that T and B blastogenic responses of human lymphocytes are affected at equal drug concentrations. The rather selective effect of CyA on T and B blast cells is compatible with the 'decloning' hypothesis suggested for CyA as a possible mode of action in certain species[4,19], though not yet in man.

We thank Dr J. F. Borel and Sandoz Pharmaceuticals for supplying the drug. This study was financed by NIH-NIAID grant no. 1 RO1 AM26882-01.

An immunological suppressor cell inactivating cytotoxic T-lymphocyte precursor cells recognizing it

Richard G. Miller

Department of Medical Biophysics, University of Toronto, and the Ontario Cancer Institute, 500 Sherbourne Street, Toronto, Ontario, Canada M4X 1K9

The immune system does not normally react against self components. Originally, it was postulated that self-reactive cells were somehow deleted or blocked[1]. More recent thinking[2,3] is that such cells are suppressed by regulatory networks similar to those limiting the immune response against non-self determinants. Both mechanisms may exist[4,5]. I describe here a type of suppression more closely related to the first postulate. In the *in vitro*, one-way, mixed lymphocyte reaction (MLR), cytotoxic T-lymphocyte precursor cells (CLP) from the responder population give rise to cytotoxic T-lymphocytes (CL) capable of lysing target cells from the stimulator population[6–8]. A subpopulation of cells in the spleen of athymic nude mice can, when added to such cultures, inactivate CLP capable of recognizing either the H-2 antigens or TNP modifications of the nude spleen. Regarding the nude spleen cells, activation of self-react ve cells is being prevented.

Table 1 presents measurements of the cytotoxic activity produced in various MLRs which demonstrate the suppression phenomenon. In experiment 1, line 1, BALB/c ($H-2^d$) lymph node (LN) cells produce a good cytotoxic response against both irradiated RNC ($H-2^k$) spleen cells and irradiated B10 ($H-2^b$) spleen cells. Addition of BALB/c.nu spleen cells to the cultures has little effect on either response (line 2). However, addition of RNC.nu spleen cells leads to a significantly lower cytotoxic response against the RNC spleen cells but not against the B10 spleen cells, that is, suppression is observed when the added nude spleen cells are syngeneic to the stimulator cells (line 3). The ability of the added nude spleen cells to cause suppression is destroyed by subjecting them to one freeze–thaw cycle (line 4), implying that the suppression results from a physiological process. These results confirm previous, more extensive studies[9] in which it was shown that B.nu or $(A \times B)F_1$.nu spleen cells suppress an A anti-B response but not an A anti-C response where A, B and C represent three H-2-different mouse strains.

An anti-TNP-modified self response can also be suppressed. Addition of RNC.nu spleen cells to RNC anti-RNC-TNP cultures suppressed the response if the RNC.nu spleen cells were also TNP-modified (Table 1, expt 2). The same nude cells, whether TNP-modified or not, were equally competent at suppressing a BALB/c anti-RNC response. Similar results have been obtained using B6.nu spleen cells in the B6 anti-B6-TNP response and BALB/c.nu spleen cells in the BALB/c anti-BALB/c-TNP response. Controls established that the effector

		$(RNC \times C57BL/6)F_1$ anti-RNC-TNP response	$(RNC \times C57BL/6)F_1$ anti-B6-TNP response
Expt 4	0	216 ± 47	50 ± 10
	RNC	216 ± 27	54 ± 10
	RNC-TNP	109 ± 16*	27 ± 5*

Each entry is the mean ± s.e.m. cytotoxic activity for a group of eight microcultures, each culture containing LN cells as responder cells, 3×10^5 irradiated (1,500 rad ^{137}Cs γ rays) spleen cells as stimulator cells and 10^5 (expt 1 and expt 3) or 3×10^5 (expt 2 and expt 4) nude spleen cells being tested for their ability to suppress the response of the culture. For the anti-H-2 responses (BALB/c anti-RNC, BALB/c anti-B10), 3×10^4 responder LN cells were used; for the remaining cultures, 2×10^5 responder LN cells were used. When required, TNP-modified cells were produced by the method of Shearer *et al.*[17] as described previously[18]. Each experiment included control groups containing nude spleen cells and stimulator cells but no responder LN cells. None of these control groups developed significant cytotoxic activity. Each culture was in 0.2 ml of α-minimal essential medium supplemented with 10% fetal calf serum, 5×10^{-5}M 2-mercaptoethanol and 10 mM HEPES buffer as described in detail elsewhere[9]. After 5 days of incubation at 37 °C, cultures were assayed for cytotoxic activity by addition of 3×10^3 ^{51}Cr-labelled target cells obtained from a 2- or 3-day culture of spleen cells identical to the stimulator cells incubated with concanavalin A ($2 \mu g \, ml^{-1}$). Fractional specific ^{51}Cr release, p, defined as (observed release − spontaneous release)/(total releasable − spontaneous release) was measured as previously described[9] and re-expressed as cytotoxic activity $= -100 \ln (1-p)$. This transformation re-expresses the ^{51}Cr release so that the cytotoxic activity is directly proportional to the number of CL present rather than the number of target cells destroyed[19]. An entry of 10 corresponds to 10% specific ^{51}Cr release; an entry of 100 to 63% specific ^{51}Cr release. NT, Not tested.

* Response significantly less ($P < 0.05$) than for the corresponding group of cultures not containing added nude spleen cells.

† The RNC.nu spleen cells were frozen and thawed once before addition to the cultures.

‡ Cultures identical to those of the preceding two lines, that is, with and without added BALB/c.nu-TNP spleen cells, were mixed immediately before assaying for cytotoxic activity.

0028–0836/80/410544—03$01.00

cells produced were T-cells that lysed syngeneic cells only after TNP modification.

The suppression produced by adding nude spleen cells could occur at one or more of several levels of the MLR and subsequent cytotoxicity assay: (1) a reduction in the number of CLP activated; (2) a reduction in the number of CL produced per activated CLP; or (3) a reduction in the measured cytotoxic activity per CL either as a result of suppression of the lytic efficiency per CL or as a result of competitive inhibition of the lysis of the labelled target cells by remaining unlabelled nude spleen cells. Experiment 3, Table 1, provides evidence against the last possibility: adding suppressed cultures to non-suppressed cultures just before the assay for cytotoxicity produced no decrease in the measured cytotoxic activity. To distinguish between possibilities (1) and (2), limiting dilution analysis was used to measure both the frequency of CLP (f_{CLP}) and the relative number of CL produced per activated CLP in the presence and absence of nude suppressor cells. In the culture conditions used, the CLP is the least frequent required cell so that failure of a culture to respond indicates that the culture contained no CLP[8,10]. The probability, P, of this happening is, from the first term of the Poisson distribution, given by $P = \exp(-f_{CLP}N)$ where N is the number of LN cells cultured. The cytotoxic activity developed in replicate RNC anti-RNC-TNP cultures containing varying numbers of RNC LN responder cells, fixed numbers of RNC.nu spleen cells with or without TNP modification, and fixed numbers of RNC-TNP stimulator cells, was measured and each culture was scored as responding or non-responding. Figure 1*a* shows the fraction of non-responding cultures and Fig. 1*b* the mean cytotoxic activity per culture, both as a function of N. The values for f_{CLP} determined from Fig. 1*a* are shown in Table 2 (line 1). The value for f_{CLP} is about two and a half times lower when the added nude spleen cells have been TNP-modified. From the slopes of the lines in Fig. 1*b* and from the measured CLP frequency, one can calculate the mean cytotoxic activity produced by the clone of CL from a single CLP (Table 2). It is significantly greater in the presence of suppression. Possibly the suppressor cells can suppress regulator cells, limiting the magnitude of the response[2] as well as preventing CLP activation. Note that this effect tends to reduce the overall observed suppression in cytotoxic activity. Equivalent results were obtained on analysing the BALB/c anti-BALB/c-TNP response (expt 2, Table 2).

The suppression observed in an anti-H-2 response also results from a reduction in the number of CLP activated (expt 3, Table 2). RNC.nu spleen cells were used to suppress a BALB/c anti-RNC response. To obtain a population of nude cells which would not suppress, but at the same time provide the accessory cells required to meet the conditions of the limiting dilution assay[8], use was made of a previous observation[9] that slowly-sedimenting nude spleen cells contain the required accessory cells but are relatively free of suppressive activity, whereas rapidly-sedimenting cells are enriched in suppressive activity. Thus, the CLP frequency measured in the presence of nude spleen cells (line 1) is about half that measured in the presence of slowly-sedimenting (2–4.5 mm h^{-1}) nude spleen cells (line 2). Addition of rapidly-sedimenting (4.5–9 mm h^{-1}) nude cells to the slowly-sedimenting nude cells restores the suppression.

The cytotoxic response against syngeneic target cells which have been virus- or TNP-modified is known to be H-2 restricted, that is, the CL obtained produce preferential lysis of target cells sharing both the modification (virus or TNP) and H-2 with the original stimulator cells[11,12]. I therefore investigated whether TNP-modified nude spleen cells could suppress an anti-TNP response on an H-2-different background. Care was taken to avoid possible allogeneic effects by working only with parent–F_1 strain combinations. In expt 4, Table 1, RNC.nu spleen cells, with and without TNP modification, were added to either an (RNC×C57BL/6)F_1 anti-RNC-TNP response or an (RNC×C57BL/6)F_1 anti-C57BL/6-TNP response. The RNC-TNP-modified nude cells suppressed both responses about twofold. Similar results were obtained on adding RNC.nu spleen cells, with and without TNP modification, to an (RNC×C57BL/6)F_1 anti-(RNC×C57BL/6)F_1-TNP response and measuring the response against RNC-TNP and C57BL/6-TNP target cells. I conclude that the nude spleen suppressor cells show at most a slight preference for suppression of a TNP-modified self response in which the H-2 of the nude cells and stimulator cells is shared. In experiments using the same microculture technique as used here to analyse TNP cross-reactivity at the level of single clones of CL (ref. 18), it was found that at least 40% of clones specific for the TNP-modified stimulator could also lyse a particular H-2-unrelated, TNP-modified target cell. Thus, the apparent lack of H-2 restriction seen here might merely reflect cross-reactivity at the level of the CLP, the presumed site of action of the suppressor.

Table 2 Frequency of CLPs activated in presence and absence of suppressor cells

Expt	Response	Added nude spleen cells	Precursor frequency per 10^6 LN cells	Cytotoxic activity per clone
1	RNC anti-RNC-TNP	RNC	182 (135–246)	5.3 ± 0.5
		RNC-TNP	73 (53–100)	6.7 ± 0.7
2	BALB/c anti-BALB/c-TNP	BALB/c	105 (65–168)	7.1 ± 0.7
		BALB/c-TNP	37 (24–58)	8.7 ± 0.9
3	BALB/c anti-RNC	RNC (unfractionated)	594 (413–853)	11.5 ± 1.2
		RNC (2–4.5 mm h^{-1})	1,140 (877–1482)	5.4 ± 0.5
		RNC (2–4.5 mm h^{-1}) +RNC (4.5–9 mm h^{-1})	468 (348–629)	8.3 ± 0.8

The frequency of CLP and cytotoxic activity per clone were measured by limiting dilution analysis as in Fig. 1, experiment 1 is the result from analysing this figure. The frequency was calculated using the method of Porter and Berry[20], the bracketed numbers after the entry giving 95% confidence limits. Experiment 2 was performed in an identical manner. In experiment 3, the added RNC.nu spleen cells were fractionated by velocity sedimentation[21] and either 3×10^5 unfractioned, or 3×10^5 (2–4.5 mm h^{-1}), or 3×10^5 (2–4.5 mm h^{-1}) plus 10^5 (4.5–9 mm h^{-1}) nude spleen cells tested for their ability to produce suppression.

What is the mechanism of the observed suppression? To obtain suppression, the added nude cells must carry the antigen against which the response is directed, H-2 in the case of an anti-H-2 response and TNP in the case of an anti-TNP response (Table 1). The reduction in cytotoxic activity results from a reduction in the number of CLP activated rather than the number of progeny CL produced per activated CLP (Table 2). Only a subpopulation of all the cells in nude spleen is capable of inducing the suppression (Table 2, expt 3 and ref. 9). The simplest explanation for these observations is that nude spleen contains a cell subpopulation which, when recognized by a CLP, sends a signal to the CLP which inactivates it. Whether the inactivation is reversible or permanent, that is, whether, using the terminology of enzymology, inhibition is competitive or non-competitive, is not firmly established at the present time although attempts to rescue inactivated CLP have so far been unsuccessful. Not all CLP can be inhibited. Although the cytotoxic activity developed in a primary MLR can be strongly inhibited, the inhibition is never complete and a secondary MLR cannot be inhibited at all (J. J. Rusthoven and R. G. M., unpublished observation). The inactivating signal could well be a factor although, if so, it must be short range or good fits would not have been obtained in the Poisson limiting dilution analysis (Fig. 1). In addition, attempts to isolate such a factor have so far been unsuccessful. The most novel feature of the model just outlined is the direction of recognition triggering the suppression: the CLP triggers its own suppression by recognizing the suppressor cell. An alternative point of view is that the suppressor cells have a repertoire of receptors capable of recognizing receptors which can recognize self antigens, that is, the suppression takes place through recognition of anti-self idiotypes[13]. Against this model is the observation (Table 1) that the suppressor cell can suppress an anti-self-TNP response only after the suppressor cell has been itself TNP-modified. It is

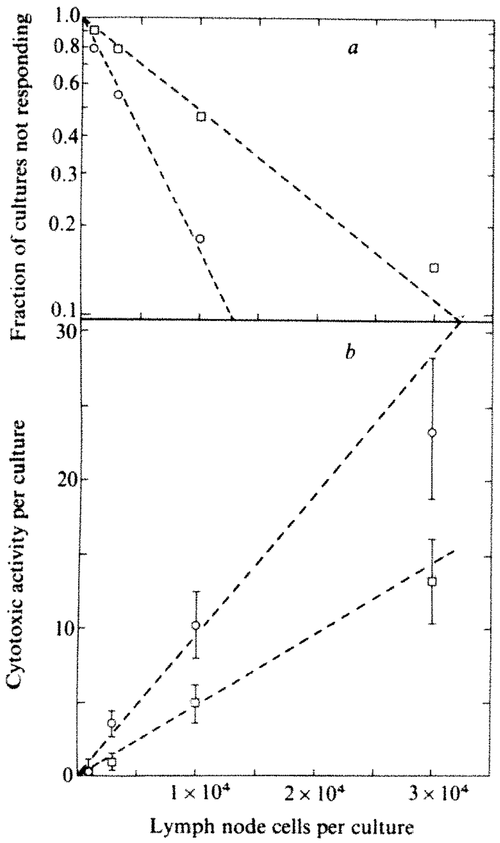

Fig. 1 Limiting dilution analysis of the RNC anti-RNC-TNP response in the presence of either RNC.nu (○) or RNC.nu-TNP (□) spleen cells. Groups of from 32 to 48 microcultures were set up and assayed as in Table 1. Each group contained RNC LN responder cells as indicated on the abscissa, 3×10^5 irradiated (1,500 rad) and TNP-modified RNC spleen stimulator cells, and 3×10^5 RNC.nu spleen cells either with or without TNP modification. The fraction of non-responding cultures as a function of the number of LN cells is plotted in *a*. A culture was scored as responding if the measured ^{51}Cr release was greater than the mean + 2 s.e.m. measured for a group of cultures from which LN responder cells were omitted. The mean cytotoxic activity per culture (including both responding and non-responding cultures) is plotted in *b* as a function of the number of LN responder cells cultured.

difficult to see how TNP modification could create a new receptor.

The unique properties of the suppressive activity described here are that the suppression is specific for antigens carried by the suppressive cell population and that the suppression is at the level of CLP activation in the responding cell population. Other tissues besides nude spleen have been screened for suppressive activity with the above properties. It is not seen in normal spleen[9,14] but is found in both normal bone marrow[14] and in thymus[15]. The suppressive activity found in bone marrow may represent a precursor population which seeds to thymus in a normal mouse but seeds to spleen in the athymic nude mouse. In the thymus, the suppressor cell could inactivate cells recognizing it before such cells are exported to the periphery. Such a mechanism is required in models for the somatic development of the specificity repertoire in which reactions against self antigens, particularly self H-2[16] are instrumental in driving the somatic variation of the repertoire. Cells reactive against foreign antigens might also be inactivated if the foreign antigens were incorporated on the surface of the suppressor cell.

Intercellular communication patterns are involved in cell determination in early molluscan development

S. W. de Laat*, L. G. J. Tertoolen*,
A. W. C. Dorresteijn† & J. A. M. van den Biggelaar†‡

* Hubrecht Laboratory, International Embryological Institute, Uppsalalaan 8, 3584 CT Utrecht, The Netherlands
†Zoological Laboratory, State University of Utrecht, Padualaan 8, 3508 TB Utrecht, The Netherlands

The formation of specialized intercellular junctions, allowing the passage of low-molecular weight regulatory molecules, has been considered as a possible mechanism for regulating embryonic development[1,2]. No direct evidence for this concept has been found in early development. In the mollusc *Pattella vulgata* it was demonstrated that cell positioning and specific cellular interactions are key factors in the control of early development[3,4]. We have now investigated the pattern of intercellular communication during early development of this embryo by intracellular iontophoresis of the fluorescent dye Lucifer Yellow CH. We demonstrate that the formation of regional- and temporal-specific cell-to-cell coupling is correlated with the determination of the mesentoblast—the stem cell of the mesoderm—and the establishment of dorso-ventral polarity.

In the *Patella* embryo, bilateral symmetry is indicated from the 4-cell stage by the appearance of a distinct cross-furrow between the blastomeres B and D and a minimal one between the blastomeres A and C (Fig. 1)[3,4]. At the early 32-cell stage the macromeres of each quadrant (3A–3D) still have the capacity to develop into mesentoblast or to form entodermal structures. At this stage these macromeres protrude into the embryo after the withdrawal of the originally centrally placed second quartet cells. As a consequence of their relative positions only one of the cross-furrow macromeres (then denoted as 3D) is in contact temporarily with the overlying animal micromere quartet ($1a^{11}$–$1d^{11}$), and it is this event which determines that this macromere will form the mesentoblast and establishes dorso-ventral polarity perpendicular to the cross-furrow. Cell deletion experiments have demonstrated that such contact between the

macromere 3D and the micromeres $1a^{11}$–$1d^{11}$ is a prerequisite for these determinative events[4].

The intercellular transfer of low-molecular weight fluorescent dyes and intercellular electrical coupling are both considered as indicators for the presence of functional cell-to-cell pathways, structurally recognizable as gap junctions in the apposed junctional membranes[5,6]. Complex intercellular communication patterns can be easily recognized from intercellular transfer of fluorescent dyes. Lucifer Yellow CH (molecular weight 457.3) is extremely suitable for this purpose[7], and its intercellular transfer was found to be associated with the presence of gap junctions and electrical coupling[8,9].

As we were interested in the possible role of intercellular coupling in mesentoblast determination, we restricted the dye application to the vegetal macromeres, both cross-furrow and non-cross-furrow, from the 4-cell stage to the 32-cell stage. Because the dorso-ventral polarity of the embryo is absent at early cleavage stages, identification of the injected cell had to be made by the unequal cleavage pattern at the sixth cleavage[3]. In all cases Lucifer Yellow CH spread through the entire cell within 5 min. No effects were observed on subsequent cell division. Until the 16-cell stage initial dye spread was restricted consistently to the impaled cell, demonstrating the absence of functional intercellular communication pathways (Fig. 1*a*–*d*). This situation changed completely after the fifth cleavage. At the 32-cell stage, as the vegetal macromeres start to protrude into the embryo, intercellular junctions that allow the passage of Lucifer Yellow CH form between the vegetal macromeres and their neighbouring cells (Fig. 2*a*, *b*), with the exception of the junctional membrane between the macromere 3D and the blastomere $2d^2$, its neighbour on the future dorsal side (Figs 2*c*, *d* and 3). This communication pattern demonstrates the establishment of dorso-ventral polarity at the 32-cell stage. No dye transfer was observed from the macromeres 3A, 3B or 3C to animal cells. In contrast, the macromere 3D becomes exclusively coupled to the central animal micromere quartet $1a^{11}$–$1d^{11}$ at this stage (Fig. 2*e*, *f*). Although the non-central micromeres $1a^{12}$–$1d^{12}$, surrounding the central micromeres $1a^{11}$–$1d^{11}$, will come temporarily into contact with any of the macromeres at the early 32-cell stage, no dye transfer was observed between them. We conclude that only the central micromere quartet is able to become coupled to a macromere. By observing whole embryos we could not exclude the possibility that there is minimal dye transfer from the macromeres to their second neighbouring cells. However, histological sections of embryos fixed after dye injection confirmed that dye transfer from the macromeres is restricted to their neighbouring cells (Fig. 3).

Our results further demonstrate the binding of Lucifer Yellow CH to cytoplasmic components, as suggested previously[7]. With dye application at the 4-cell stage, fluorescence is only detectable in all daughter cells at later stages (Fig. 1*e*–*h*), in contrast to the dye spread observed immediately on dye injection into a macromere at the 32-cell stage (Fig. 2). From such considerations we estimated that cytoplasmic binding prevents further transfer of Lucifer Yellow CH in these embryos within about 30 min.

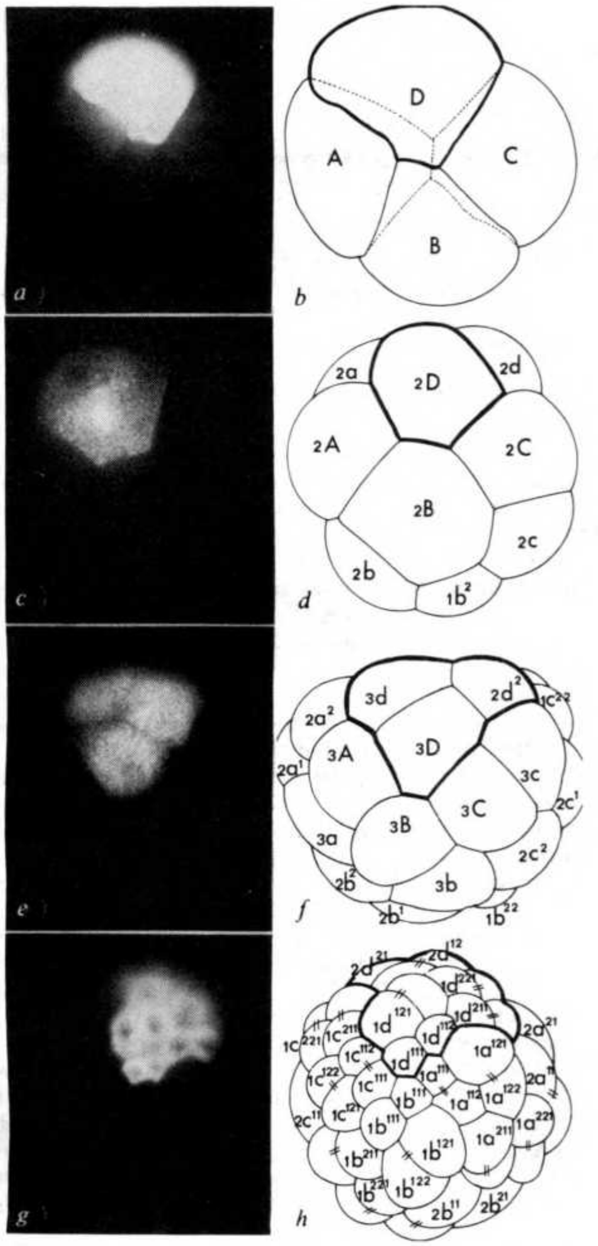

Fig. 1 Left column: micrographs of unfixed embryos of *Patella vulgata* after iontophoresis of Lucifer Yellow CH into one of the two cross-furrow cells at the 4- and 16-cell stage ×200. Right column: diagrams of the corresponding cell patterns. Before the mid 32-cell stage the two cross-furrow quadrants cannot be distinguished. For convenience the labelled quadrant has then been designated as D. *a*, *b*: 4-cell embryo 20 min after labelling of the D-cell; no dye transfer to adjacent cells. *c*, *d*: 16-cell embryo 20 min after labelling the macromere 2D; no dye transfer to adjacent cells. *e*, *f*: Vegetal view of the same embryo as in *a* at the onset of the 32-cell stage; only the progeny of D (3D, 3d, $2d^2$; others not visible) have received the dye. *g*, *h*: Animal view of the same embryo as in *a* at the 60-cell stage; only the micromeres of the injected quadrant have received the dye at successive cell divisions. *P. vulgata* used in this study were collected in the region of Point aux Oies, near Wimereux in France. Eggs were obtained, fertilized and cultured as described elsewhere[3]. The eggs were decapsulated by a brief treatment with acidified sea water, *p*H 3.8. Conventional glass microelectrodes were used for intracellular application of Lucifer Yellow CH. The tip of the micropipette was filled with a 3% aqueous solution of the dye whereas the remainder of the electrode system was filled with 3 M LiCl. Electrode resistances reached values greater than 200 MΩ. The dye was introduced iontophoretically into the cell by applying repetitive hyperpolarizing current pulses of 5 nA and 1.5 s with a time interval of 0.5 s for 3 min. The microelectrodes were connected to a high-impedance pre-amplifier equipped with a bridge circuit so that the membrane potential (−35 to −65 mV, depending on developmental stage) could be recorded as an indicator for proper cell penetration. During dye iontophoresis the embryos were observed in a dissecting microscope. The spread of fluorescence was observed in a Leitz Orthoplan epiluminescence fluorescence microscope with a ×32 objective (excitation: 450–490 nm; emission: >515 nm). Photomicrographs were taken on Kodak High Speed Ektachrome or Kodak High Speed Recording Film, with exposure times of 15–30 s.

The present results are the first demonstration that the formation of specific intercellular communication patterns is involved in cell determination in early development. In *P. vulgata* the interaction between the central micromere quartet and a macromere at the 32-cell stage results in the determination of this macromere as the stem cell of the mesoderm and of the dorso-ventral polarity in the embryo. The reported formation of intercellular communication pathways, probably via gap junctions, is exactly correlated in time and space with these determinative events. In this embryo the relative positions of the macromeres, together with the capacity of the cells along the animal–vegetal axis to become coupled at the 32-cell stage, determine bilateral symmetry.

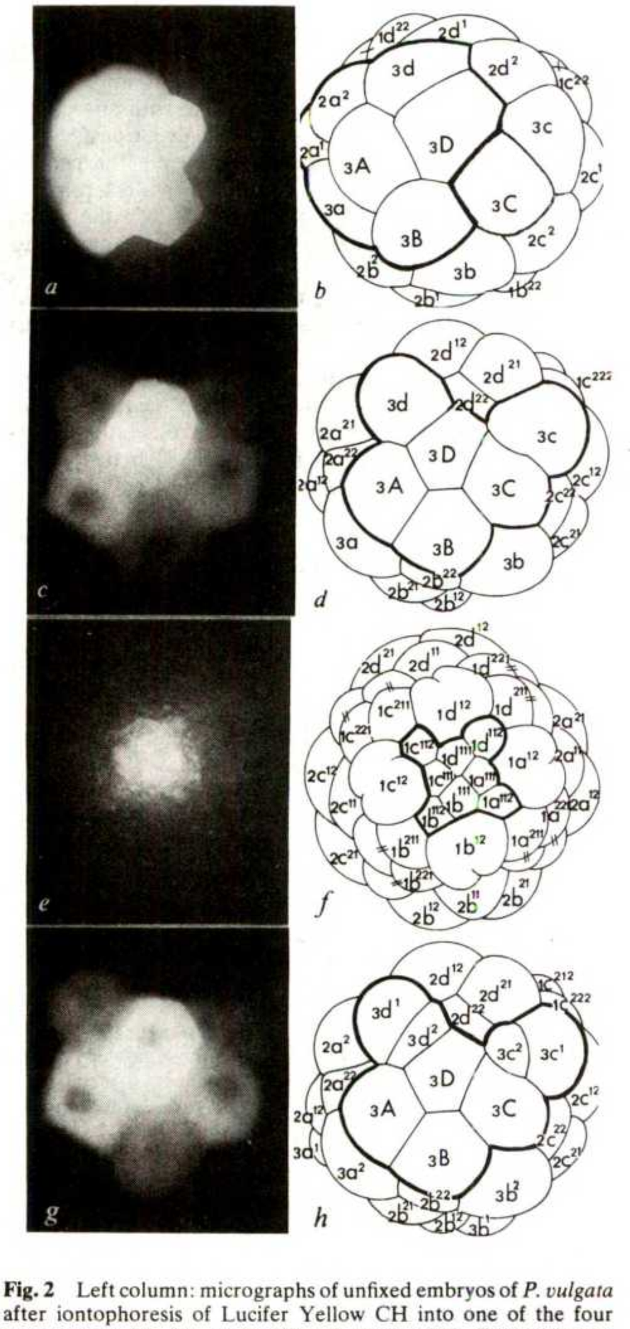

Fig. 2 Left column: micrographs of unfixed embryos of *P. vulgata* after iontophoresis of Lucifer Yellow CH into one of the four macromeres 3A–3D at the 32-cell stage ×200. Right column: diagrams of the corresponding cell patterns. *a*, *b*: Vegetal view of a 32-cell embryo after labelling macromere 3A; dye transfer is restricted to all adjacent cells. *c*, *d*: Vegetal view of a 32-cell embryo after labelling the macromere 3D; dye transfer is restricted to adjacent cells, except 2d^2. *e*, *f*: Animal view of the same embryo as in *c*, about 45 min later; dye transfer from the macromere 3D to the central animal micromeres. *g*, *h*: Vegetal view of the same embryo as in *c*, about 60 min later; no further transfer in comparison with *c*.

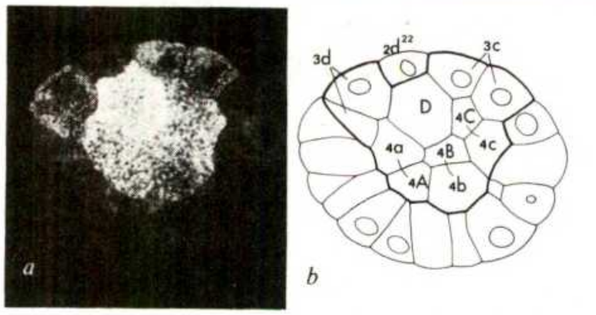

Fig. 3 *a*, Micrograph of an oblique section through an older stage of the same embryo as in Fig. 2*c*, *e*, *g* after fixation in 4% formaldehyde in 0.1 M cacodylate buffer, *p*H 7.4. Dye is only detectable in cells adjacent to the injected macromere 3D (3A, 3B, 3C, 3d, 3c) and their progeny, except its dorsal neighbour 2d^{22}. *b*, Diagram of the corresponding cell pattern ×200.

We thank Dr W. W. Stewart for his gift of Lucifer Yellow CH.

Pharmacological specificity of brain histamine H_2-receptors differs in intact cells and cell-free preparations

M. Dam Trung Tuong, M. Garbarg & J. C. Schwartz

Unité 109 de Neurobiologie, Centre Paul Broca de l'INSERM,
2ter, rue d'Alésia, 75014 Paris, France

Despite increasing evidence that histamine may be a neurotransmitter in brain, the functions of putative histaminergic neurones are just beginning to be known[1,2]. Both H_1- and H_2-receptors[3] seem to be present in brain[4–7] and histaminergic neurones might control arousal mechanisms or carbohydrate metabolism, via H_1-receptors[8–11]. The actions mediated by cerebral H_2-receptors are less clear mainly because available agonists and antagonists[3,12–15] do not cross the 'blood–brain barrier'. However, on a histamine-sensitive adenylate cyclase from guinea pig brain homogenates with pharmacological properties similar to those of H_2-receptors[16,17] compounds like tricyclic antidepressants or promethazine were extremely potent antagonists[18,19] suggesting that this might represent the molecular basis of clinical antidepressant activity[19]. Although electrophysiological[20] and behavioural[21] studies partially confirmed that one of these compounds, amitryptiline, could block cerebral histamine receptors in the living animal, their potency as H_2-antihistamines has never been precisely established in intact brain cell preparations. Histamine strongly stimulates cyclic AMP synthesis in brain slices but, in contrast with homogenates, both H_1- and H_2-receptors are involved[4,5,22]. As compounds like promethazine are potent H_1-antihistamines[7,8], we have developed a test specific for H_2-receptors consisting of the stimulation of cyclic AMP accumulation by impromidine, a potent and highly selective H_2-receptor agonist[14], in slices from guinea pig hippocampus and using it find that H_2-receptors differ considerably in their drug discriminatory properties from those mediating the stimulation of adenylate cyclase activity in homogenates.

0028–0836/80/410548—04$01.00

The involvement of both H_1- and H_2-receptors in the cyclic AMP response to histamine in hippocampal slices was shown mainly by the biphasic rightward shift of concentration–response curves to this amine in the presence of low concentrations of mepyramine, a pure H_1-antihistamine and the additive responses to H_1- and H_2-agonists[22]. This is further illustrated when considering the antagonism of histamine-induced accumulation of the nucleotide in slices of guinea pig hippocampus by promethazine, a potent H_1-antihistamine[23], also recently shown to inhibit the brain histamine-sensitive adenylate cyclase[19,24]. Thus the response to a fixed concentration of histamine (50 μM) is inhibited in a clearly biphasic manner by promethazine in increasing concentrations (Fig. 1). Approximately 50% of the response is inhibited with an IC_{50} of 0.13 μM whereas the remaining is abolished, after a plateau, for much higher concentrations (IC_{50} = 32.9 μM). A similar pattern of inhibition is obtained with cyproheptadine leading to IC_{50} values of 0.03 μM and 12 μM (not shown). Among the two components of the histamine response distinguished by promethazine, the first is likely to be mediated by H_1-receptors as proposed earlier[22], whereas the second is mediated by H_2-receptors as shown by the antagonism of highly selective agonists of these receptors. One of them, impromidine, is a particularly useful tool being 40–50 times as potent as histamine on a variety of biological responses mediated by H_2-receptors but having negligible potency on H_1-receptors[14]. As shown in Fig. 2a, this compound stimulates cyclic AMP accumulation in hippocampal slices with an EC_{50} value of 0.17 μM, that is, approximately 60 times lower than that of histamine and this effect is competitively antagonized by cimetidine, a H_2-antihistamine, with a K_i value of 0.95 μM similar to that found against histamine on peripheral H_2-receptors[13]. Thus, both its relative potency and the inhibition constant of cimetidine indicate that H_2-receptors mediate the stimulation elicited by impromidine. Promethazine antagonizes in a monophasic manner the response to impromidine with an IC_{50} of 22 μM (Fig. 1). This antagonism is of the competitive type as shown by the parallel rightward shift of the concentration–response curve to this H_2-agonist (Fig. 2a) and a K_i value of 6.2 μM is thus obtained. This value closely agrees with that (5.5 μM) obtained from the IC_{50} value regarding the second component of the response to histamine (Fig. 1). Again, as shown in Fig. 2b, a closely similar K_i value for promethazine (5.2 μM) is obtained regarding its apparently competitive antagonism of the response to dimaprit, another selective agonist of H_2-receptors possessing approximately 20% of the potency of histamine on peripheral biological systems[15].

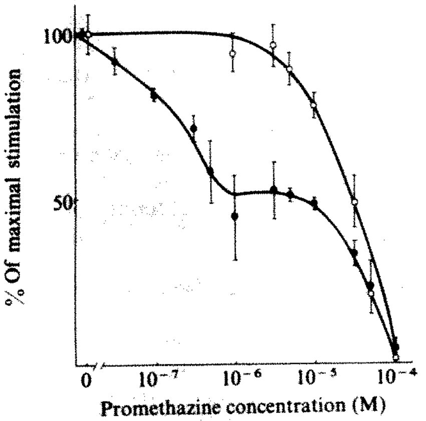

Fig. 1 Inhibition by promethazine of histamine- and impromidine-induced stimulation of cyclic AMP accumulation in slices from guinea pig hippocampus. Hartley guinea pigs were killed by decapitation and slices (250 μm thick) were prepared from hippocampus. Pooled slices from four animals were incubated for 30 min at 37 °C in Krebs–Ringer bicarbonate medium (40 ml per g of tissue) under a constant stream of O_2:CO_2 (95:5) in a Dubnoff metabolic shaker. Slices were then washed twice with fresh medium and 200 μl aliquots (about 500 μg protein) were distributed in incubation tubes containing promethazine. After 15 min at 37 °C under agitation, histamine or impromidine were added and a further 15-min incubation was performed. Incubations were terminated by sonication of the slices and heating for 10 min at 95 °C. Cyclic AMP concentration was determined by the protein kinase binding assay[39]. Results are expressed as per cent of stimulation elicited in the absence of promethazine. Each point represents the mean ±s.e.m. of six values obtained in two separate experiments. The accumulation of cyclic AMP (in pmol per mg protein) was 64.0±2.7 for 50 μM histamine and 39.7±2.2 for 1 μM impromidine. Basal levels (11.6±1.3 pmol per mg protein^{-1}) were not altered in the presence of promethazine in concentrations up to 100 μM. The IC_{50} values for promethazine, established by log-probit analysis, were 0.13 μM and 32.9 μM against histamine, and 22.0 μM against impromidine. Assuming competitive inhibition, the K_i values were calculated according to the equation[40] $K_i = IC_{50}/1 + S/EC_{50}$, where S represents the concentration of histamine or impromidine. The EC_{50} value of histamine was 10 μM (ref. 22) and that of impromidine, 0.16 μM (mean of values obtained in seven experiments similar to that of Fig. 2). K_i values were 0.022 μM against the first component of the response to histamine, 5.5 μM against the second component and 3.0 μM against impromidine. ●, Histamine (50 μM); ○, impromidine (1 μM).

Table 1 Comparison of the potency of several drugs on the histamine H_2-receptor-mediated stimulation of cyclic AMP formation in slices and homogenates from guinea pig hippocampus

	Inhibition constants (K_i, μM)	
Drugs	Slices	Homogenates
H_2-receptor antagonists		
Cimetidine	0.62	0.89* 0.60†
Metiamide	0.82	0.89* 0.87†
H_1-receptor antagonists		
Promethazine	3.0	0.030‡

Mianserin	10.0	0.065*
Miscellaneous		
Chlorpromazine	5.9	0.041‡
Haloperidol	>10	0.081‡
Quinacrine	>10	0.26*

The antagonist potency on slices was determined against 1 μM impromidine as described in Fig. 1 legend. Drugs were added 15 min before impromidine in at least five concentrations and IC_{50} values obtained by log-probit analysis of mean data from sextuplate experiments. The EC_{50} mean value of impromidine in the absence of antagonist (0.16±0.02 μM) was determined from seven different concentration-response curves. None of the drugs modified the basal level or interacted with the kinase binding assay. The K_i values for homogenates are from: *, ref. 24; †, ref. 18; ‡, ref. 19; §, ref. 17.

Hence, the almost identical K_i values of promethazine regarding inhibition of the responses to histamine and to two H_2-agonists differing largely in chemical structure as well as in relative potency strongly support the conclusion that this compound has H_2-antihistamine activity. However, it is important to notice that its potency in the guinea pig hippocampal slice preparation is approximately 100-fold lower than on the histamine-sensitive adenylate cyclase of the cell-free preparation from the same region of guinea pig brain[19,24].

It was, therefore, of interest to determine the potency of other drugs that have been shown to strongly inhibit the cyclase in the cell-free preparation[18,19,24]. Most of the compounds listed in Table 1, including H_1-antihistamines, tricyclic antidepressants, antipsychotics and quinacrine, an inhibitor of histamine-N-methyltransferase, are significantly less potent on intact cells than on homogenates, the difference being, in most cases, more

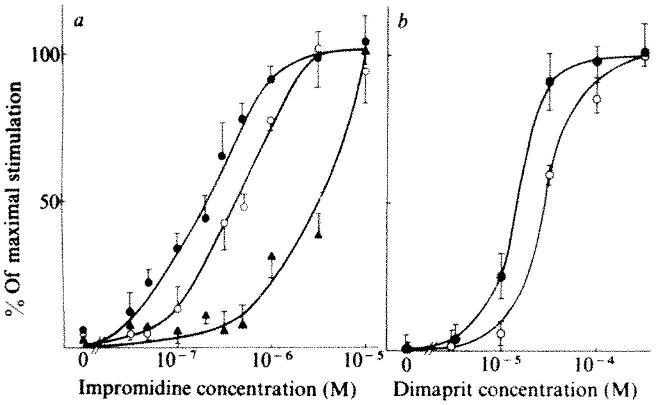

Fig. 2 Inhibition by promethazine or cimetidine of the stimulation of cyclic AMP accumulation in hippocampal slices elicited by two histamine H_2-receptor agonists. Promethazine and cimetidine were added 15 min before the agonists and incubations performed as described in Fig. 1 legend. Results are expressed as the per cent of maximal stimulation elicited in the absence of antagonist, that is, (in pmol of cyclic AMP per mg protein) 17.5 ± 1.1 for impromidine (*a*) and 16.2 ± 0.5 for dimaprit (*b*), the mean basal level being 5.9 ± 0.4. Mean ± s.e.m. of data from 3–6 values. The apparent dissociation constants of cimetidine, and promethazine were calculated according to the equation $K_i = A/(EC'_{50}/EC_{50} - 1)$ where A is the concentration of antagonist, and EC_{50} and EC'_{50} the concentrations of agonist required to give half-maximal response in the absence or in the presence of antagonist. The K_i values for cimetidine and promethazine inhibiting the response to impromidine were 0.95 μM and 6.2 μM, respectively. The K_i value for promethazine inhibiting the response to dimaprit was 5.2 μM. ●, Control; ○, promethazine (10 μM in *a*, 8 μM in *b*); ▲, cimetidine (5 μM).

than two orders of magnitude. However, this difference does not extend to the two H_2-antihistamines, metiamide and cimetidine, which have a similar effect on the two systems, with apparent dissociation constants in close agreement with those (0.75–0.96 μM) regarding inhibition of histamine effects on biological systems on which H_2-receptors have been initially defined, like the increase of contraction of guinea pig atrium or the inhibition of electrically induced contractions of rat uterus[13,25]. Hence it seems that the response to histamine on both systems can be considered to be mediated by H_2-receptors as in both cases several H_2-agonists exhibit the expected relative potencies and H_2-antagonists the expected affinities. However, compounds like the tricyclic antidepressants clearly discriminate between the 'H_2-receptors' from the two preparations, being much more potent than cimetidine on homogenates but less potent than this compound on intact brain cells.

The reasons for this discrepancy are not entirely clear at present but it is unlikely that the lower potency of compounds like promethazine or tricyclic antidepressants on the slice preparation results from their restricted diffusion into the intact tissue, for several reasons. First, their antagonist potency has been always determined following a 15-min period of preincubation to allow penetration into slices before the addition of histamine or agonists. Furthermore, we have observed for at least one compound, promethazine, that its potency was the same when it was added at the same time as histamine or impromidine. Second, promethazine has also a low potency (K_i of about 10 μM, as in hippocampal slices) regarding blockage of H_2-receptors mediating cyclic AMP accumulation in intact but isolated cells from stomach[26] or blood[27], that is, on preparations for which there is no diffusion problem. Indeed, as previously shown[22], the affinity of promethazine is also lower for H_1-receptors in slices compared to guinea pig ileum or ^3H-mepyramine binding sites, suggesting some nonspecific mechanism leading to a decreased potency of drugs at different receptor types in this preparation. But this is not the case for cyproheptadine which inhibits the response due to H_1-receptors in slices with an affinity (K_i, 0.005 μM) closely comparable to that found in other preparations[7] and nevertheless is 150 times less potent on H_2-receptors from slices than from homogenates.

It could be argued that, being highly lipophilic molecules, the relatively low potency of central nervous system (CNS)-active compounds like promethazine on the slice preparation might be related to extensive fixation on to 'sites of loss' like lipids. This seems unlikely because the concentration of ^3H-promethazine in the supernatant at the end of incubation is unchanged (data not shown).

It is also unlikely that the largely different potencies of these compounds on the two preparations reflect the interaction with two distinct subclasses of H_2-receptors. Thus the cyclic AMP response to histamine in homogenates parallels that in slices in various brain regions: for instance in the guinea pig (one of the few responsive species with both preparations) it is observed only in three regions which exhibit the same order of amplitudes (hippocampus > neocortex > striatum) for both preparations[16,28].

It seems more likely that the distinct pharmacology of H_2-receptors, when studied on a cell-free preparation as compared to intact cells, reflects modified drug discriminatory characteristics of these receptors which could be introduced either by the trauma of cell disruption or by the conditions required for optimal assay of adenylate cyclase activity. Several data already suggest that H_2-receptors on this test system may differ from those mediating physiological responses to histamine in intact organs, even when these responses may be triggered by cyclic AMP acting as second messenger. Hence promethazine and tricyclic antidepressants exhibit, as in brain, high affinities for the histamine-activated adenylate cyclase of homogenates from guinea pig heart[29,30] whereas both classes of agents seem to have inconsistent effects on the positive chronotropic and inotropic actions of histamine mediated by H_2-receptors in the intact organ[31,32].

One could postulate that the histamine-binding portion of H_2-receptors adopts a modified conformation when membranes which bear them are disrupted or when they are incubated in the presence of compounds like ATP, Mg^{2+}, GTP or EGTA which are required for optimal activation of the enzyme[33]. Selective modifications of the drug specificity of several classes of membrane receptors in the presence of guanylnucleotides or metal ions have already been evidenced in the last years by radioligand binding methods[34–36]. Alternatively, in the disrupted cell preparation some compounds might have access to regulatory or coupling units of the receptors that are normally hidden to them in the intact cell and thereby become potent inhibitors. Although this possibility seems *a priori* incompatible with the apparently competitive nature of the inhibition, established for most compounds[18,19,24], it cannot be entirely excluded in view of the complex interactions of histamine with the postulated allosteric sites for Mg^{2+} or nucleotides[33]. These various hypotheses may be checked when ^3H-ligands are available for studies of H_2-receptors.

Whatever the mechanism involved, note that a large difference in pharmacological specificity of striatal dopamine receptors mediating the stimulation of cyclic AMP formation in slices and homogenates, respectively, has recently been observed[37], whereas this does not seem to be the case of β-adrenergic receptors[38]. This suggests that the drug specificity of various types of receptors in cell-free systems has to be carefully compared to that in intact cell systems and that the idea that blockade of histamine H_2-receptors represents the common molecular basis of clinical activity of tricyclic antidepressants requires confirmation by other approaches.

Induction of experimental allergic encephalomyelitis in genetically resistant strains of mice

Zeev Lando, Dvora Teitelbaum & Ruth Arnon

Department of Chemical Immunology, The Weizmann Institute of Science, Rehovot, Israel

Experimental allergic encephalomyelitis (EAE) is an acute autoimmune disease of the central nervous system. It is elicited in various laboratory animal species by a single injection of either whole central nervous system tissue homogenate, or the purified basic encephalitogenic protein isolated therefrom. Clinical manifestations of hind leg paralysis usually occur 11–21 days after challenge, preceded by histological lesions of perivascular infiltration in the brain[1]. EAE has been intensively investigated both as a model for human demyelinating diseases and as a prototypic organ-specific autoimmune disease[1]. EAE is under genetic control in guinea pigs, rats and mice, and strains that are genetically susceptible or resistant to EAE have been demonstrated[2–4]. We have previously[4,6] investigated the genetic control of susceptibility to EAE in mice and demonstrated that the disease could be induced only in the SJL/J strain of mice, or in its crosses with various resistant strains. The resistance to EAE is not associated with genetic differences in the response of the various strains to pertussis vaccine, which is used as adjuvant in the induction of EAE in mice, as both the sensitive SJL/J strain and the resistant strains BALB/c, DBA/2 and C57BL/6J are responsive to pertussis[7]. A great difference was observed, however, in the sensitivity to EAE of the various F_1 hybrids of SJL/J. Thus, crossing the sensitive SJL/J strain with part of the resistant strains, such as NZB, BALB/c or its congenic strains BALB . B10 and BALB . C3H, led to fully susceptible hybrids, with even higher incidence of EAE than that observed in the parental SJL/J strain. On the other hand, crossing SJL/J with other strains, such as C57BL/6J or DBA/2, led to hybrids with very low susceptibility to EAE. These results suggested that in the crosses with the various resistant BALB strains and NZB strain, there is probably complementation with another gene. It was therefore postulated that in these resistant strains, the influence of the gene determining susceptibility to EAE is masked by the presence of naturally occurring suppressor cells. We present here experimental evidence which corroborates this assumption.

Mice of the resistant strain BALB/c were treated with various doses of cyclophosphamide (CY) 2 days before challenge with the basic protein (BE). This treatment, if carried out with appropriate low doses of CY, was previously shown to eliminate selectively suppressor cell population in several systems, resulting in depression of suppressive cell-mediated activity and augmentation of both cellular and humoral immune responses[8–11]. Figure 1 depicts the effect of CY on the susceptibility of BALB/c mice to the induction of EAE, showing that CY had a marked effect which is dose-dependent. At low doses (20 mg per kg), it drastically affected the resistance of the mice

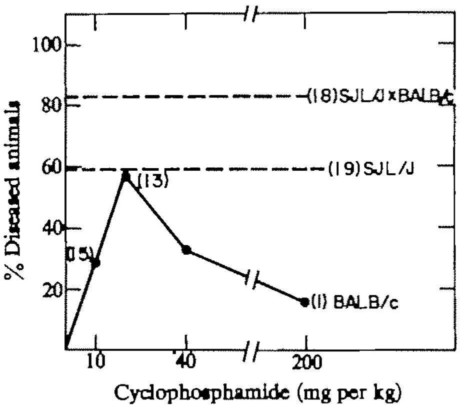

Fig. 1 Dose–response effect of CY on EAE induction in resistant BALB/c mice. EAE was induced by injecting 5 mg of dry lyophilized mouse spinal cord homogenate emulsified in 1:1 ratio in complete Freund's adjuvant supplemented with 4 mg ml^{-1} of *Mycobacterium tuberculosis* ($H_{37}Ra$) (Difco). The emulsion in total volume of 0.12 ml was injected in all four footpads. Immediately after and 48 h later, pertussis vaccine (*Bordetella pertussis*, Rafa Laboratories) 10×10^9 organisms, were injected intravenously. Mice were examined daily from day 11 post-induction for signs of EAE. Signs of disease were scored from 1 to 3 according to the clinical situation as follows: 1, loss of weight and loss of tail tonicity; 2, mild disease: paresis and paralysis of hind legs; 3, severe paralysis often leading to death. Animals were killed 18–24 days after injection and the whole brain and spinal cord were taken into 10% formalin solution for histological examination. Sagittal sections of brains and spinal cords, fixed in formalin and stained with Luxol fast blue, were examined microscopically for perivascular infiltration of mononuclear cells. The observations were done under code without knowledge of the injection regime. Solutions of CY (Polysciences), were freshly prepared by dissolving in minimal volume of ethanol and then diluted 100-fold in phosphate-buffered saline. CY was injected intraperitoneally 2 days before EAE induction. The numbers in the parentheses represent the mean score of disease signs. The broken lines represent the incidence of EAE in SJL/J and SJL/J × BALB/c mice without CY.

0028–0836/80/410551—02$01.00

to EAE—in these conditions BALB/c mice succumbed to the disease to the same extent and with the same severity as the susceptible strain SJL/J. Lower or higher doses of CY were less effective. High doses of CY (>200 mg per kg) affect the whole lymphoid system and suppress EAE induction altogether[12].

The effect of CY at its most effective concentration (20 mg per kg) was tested in additional resistant strains of various H-2 types. The results summarized in Table 1 demonstrate that in BALB.B10 and BALB.C3H, the congeneic strains of BALB/c, and to a lesser extent in the NZB strain, CY had a similar effect on the susceptibility to EAE to that demonstrated in BALB/c. On the other hand, in the other strains, such as C57BL/6J, DBA/2, AKR/J, ASW, B10.A and A/J, CY had no effect on the development of EAE. This phenomenon is therefore not linked to the H-2 type. It should be pointed out that in two of the these strains, C57BL/6J and B10.A, we have tested the effect of different doses of CY. No effect on EAE induction was observed at doses of 10, 20, 40 or 200 mg per kg. This experiment rules out the possibility that a non-optimal dose of CY was the factor responsible for the persistent unresponsiveness to EAE in those strains, and strengthens the conclusion that the involvement of suppressor cells in the resistance to EAE is not H-2 linked.

Similar effects to those demonstrated by CY on suppressor cells were also demonstrated in other systems by other immunosuppressive drugs, antilymphocyte serum, as well as by low-dose irradiation[8,11]. We therefore tested whether a similar effect to that demonstrated for CY on EAE induction could also be achieved using irradiation. BALB/c mice were exposed to whole body low-dose irradiation (200 R and 350 R) at various times before EAE induction. The results summarized in Table 2 demonstrate that when the mice were irradiated with 350 R 2 days before the encephalitogenic challenge, 50% of the otherwise resistant mice developed EAE.

It thus seems that there are two types of inbred strains that are resistant to EAE. Treatment with CY or low-dose irradiation can convert one type from resistant into susceptible, while it has no effect on the other type. It is suggested that in strains of the first type, a gene that is responsible for susceptibility to EAE does exist, but these strains probably maintain a natural high level of suppressor cells which prevent the manifestations of disease. Following treatment with CY, these suppressor cells are eliminated and disease is overt. In the F_1 hybrid, the balance between effector cells and suppressor cells is shifted towards the effector cell function, and therefore EAE can be induced. In addition, there is complementation of genes from the two parents and the resultant F_1 may be even.more sensitive. In rare cases, some animals of such strain may possess a lower level of suppressor cell, leading to the very low incidence of EAE in three resistant strains, even without CY treatment. In the second type of resistant strains, such as DBA/2, there is no Ir gene for EAE and therefore CY has no effect.

Table 1 Effect of low-dose CY on EAE induction

		Mice with EAE					
		Without CY			With CY		
	H-2 type	Clinical	Mean score	Histological	Clinical	Mean score	Histological
SJL/J	s	10/16	2.0	10/10	7/16	1.8	6/6
(SJL/J ×BALB/c)F_1	s/d	18/20	1.8	20/20	20/22	2.2	10/10

The results with CY and low-dose irradiation, although suggesting involvement of suppressor cells in regulation of sensitivity to EAE, do not provide unequivocal proof of the existence of such cells in resistant strains. However, we have recently demonstrated that CY eliminates suppressor cells involved in antigen-induced unresponsiveness to EAE[13]. In that study, protection against EAE[14] was induced in susceptible mice (SJL/J × BALB/c hybrid) by injection of an adequate protective antigen (spinal cord homogenate, BE or the synthetic polymer Cop 1) in incomplete Freund's adjuvant, before EAE induction. This unresponsiveness could be adoptively transferred by spleen T lymphocytes to normal syngeneic recipients. Low dose of CY (20 mk per kg) abrogated both actively induced and adoptively transferred unresponsiveness to EAE. It thus appears that in that system as well, the treatment with CY results in the elimination of suppressor cells, which interfere with the effector mechanisms responsible for EAE.

It is now well established that suppressor cells have a critical role in immune regulation, including maintenance of tolerance, antigenic competition and genetic control of immune responses[15]. It was also suggested that specific T-cell-mediated suppression could be one of the physiological processes of immune responsiveness against autoantigens[16]. In NZB mice it has been demonstrated that loss of effective suppressive T cell function can lead to autoimmune diseases[17]. The use of selective means for elimination of suppressor cells may assist in the elucidation of such activity in autoimmunity. Indeed, it was demonstrated that CY can induce a transient appearance of 'autoreactive' T lymphocytes in spleens of mice[18]. This accumulated information corroborates our present conclusion suggesting suppressor cell involvement in both natural and induced resistance to EAE.

Hormonal control of neurotransmitter choice in sympathetic neurone cultures

Keiko Fukada

Department of Neurobiology, Harvard Medical School, Boston,
Massachusetts 02115

Manipulation of the cellular and hormonal environment of cultures of dissociated primary neurones can be used to explore a neurone's developmental potential and to investigate the factors required for normal development. For example, developing adrenergic sympathetic neurones can be influenced to become cholinergic by both diffusible[1] and membrane-bound[2] factors from certain types of non-neuronal cells; when medium conditioned by incubation on heart cell cultures (CM) is placed on the neurones, they develop the ability to produce acetylcholine (ACh) and they form functional cholinergic synapses with each other[3]. Hormones could also contribute to the control of this transmitter choice[4], and McLennan *et al.*[5] recently reported that corticosterone treatment of whole superior cervical ganglia (SCG) greatly inhibited the cholinergic development of these ganglia in culture. It was not clear, however, whether the hormone acted directly on the neurones or indirectly via the non-neuronal cells. To study the role of hormones on this transmitter choice, I have now developed a serum-free medium (based on that of Sato and co-workers[6,7]) for the preparation of conditioned medium. The results obtained with this system show that glucocorticoids and epidermal growth factor (EGF) exert dramatic and antagonistic effects on the adrenergic–cholinergic transmitter choice and do so indirectly, by controlling the ability of heart cells to produce cholinergic CM.

Heart myocytes and heart fibroblasts (both simply called 'heart cells') were obtained by collagenase treatment of whole hearts from neonatal rats and grown in flasks containing 10% fetal calf serum (FCS, MA Bioproducts) in L-15 CO_2 medium[1]. After the cells had grown to confluency, they were either used for conditioning or were trypsinized and replated to be used as secondary cultures. To obtain conditioned medium, the flasks were washed with serum-free medium and incubated for 24 h with the medium to be conditioned. The CM was collected and frozen at −20 °C and the flasks were incubated for 24 h with the 10% FCS medium again. After washing, a second batch of medium to be conditioned was placed in the flasks for 24 h. This CM was collected and also frozen. Before addition to the neuronal cultures, the CM was thawed and mixed with an equal volume of fresh L-15 CO_2 medium containing, in addition to the usual components of the neuronal growth medium[8], 10% rat serum and 3 mg ml^{-1} Methocel. Control neuronal cultures received medium containing 5% rat serum and 1.5 mg ml^{-1} Methocel. In both cases, the medium was changed every 2 days. The neurones were mechanically dissociated from neonatal rat SCG and plated as previously described[8]. All neuronal cultures received control medium for the first 2 days and then experimental media until days 14–18, when they were assayed. Ganglionic non-neuronal cells were killed by treatment with cytosine arabinoside[8]. ^{3}H-ACh synthesis from ^{3}H-choline and ^{3}H-catecholamine (CA) synthesis from ^{3}H-tyrosine were assayed as previously described[1,9]. The ratio of synthesis of these transmitters, ACh/CA, is a sensitive indicator of the number of cholinergic as opposed to adrenergic neurones in this culture system[10].

Table 1 Effects of hormones on cholinergic induction

Additives	ACh/CA	ACh (pmol per dish)	CA (pmol per dish)
a BSA	0.03±0.01	0.20	7.26
EGF	0.18±0.03	1.22	6.53
EGF+BSA	2.47±0.10	12.53	5.07
EGF+BSA+insulin	7.53±0.71	25.25	3.38
EGF+BSA +transferrin	2.00±0.09	13.91	6.99
EGF+BSA+insulin +transferrin	9.09±0.15	32.86	3.62
EGF+insulin +transferrin	0.26±0.01	2.48	9.73
BSA+insulin +transferrin	0.04±0.01	0.51	11.98
Insulin+transferrin	0.04±0.01	0.44	11.12
b 5% Rat serum	4.20±0.09	18.56	4.41
5% Rat serum +hydrocortisone	1.57±0.12	8.40	5.33
EGF+BSA+insulin +transferrin	9.09±0.15	32.86	3.62
EGF+BSA+insulin +transferin +hydrocortisone	0.62±0.12	9.85	15.60
5% Rat serum+EGF +insulin+transferrin	6.00±0.88	24.14	4.08
5% Rat serum+EGF +insulin+transferrin +hydrocortisone	4.92±0.40	24.67	4.94

Confluent heart cells were incubated in L-15 CO_2 medium with various combinations of hormones and growth factors as substitutes for serum. The concentrations used were: BSA, 2.5 mg ml^{-1} (Sigma); EGF, 20 ng ml^{-1} (purified according to Savage and Cohen[13] or from Collaborative Research); hydrocortisone, 10^{-6}M (Sigma); insulin, 5 μg ml^{-1} (Sigma); selenium, 30 nM (Johnson Matthey, treated as in ref. 14); transferrin, 25 μg ml^{-1} (Sigma). Sympathetic neurones were grown in 50% CM from these cultures and transmitter synthesis was assayed on day 18.

Table 2 Identification of target of EGF action

	ACh/CA	ACh (pmol per dish)	CA (pmol per dish)
a Complete serum-free medium incubated in an empty flask	0.05±0.01	0.17	3.26
b Complete serum-free medium incubated on heart cells	3.66±0.25	12.57	3.44
c Serum-free medium, without hormones, incubated on heart cells, with fresh hormones added before placing on neurones	0.05±0.01	0.25	4.70
d Complete serum-free medium (−EGF) incubated on heart cells, with fresh EGF added before placing on neurones	0.05±0.01	0.19	3.90

Sympathetic neurones were grown for 14 days in 50% CM made by incubation in conditions *a* – *d*.

Heart cells were grown with various combinations of hormones and growth factors as substitutes for serum. CM from these cultures were tested for induction of ACh synthesis in neuronal cultures. The results of a typical experiment testing a variety of hormones are shown in Table 1*a*. CM from heart cells treated with medium containing bovine serum albumin (BSA) as the only additive gave the usual low ACh/CA ratio expected for medium with no additions at all. If EGF was used as the only additive, there was a significant increase in the ACh/CA ratio. This effect of EGF was greatly enhanced by the addition of BSA. Similarly, insulin had a synergistic effect on the transmitter ratio

0028–0836/80/410553—03$01.00

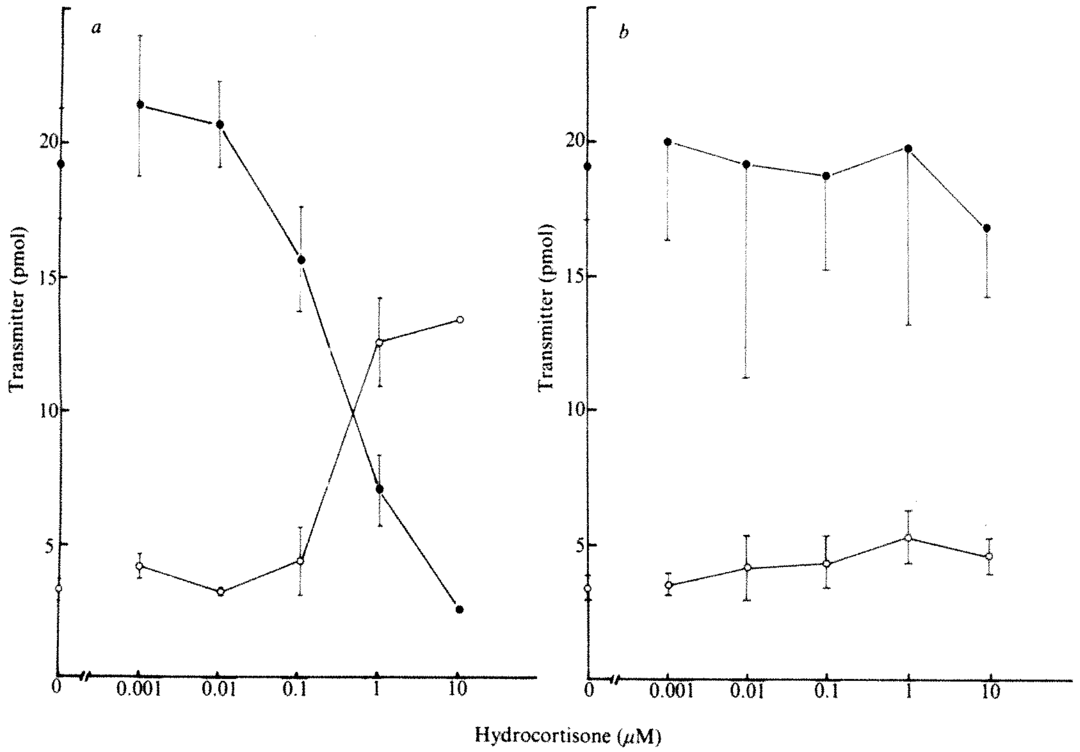

Fig. 1 *a*, Hydrocortisone was added at various concentrations to heart cells in complete serum-free medium for 24 h and the CM was tested for induction of neuronal ACh synthesis. *b*, Fresh hydrocortisone was added directly to neurones in complete serum-free medium conditioned on heart cells. The amounts of transmitters synthesized at day 17 (●, acetylcholine; ○, catecholamine) are expressed as pmol per dish. Points are means ±s.e.m. of triplicate cultures.

when added along with EGF, but had no effect in the absence of EGF. The effect of transferrin was variable and small. The most potent CM was consistently obtained using EGF, BSA, insulin and transferrin, and medium containing these additives is termed 'complete' serum-free medium.

In comparison, hydrocortisone had a striking inhibitory effect on the transmitter ratio. As shown in Table 1*b*, this hormone antagonizes the cholinergic effects of both the complete serum-free CM and CM containing the usual 5% rat serum. The 15-fold effect of hydrocortisone on the transmitter ratio in serum-free conditions is typical of the values seen in more than 10 such experiments. Other glucocorticoids (corticosterone, cortisone and dexamethasone) showed similar antagonistic effects on ACh induction. Both the cholinergic effect of complete serum-free conditioned medium and the antagonistic effect of hydrocortisone are reduced in the presence of 5% rat serum, suggesting that the complex mixture of hormones in serum obscures the effect of individual hormones.

Other hormones which showed small positive effects on the transmitter ratio were fibroblast growth factor (100 ng ml^{-1}, Collaborative Research) and relaxin (10 ng ml^{-1}) when added together with BSA, insulin and transferrin. Hormones showing little effect on the ratio were growth hormone (20 ng ml^{-1}), 3,3′,5-triiodothyronine (10^{-10} M, Sigma), prolactin (10 ng ml^{-1}), partially purified thyroid stimulating hormone (100 ng ml^{-1}) and follicle stimulating hormone (0.5 μg ml^{-1}), progesterone (10^{-9}M, Sigma), testosterone (5 × 10^{-9}M, Sigma), oestradiol (5 × 10^{-9}M, Sigma) and aldosterone (10^{-9}M, Sigma). Selenium, which is essential in some serum-free systems[7], had little effect on the transmitter ratio.

Do the hormones influence transmitter choice by acting directly on the neurones, or indirectly, by altering the ability of the heart cells to produce cholinergic CM? These possibilities were tested in the experiments shown in Table 2 and Fig. 1. Complete serum-free medium was incubated for 24 h in either an empty flask (*a*) or in one containing heart cells (*b*), and these CM were tested on the neurones. As expected, the heart cells were essential for the induction. Furthermore, if the hormones were added to serum-free conditioned medium (minus hormones, incubated on the heart cells) immediately before it was placed on the neurones (*c*), no cholinergic induction occurred. Addition of fresh EGF to complete (except for EGF) serum-free CM was similarly ineffective when added directly to the neurones (*d*). EGF had a very striking cholinergic inductive effect when added at 10 ng ml^{-1} on the heart cells, but had no effect when added directly to the neurones, even at higher concentrations (data not shown). Thus, the EGF effect on neuronal transmitter choice is an indirect one, via the heart cells.

When the same type of experiment was conducted with hydrocortisone, two different effects were seen (Fig. 1). When added to the heart cultures (Fig. 1*a*), this hormone antagonized the cholinergic effect of the complete serum-free CM, resulting in both lower ACh and higher CA production by the neurones. On the other hand, addition of hydrocortisone to the CM just before placing it on the neurones had little effect on cholinergic development, but may have slightly increased CA production (Fig. 1*b*). This latter effect has been observed before in this system (L. Chun, P. Walicke & P. H. Patterson, unpublished

Table 3 Effects of hormones on heart cells

	Labelled protein (c.p.m.)	Total protein (μg per dish)
a No hormones	7,951 ± 243	0.23 ± 0.04
EGF + BSA + insulin + transferrin	11,620 ± 448	0.26 ± 0.01
EGF + BSA + insulin + transferrin + hydrocortisone	10,732 ± 110	0.27 ± 0.04
5% Rat serum	12,850 ± 2,095	0.28 ± 0.01
5% Rat serum + hydrocortisone	13,708 ± 1,288	0.27 ± 0.01
		DNA (μg per flask)
b BSA + insulin + transferrin		26.2
EGF + BSA + insulin + transferrin		26.6
EGF + BSA + insulin + transferrin + hydrocortisone		30.7
5% Rat serum		34.3
5% Rat serum + hydrocortisone		32.9

a, Confluent heart cells were labelled with ^{3}H-leucine in L-15 CO$_2$ medium supplemented with hormones as indicated. After a 24-h incubation, the cells were washed with several changes of unlabelled medium for 30 min and then lysed with 2% SDS. The lysate was used for measuring both synthesized protein (total counts) and total protein (by Lowry's method[15]). *b*, The DNA content of heart cells in a similar experiment as in Table 1 was determined by pentose analysis[16].

results) and could be due to a NGF-mediated induction of tyrosine hydroxylase and dopamine-β-hydroxylase[11]. Thus, the dramatic effect of hydrocortisone on transmitter choice, like that of EGF, is primarily an indirect one, via the non-neuronal cells. Note that the concentrations of glucocorticoids which were effective in these experiments (10^{-7}–10^{-5}M) are similar to the plasma corticosterone level in neonatal rats (10^{-6}M)[12].

These results raise the question of whether the hormonal actions are due to nonspecific effects on growth or health of the heart cells. At the crudest level, EGF and hydrocortisone could have stimulatory and deleterious effects, respectively, on the number or growth of the heart cells. While this may be the case over extended periods of incubation, the 24-h incubation with hormones used in these experiments results in little alteration in the total DNA or protein content of the heart cell cultures (Table 3). Could the hormones be having effects on overall heart cell protein synthesis which was not reflected in the total protein content after only 24 h of incubation? This seemed unlikely as the hormones had little effect on ^{3}H-leucine incorporation into protein during the 24-h incubation (Table 3). Furthermore, in preliminary experiments, when ^{3}H-leucine-labelled protein secreted into the medium by heart cells was examined by SDS-gel electrophoresis, there were no gross differences in the patterns due to the presence of EGF or hydrocortisone (data not shown). The hormones thus appeared to have no obvious stimulatory or deleterious effects on the growth or health of the heart cells or on major proteins secreted during the 24-h incubation.

The results presented here suggest a further level of subtlety in the control of neurotransmitter choice in sympathetic neurones: specific hormones can act on non-neuronal cells to alter selectively the production or liberation of a factor (or factors) that induces neuronal cholinergic development and reduces adrenergic development.

Relaxin and the pituitary hormones were gifts of the NIH Hormone Distribution Program. I thank Dr Paul H. Patterson for his valuable discussions and encouragement throughout this work and for help in preparing the manuscript, Dr Izumi Hayashi for advice and information on serum-free culture systems, Dr Kathleen Sweadner for help in analysing the released protein from the heart cells, and Dr Edward Kravitz for the use of his equipment. This work was supported by a fellowship from the Muscular Dystrophy Association and an NINCDS grant to Paul H. Patterson.

A neuropeptide in mammalian tissues with physalaemin-like immunoreactivity

Lawrence H. Lazarus, R. Ilona Linnoila, Oscar Hernandez* & Richard P. DiAugustine

Endocrinology Group, Laboratory of Pulmonary Function and Toxicology and *Laboratory of Environmental Chemistry, National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina 27709

Erspamer *et al.*[1-3] isolated several structurally related non-mammalian peptides, termed tachykinins[2,3], with biological activities similar to substance P (refs 2, 3). This similarity is due to a common COOH-terminal region[2,3], whereas the specific action of each member of the group depends on its unique NH_2-terminal sequence[3-6]. Based on these properties, parallel bioassays using numerous smooth muscle preparations and physiological parameters allow them to be generally distinguished[2,3,6]. However bioassays are time consuming and not highly specific. Thus, we developed a rapid physalaemin-specific radioimmunoassay that led to the initial discovery of a substance in mammalian tissues with an immunoreactivity resembling that of the original amphibian peptide[7]. We now present data on the distribution, localization and partial characterization of physalaemin-like immunoreactivity (PSLI) in tissues of several mammalian species.

Details of the preparation of the antiserum and the radioimmunoassay are described elsewhere[7]. Antiserum (PS-1) had a titre of 1:40,000 and specifically recognized the NH_2-terminal region of physalaemin with only minimal cross-reactivity with the other tachykinins (Table 1). Other bioactive peptides had negligible cross-reactivity ($<0.0001\%$)[7]. Antiserum PS-1 cross-reacted with uperolein $2.03 \pm 0.94\%$ (mean ± s.d., $n = 4$) (Table 1), but compared with physalaemin the displacement curve was nonparallel (the ratio of the slopes of physalaemin:uperolein = 2.10 ± 0.20; Fig. 1). The cross-reactivity of antiserum PS-1 using ^{125}I-uperolein yielded a complementary set of data: at a constant bound/free ratio (B/F) a lower antiserum dilution was required (1:6,000) and the sensitivity of the assay to physalaemin decreased fourfold to 29.8 ± 6.4 pg ($n = 4$) (Table 1); the cross-reactivity of physalaemin was also nonparallel relative to uperolein (ratio $= 2.43 \pm 0.88$, $n = 3$; Fig. 1); and 50% displacement by uperolein was 51.0 ± 14.2 pg (40.7 ± 11.3 fmol, $n = 4$; Fig. 1). As also shown in Fig. 1, a crude extract of guinea pig stomach and the peak material from either Bio-Gel P-4 or HPLC (Fig. 3) produced parallel displacement curves relative to the labelled peptide used. Thus, it appeared that PSLI in tissue extracts contained an amino acid sequence common to the NH_2-terminal region of both physalaemin and uperolein (-Asp-Pro-Asn-; Table 1). Predictably, the ratio between their slopes should be identical, and within experimental limitations this was the case. Although the concentration of immunoassayable substance would be higher by nearly an order of magnitude using ^{125}I-uperolein, PSLI was quantified on the basis of physalaemin as the antiserum was raised against this peptide.

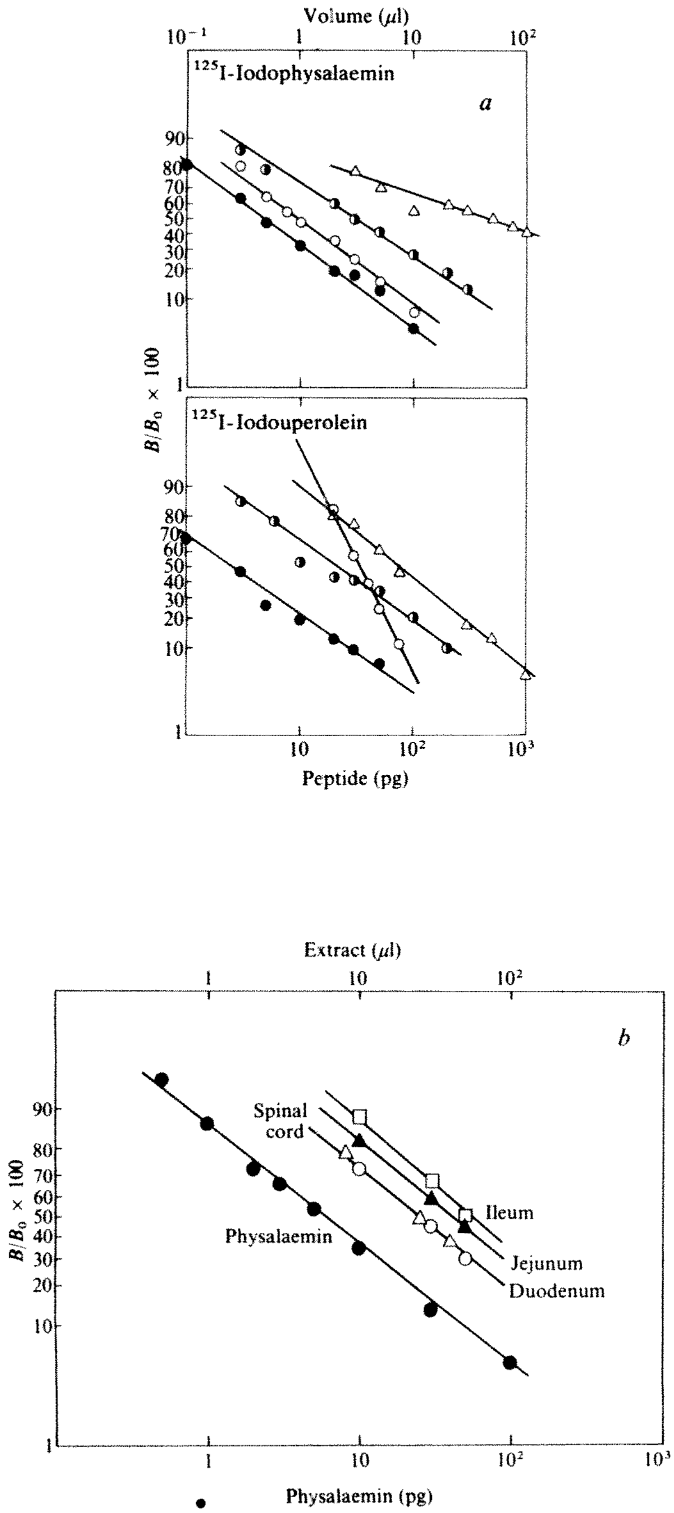
PSLI was found throughout the gastrointestinal tract of all the mammalian species examined and exhibited parallel displacement to physalaemin (Fig. 1). The actual concentration in each region of the stomach varied considerably between species (Table 2), with the rabbit containing the highest levels[7]. Guinea pig stomach contained more PSLI than any other region of the gastrointestinal tract: it was higher in the duodenum than in either the jejunum or ileum and a similar quantity was found there to that in the pylorus and fundus (Table 2). In rabbit, the level of PSLI in the duodenum was considerably less than that found in the stomach. PSLI was also found in porcine oesophagus in the mucosal and muscle layers, and mucosa of the trachea, as well as in rabbit trachea. Inconsistent values and nonparallel displacement curves, similar to that produced by proteases, frequently occurred with extracts of brain, lung and plasma from rat and guinea pig.

The large amounts of PSLI in the gastrointestinal tract may indicate a functional role for this material. The detection of relatively small quantitites of PSLI in tissues containing a high

Table 1 Specificity of physalaemin antiserum PS-1 among the tachykinin group of polypeptides

		Molar cross-reactivity (%)	
Peptide	Sequence	^{125}I-physalaemin	^{125}I-uperolein
Physalaemin	pGlu-Ala-Asp-Pro-Asn-Lys-Phe-Tyr-Gly-Leu-Met-NH$_2$	100	174.0±38.9
Uperolein	——Pro——————Ala————————————	2.03±0.94	100
Phyllomedusin	pGlu-Asn—————Arg————————————	0.36±0.04	0.32
Substance P	Arg-Pro-Lys———Gln-Gln——Phe———————————	<0.00013	0.05
Eledoisin	——Pro-Ser-Lys-Asp- Ala——Ile————————————	<0.0001	NT
Kassinin	Asp-Val-Pro-Lys-Ser-Asp—Glu——Val———————————	0·013±0.003	NT

Cross-reactivity is derived from the 50% displacement values by unlabelled peptide and given as the mean±s.d. The sensitivity of antiserum PS-1 for physalaemin using ^{125}I-physalaemin is 6.79±1.98 pg (5.29±1.54 fmol, $n = 34$) and for uperolein using ^{125}I-uperolein (at a titre of 1:6,000 final dilution) 51.0±14.2 pg (40.7±11.3 fmol, $n = 4$). NT, not tested.



density of nerve fibres, for example, the sphincter areas of the stomach[8], may be masked by extraneous protein in the extract. On the other hand, subtle structural modifications may also affect its quantification: studies on amino acid variants of kassinin and physalaemin[6], charge differences in luteinizing hormone releasing factor[9] and vasoactive intestinal polypeptide (VIP)[10], and NH$_2$-terminally extended bombesin[11] and somatostatin[12] support this possibility. However, relatively small amounts of PSLI could exert profound effects as physalaemin is one of the most potent pharmacologically active peptides known[3].

Immunostaining was observed in both epithelial cells and nerve fibres in the gastrointestinal tract of guinea pig and rat. In guinea pig, the immunostaining can be summarized as follows: (1) scattered epithelial cells with PSLI in villi throughout the gastrointestinal tract; (2) the most conspicuous feature was the numerous, strongly immunostained cells in Brunner's glands[13] of the proximal duodenum (Fig. 2*a*); (3) submucosal glands of the ileum; (4) beaded, fibre-like structure, probably representing terminal and preterminal nerves in Meissner's and Auerbach's plexi in the duodenum; and (5) beaded fibres with PSLI among pancreatic acinar cells that are also lightly immunostained. In rat, immunostained cells were also widely distributed throughout the gastrointestinal tract, but scattered immunostained epithelial cells were most frequent in the colon (Fig. 2*b*). Also in rat, beaded fibres with PSLI were observed in the muscle layers of the gastro-oesophageal sphincter and surrounding unstained ganglion cells of Auerbach's plexus in the same region (Fig. 2*c*). The localization of PSLI in epithelial cells and nerve fibres of the gastrointestinal wall resembled that of substance P (refs 14–16), neurotensin[17–19], motilin[14], enkephalin[16,20],

Fig. 1 *a*, Specificity of the physalaemin raioimmunoassay. The assay contained 50 mM sodium cacodylate, *p*H 5.75, 1.0 mg bovine serum albumin, 4,000–5,000 c.p.m. ^{125}I-physalaemin or ^{125}I-uperolein, antiserum PS-1 (final dilution 1:40,000 with ^{125}I-physalaemin and 1:6,000 with ^{125}I-uperolein) and sample or standard peptide in a total volume of 100 μl. After incubation at 2–4 °C for 16 h, nonimmune rabbit serum and goat anti-rabbit antiserum (Cappel) were added to final dilutions of 1:2,000 and 1:50, respectively. The assays were incubated for 3 h at 22 °C, diluted with 1.0 ml buffer, centrifuged (2,500*g* for 30 min) and the residue counted[7]. Control tubes lacking antiserum PS-1 or in the presence of 60 pmol physalaemin had <1.0% of the total radioactivity. The plots contain standard curves for physalaemin (○), uperolein (△), an extract of guinea pig stomach (●) and the peak material from either Bio-Gel P-4 column or HPLC (Fig. 3) (◑). The upper panel shows the assay containing ^{125}I-physalaemin whereas the assay in the lower panel contains ^{125}I-uperolein. *b*, Physalaemin-like immunoreactivity in extracts of guinea pig tissue. Lyophilized tissues were powdered, then extracted in 10 volumes (wet weight) 1 mM EDTA-1 mM dithiothreitol at 98 °C. After cooling, they were acidified (1.0 M formic acid), homogenized (Polytron) and centrifuged (27,000*g* for 15 min at 4 °C). The pellets were re-extracted and the combined supernatants lyophilized[7]. The residue was dissolved in 50 mM cacodylate buffer, *p*H 5.75, and clarified before use. The data from a typical experiment are presented as the per cent *B*/*B*$_0$ against pg physalaemin (●), or volume of extract from duodenum (○), jejunum (▲), ileum (□) or spinal cord (△). The maximum variation between the slopes of the lines relative to physalaemin was 3%.

Table 2 Physalaemin-like immunoreactivity in mammalian tissue

Tissue	Amount in lyophilized tissue* (ng g^{-1})	
Guinea pig

‡ Data are from five adult male CD-2 rats and seven neonatal pups killed at 24 h postpartum.

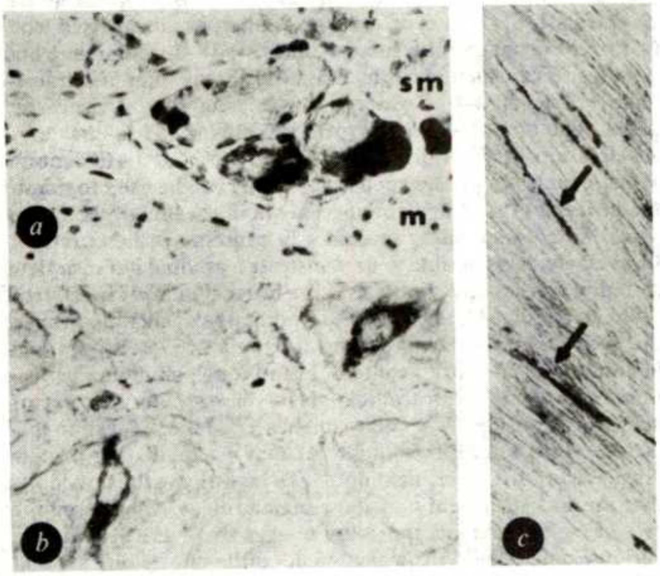

Fig. 2 Immunocytochemical localization of physalaemin-like immunoreactivity in the gastrointestinal tract. Immunostaining was carried out using the immunoperoxidase bridge technique[35]. The best results were obtained by freezing the tissue in 2-methylbutane at the temperature of liquid nitrogen, freeze-drying and fixing in the vapours of diethylpyrocarbonate[36]. Antiserum PS-1 gave satisfactory staining at a dilution of 1 : 1,000. Immunostaining was eliminated with the incubation of serial sections with either normal rabbit serum or antiserum PS-1 that was preadsorbed with 100 μg of physalaemin antigen. Immunostaining was not affected by preadsorption with 100 μg substance P or uperolein. *a*, Brunner's gland in the guinea pig duodenum showing dark, homogeneous staining (on the right side) in selected cells in the gland; sm = submucosa, m = muscle (circular layer). ×290. *b*, Two epithelial cells in rat colon; note that the nuclei are unstained. ×730. *c*, Beaded nerve fibres (*arrows*) with PSLI among the smooth muscle fibres of the gastro-oesophageal sphincter of the rat. ×290.

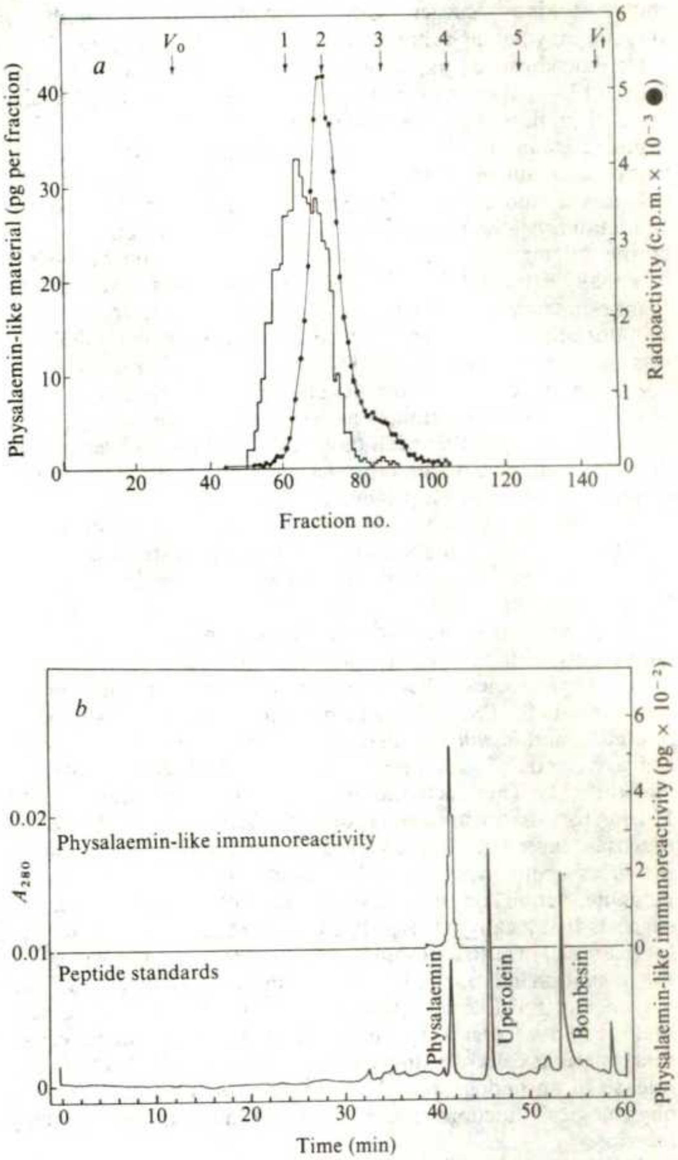

Fig. 3 *a*, Column chromatography of extracts of guinea pig stomach. Bio-Gel P-4 (100–200 mesh; Bio-Rad) columns (0.7 × 48.5 cm) were equilibrated and eluted with 0.1 M formic acid. Fractions (0.23 ml) were collected at a flow rate of 10.4 ml h^{-1} at a hydrostatic pressure of 100 cm. Each fraction was lyophilized and redissolved in 0.15–0.4 ml water or cacodylate buffer before assaying. Immunoreactivity (bar graph) and ^{125}I-iodophysalaemin (●) are presented. A physalaemin standard (determined by radioimmunassay) eluted in the same fractions as iodinated physalaemin due to variability in column chromatography: the s.d. in the peak is ±1.7 fractions[7]. The arrows indicate the position of the standards: V_0, Bovine serum albumin, 1, ^{125}I-[Tyr^8]-bombesin; 2, ^{125}I-physalaemin; 3, ^{125}I-[Des-Gly^9-Met-NH$_2$^{11}]-physalaemin; 4, ^{125}I-[des-pGlu^1-Phe^7]physalaemin; 5, ^{125}I-Tyr-Phe; and V_t, ^{125}I-Tyr or DNS–Ala. *b*, HPLC fractionation of the PSLI peak material from Bio-Gel P-4 columns. Fractions 55–75 were pooled, lyophilized, and the samples (100 μl) were fractionated on a Particil 5 ODS reverse-phase column (0.45 × 25 cm) (Whatman) in 10 mM Tris–phosphate, *p*H 7.05, and 20% methanol. Elution was carried out with a 20–65% linear methanol gradient in 45 min after an initial delay of 5 min at a flow rate of 0.8 ml min^{-1} (O.H. *et al.*, in preparation). Fractions were collected at either 0.1- or 0.2-min intervals, the methanol evaporated under N_2, lyophilized and dissolved in buffer. The lower tracing is the absorbance of a mixture containing 6 μg of physalaemin, uperolein and bombesin; the retention times of each were determined independently. The bar graph in the upper curve indicates PSLI.

somatostatin[14,16], VIP (refs 8, 13, 21, 22), bombesin[13,23,24] and cholecystokinin[25], suggesting that the mammalian form of physalaemin may belong to this diverse group of neuropeptides.

Column chromatography of extracts of guinea pig stomach on Bio-Gel P-4 columns ($n = 15$) gave only one symmetrical peak of PSLI (molecular weight 1,700) regardless of the area of the stomach examined. This was larger than any of the known tachykinins[6] and no other major peak with PSLI eluted from the columns. Cyanogen bromide digestion of the peak material gave an immunoreactive profile with the same elution volume as that of the original extract, suggesting that PSLI could be NH_2-terminally extended. This indeed was found for a mammalian bombesin-containing peptide[11], angiotensin from frogs[5] and somatostatin from porcine intestine[12]. Reverse-phase HPLC was used to resolve whether PSLI resembled physalaemin or uperolein: in acidic or neutral conditions, PSLI co-eluted with physalaemin several minutes earlier than uperolein (Fig. 3*b*). These data suggest that even though PSLI seemed to be larger than physalaemin, its ionic properties are very similar, if not identical, to those of physalaemin.

PSLI differs from substance P on the basis of several criteria: specifity of antiserum PS-1 (Table 1); tissue distribution and cellular localization[21]; substance P has not been localized in Brunner's glands[27] which contain cells immunopositive to the COOH terminus of gastrin[28] and bombesin[23]; and PSLI co-eluted only with physalaemin on HPLC (Fig. 3*b*).

The physiological effects of physalaemin may indicate a possible role for PSLI. Physalaemin affects mucous production *in vitro*[29], and *in situ* stimulates secretion of the lachrymal and salivary glands[3,30] with the secretion of K^+ and reabsorption of Na^+ (ref. 31). These activities may account for the presence of PSLI in tissues with mucous production, Brunner's glands and in mucosal layer of trachea and oesophagus. Physalaemin produces acute hypotension by vasodilation[2,3,6], and a spasmogenic action on extravascular smooth muscle[2,3] which suggests that locally released PSLI could regulate muscle tone; for example, in gastro-oesophageal sphincter[8] or enteric plexi[22] the relaxation induced by VIP may be antagonized by PSLI. The presence of PSLI nerves in the vicinity of acinar cells suggests that it could interact on specific physalaemin membrane receptors on acinar cells[32] leading to cellular secretion[32–34]. Thus the release of an endogenous PSLI may be involved in different physiological functions depending on its neuronal or cellular location.

We thank J. E. Rivier for physalaemin, J. Frushstick, C. Soldato, P. Merritt, M. Matherson, P. McLain and N. Peedin for technical assistance, R. Hester for literature retrieval, G. Jahnke and M. D. Erisman for their comments, and V. Erspamer for uperolein, phyllomedusin and kassinin and his encouragement.

Dual ionic controls for the activation of protein synthesis at fertilization

M. M. Winkler, R. A. Steinhardt,* J. L. Grainger & L. Minning

Department of Zoology, University of California, Berkeley,
California 94720

The general metabolic activation of the sea urchin egg at fertilization is dependent on a release of intracellular stores of calcium and the subsequent transient elevation of intracellular Ca^{2+} (refs 1–3). However, this elevation does not by itself lead to increased macromolecular synthesis and development but initiates steps which result in a long-term elevation of intracellular *p*H (refs 4–6). Among the developmental processes dependent on the elevation of intracellular *p*H is the large acceleration in the rate of protein synthesis at fertilization[6]. Weak penetrating bases such as ammonia can be used to mimic the processes resulting in an increase in intracellular *p*H and so show the corresponding increases in protein synthesis rate[6–9]. Conversely, it is possible to demonstrate a gradual but complete shut down of protein synthesis if the intracellular *p*H is reduced to the unfertilized level with penetrating weak acids[6]. However, the rate of protein synthesis in ammonia-activated eggs lags behind that of fertilized controls even though ammonia activation can result in an intracellular *p*H increase greater than occurs in the fertilized egg[6,8,10]. This result has led to the suggestion that factors other than intracellular *p*H may be regulating protein synthesis following fertilization[6,10]. To investigate the possibility that the Ca^{2+} transient may have such a role, we measured the rate of amino acid incorporation in eggs that were activated in various ionic conditions which enabled the effects of Ca^{2+} and *p*H changes to be studied separately. Our results, reported here, show that if intracellular *p*H is elevated, increases in intracellular Ca^{2+} play an additional part in the activation of protein synthesis at fertilization.

Figure 1 shows the amount of ^{3}H-valine incorporated after activation in these different ionic conditions. Eggs were preloaded with ^{3}H-valine to circumvent problems of differential uptake of label in different experimental conditions. Fertilization typically results in a 10–30-fold stimulation of protein synthesis over the unfertilized rate. The variation between experiments stems from differences in both the basal unfertilized rate and the degree of stimulation resulting from activation.

Fertilization results in an increase of intracellular *p*H of about 0.45 *p*H units[5]. This seems to occur by a mechanism by which protons are released from the egg in the presence of external Na^+ (ref. 4). To determine how Ca^{2+} release in the absence of an

intracellular *p*H increase would affect the protein synthesis rate, eggs were activated with the Ca^{2+} ionophore A23187 in zero-sodium (0-Na^+) artificial seawater. The ionophore causes the release of intracellular Ca^{2+} and the discharge of the cortical granules, but in the absence of external Na^+ there is no intracellular *p*H increase[11], and the rate of protein synthesis is the same as in the unfertilized controls (Fig. 1*a*). Similarly, if eggs are fertilized in seawater and immediately transferred to 0-Na^+ artificial seawater before the onset of the Na^+-dependent H^+ efflux, there will be a Ca^{2+} release without an increase in intracellular *p*H. Protein synthesis remains at the unfertilized rate until Na^+ is added back and the intracellular *p*H increases (Fig. 2). Thus, a Ca^{2+} release in the absence of a *p*H rise does not stimulate protein synthesis.

Treatment with 10 mM NH_4Cl increases the intracellular *p*H by about 0.80 *p*H units and does so by an entirely different mechanism[5,9]. NH_4Cl in alkaline solutions will generate ammonia, which passively diffuses across the egg plasma membrane raising the intracellular *p*H, bypassing the transient intracellular Ca^{2+} release and not causing the discharge of the cortical granules. However, NH_4Cl in seawater containing Ca^{2+} does provoke a transient Ca^{2+} influx[12]. NH_4Cl activation in seawater or zero 0-Na^+ artificial seawater (both of which have the normal amount of Ca^{2+}) will result in similar stimulations of protein synthesis to levels less than those achieved by fertilization. If extracellular Ca^{2+} is present during NH_4Cl activation there will be a measurable influx of Ca^{2+}, which although insufficient to cause discharge of the cortical granules, does affect the level of protein synthesis. If protein synthesis is compared in eggs activated in 0-Na^+ seawater where Ca^{2+} influx can occur (Fig. 1*c*) and in 0-Ca^{2+} artificial seawater where there is no measurable Ca^{2+} influx, there is a significantly lower level of protein synthesis in the absence of the Ca^{2+} influx (Fig. 1*b*).

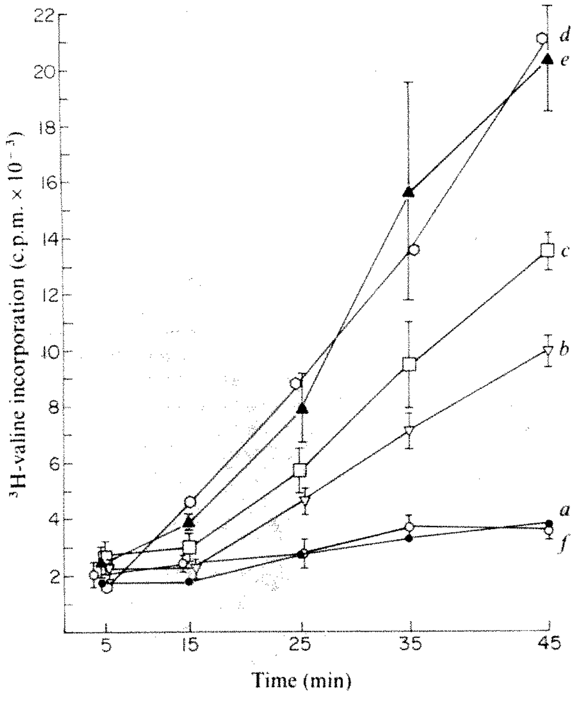

Fig. 1 Total ^{3}H-valine incorporation over a 45-min period starting 5 min after activation in various ionic media. The mean incorporation of label into unfertilized eggs from four experiments was determined for each time point. The ratio of this mean to the unfertilized rate in each of these four experiments was used to normalize the data presented for the different ionic conditions. The plotted data points represent the mean of the normalized incorporation data. The value shown represents the amount of incorporation ±s.e.m. for four repeats of this experiment testing five different conditions plus fertilization. The standard errors for fertilization have been omitted and the time points slightly spread out for clarity. *a*, Eggs activated by 2.5 μM A23187 in 0-Na^+ artificial seawater: intracellular Ca^{2+} release without an intracellular *p*H rise. *b*, Eggs activated by 10 mM NH_4Cl in 0-Ca^{2+} artificial seawater: a rise in intracellular pH without a Ca^{2+} release or influx. *c*, Eggs activated in 10 mM NH_4Cl in 0-Na^+ artificial seawater: an intracellular *p*H rise with some Ca^{2+} influx. *d*, Eggs activated in 10 mM NH_4Cl and 2.5 μM A23187 in 0-Na^+ artificial seawater: both an intracellular *p*H rise and a intracellular Ca^{2+} release. *e*, Eggs fertilized normally in natural seawater for comparison purposes. *f*, Unfertilized eggs in natural seawater. Artificial seawater: 484 mM NaCl, 10 mM KCl, 27 mM $MgCl_2$, 29 mM $MgSO_4$, 11 mM $CaCl_2$, 2.4 mM $NaHCO_3$, *p*H 8.0. 0-Na^+ artificial seawater had choline Cl substituted for NaCl and $KHCO_3$ for $NaHCO_3$. 0-Ca^{2+} artificial seawater had 16 mM NaCl substituted for $CaCl_2$ and 1 mM EGTA added. Eggs of the sea urchin *Lytechinus pictus* were obtained and preloaded as described previously[6]. Briefly, a 0.75-ml volume of packed dejellied eggs was preloaded in 15 ml of seawater containing 5 μCi ml^{-1} [2, 3-^{3}H]valine (Schwarz–Mann, 26 Ci $mmol^{-1}$) for 45 min. The eggs were then washed twice in seawater and once in the test solution before resuspending to a 0.1% concentration in the test solution. Aliquots (2 ml) were taken at 10-min intervals and processed for scintillation counting as described previously[6].

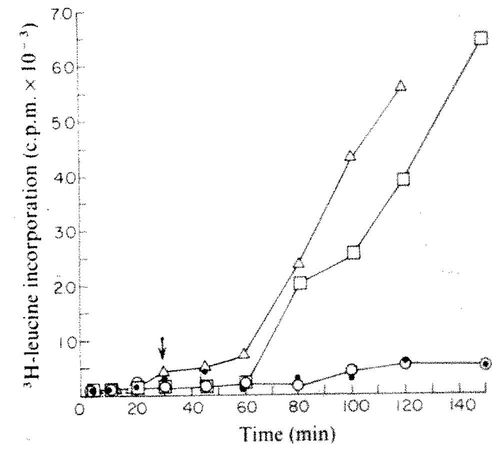

Fig. 2 Total ^{3}H-leucine incorporation over a 150-min period showing the effect of Na^+ on the acceleration of protein synthesis at fertilization. ●, Unfertilized eggs in seawater; ○, Eggs fertilized in normal seawater and completely transferred to 0-Na^+ seawater 50 s after fertilization; △, fertilized eggs in seawater; □, eggs fertilized in normal seawater and completely transferred to 0-Na^+ seawater 50 s after fertilization. At the arrow, 30 min after fertilization, eggs were transferred back to normal seawater. Eggs of the sea urchin *Strongylocentrotus purpuratus* were treated with 5 mM dithiothreitol (DTT), *p*H 8.5, until test aliquots showed that fertilization would not produce a fertilization envelope. Eggs were then preloaded with 5 μCi ml^{-1} [4, 5-^{3}H]leucine for 1 h. Aliquots (2 ml) of a 1% suspension of eggs were put into polylysine-coated Petri dishes, one for each time point. This treatment firmly attaches the eggs to the Petri dish where they will remain even if fertilized because the DTT treatment prevents the elevation of the fertilization envelope. These attached eggs could then be quickly and completely transferred in and out of the 0-Na^+ seawater. The attachment of DTT-treated eggs to polylysine-coated surfaces delays the response of protein synthesis to fertilization by 20 min in both the experimental and the control conditions. At each time point the seawater was removed and 5 ml of 10% trichloroacetic acid added to the Petri dish. At the completion of the experiment the eggs were scraped from the dishes using rubber policemen, collected on glass fibre filters and processed as described previously[6].

If eggs are treated with A23187 and 10 mM NH_4Cl in 0-Na^+ artificial seawater, there will be both an intracellular Ca^{2+} release caused by the ionophore and an intracellular *p*H increase caused by the NH_4Cl. The rate of protein synthesis approaches that of normal fertilized eggs (Fig. 1*d*). Thus, Ca^{2+} release and an increase in intracellular *p*H, although induced by mechanisms other than the normal ones used by the egg at fertilization, will lead to the fertilized level of accelerated protein synthesis. The higher levels of amino acid incorporation with both a Ca^{2+} and *p*H stimulation are unlikely to be due to a change in amino acid pools because pulse labelling experiments give an identical ordering of incorporation rates (unpublished results).

Thus, Ca^{2+} release in the absence of an intracellular *p*H increase does not stimulate protein synthesis. A *p*H increase in the absence of a Ca^{2+} release will yield a partial stimulation of protein synthesis. A small Ca^{2+} influx in the presence of a *p*H increase will yield higher levels of protein synthesis. Only in the presence of both an intracellular Ca^{2+} release and a *p*H increase will protein synthesis be maximally stimulated.

Brandis and Raff[10] have provided evidence for a increase in the peptide elongation rate associated with fertilization that is not seen with NH_4Cl stimulations. It is possible that the increased elongation rate is dependent on the Ca^{2+} release at fertilization. However, it is difficult to be sure of such an interpretation of the differences between NH_4Cl activation and fertilization because (1) the rate of protein synthesis is changing very rapidly, (2) it is affected by the cell cycle changes, and (3) extracellular Ca^{2+} enters during NH_4Cl activation in seawater. In our experiments, however, the magnitude of the response to NH_4Cl stimulation with varying amounts of Ca^{2+} entry or release clearly show that if the intracellular *p*H is elevated, Ca^{2+} plays an additional role in accelerating the rate of protein synthesis at fertilization.

Mutagenic deamination of cytosine residues in DNA

Bruce K. Duncan*

Department of Microbiology, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205

Jeffrey H. Miller

Département de Biologie Moléculaire, Université de Genève, Switzerland

Spontaneous deamination converts cytosine to uracil, which is excised from DNA by the enzyme uracil-DNA glycosylase, leading to error-free repair. 5-Methylcytosine residues are deaminated to thymine, which cannot be excised and repaired by this system. As a result, 5-methylcytosine residues are hotspots for spontaneous transitions, as demonstrated in the *lacI* gene of *Escherichia coli*. We show here that in bacteria which lack uracil-DNA glycosylase (Ung^-) and cannot excise uracil residues from DNA, the rate of spontaneous transition at cytosine residues is raised to the hotspot rate at 5-methylcytosine residues. These studies provide direct evidence that the deamination of cytosine is a significant source of spontaneous mutations.

The observation by Lindahl that potentially mutagenic cytosine deamination occurs at observable rates in *in vitro* physiological conditions led to the discovery of uracil-DNA glycosylase[1]. This enzyme initiates the repair of uracil from DNA by a 'base-excision' repair pathway[2,3]. *E. coli* uracil-DNA-glycosylase-deficient mutant strains[4] have been shown to have a weak G:C → A:T specific mutator phenotype[5]. Presumably, a G:U mismatched base pair resulting from cytosine deamination generates an A:U base pair after replication. Thus, one of the physiological roles of uracil-DNA glycosylase may be to repair such pre-mutational lesions resulting from deamination.

A more general description of the possible significance of cytosine deamination as an important mutagenic process comes from studies of the *E. coli lacI* gene[6–8]. Large numbers of independent *lacI* mutations have been characterized by genetic and biochemical methods. Of spontaneous base substitutions leading to nonsense mutations, approximately 75% arise by G:C → A:T transitions[6–8]. Two highly mutable 'hotspot' sites are conspicuous among 14 G:C → A:T amber mutation sites in the *lacI* gene; half of the observed amber transition mutations occur at these two sites. DNA sequence studies have demonstrated the presence of 5-methylcytosine residues at the hotspot sites[6]. It is clear that cytosine methylation increases the mutagenic susceptibility of a cytosine residue, presumably because of the inability of the cell to repair the deamination product, thymine.

Strain	Approx. I^- mutant frequency	% Amber mutants
GM1	2.5	1.0
BD1322	2.5	1.3
BD1323 (Ung^-)	2.5	4.6

I^- mutants were selected and screened against different suppressors to detect amber mutations, as described previously[7,8]. BD1322 is an Ung^+ derivative of the Ung^- strain BD1323. It is isogenic to GM1.

Table 2 Distribution of amber mutations in Ung^+ and Ung^- strains

		No. of occurrences		
Base substitution	Site	Ung^+ GM1	Ung^- BD1323	Ung^- BD1323 (2AP)
G:C → A:T	*A5*	0	2	0
	*A6**	51	4	39
	A9	8	18	4
	*A15**	37	0	29
	A16	9	1	2
	A19	11	2	1
	A21	8	2	0
	A23	8	7	2
	A24	10	1	5
	A26	6	2	2
	A31	1	2	3
	A33	5	4	1
	*A34**	12	3	11
	A35	1	2	0
Total G:C → A:T mutations		167	50	99
Transversions		55	4	0
Total amber mutations detected		222	54	99

Distribution of amber mutations in Ung^+ and Ung^- strains, showing the distribution found in GM1 and in BD1323 with and without 2-aminopurine (2AP). The number of occurrences refers to the number of mutations detected at a given locus in the collections of 222, 55 and 99 *lacI* mutations, respectively. The characterization of the GM1 amber mutations has been reported previously[6–8]. The I^- collection from BD1323 was analysed in the same manner.

* Presence of 5-methylcytosine at the mutational site[6].

We have studied the effect of the *ung* mutation, which results in the loss of uracil-DNA glycosylase activity, on the distribution of I^- nonsense mutations. The *ung-1* allele was inserted by P1 transduction into the *E. coli* GM1 used in previous studies of the *I* gene[6–8]. Table 1 shows that the frequency of amber mutations increased almost fourfold in the presence of the ung^- mutation. Thus, a deficiency of uracil-DNA glycosylase led to an increase in the frequency of mutations due to base substitutions. The I^- amber mutations were assigned to one of the known amber sites by deletion mapping and by examining the response to different amber suppressors, as described previously[7,8].

G:C → A:T transitions generate amber mutations at 14 different sites in the *lacI* gene. This represents 38% of the 37 characterized amber mutation sites in *lacI* which can be derived by a single base change. As Table 2 shows, 93% of the amber mutations detected in the Ung^- background arose by way of a G:C → A:T transition. In Ung^+ cells (GM1), 75% of all the amber mutations were G:T → A:T transitions, principally due to the 5-methylcytosine hotspots *A6* and *A15* (and to a lesser extent *A34*).

A comparison of the distribution of the $G:C \rightarrow A:T$ mutations yields a more striking difference between *ung*$^+$ and *ung*$^-$ cells. The general increase of transition mutations in the *ung*$^-$ cells results from an increase in transitions at non-methylated cytosines, bringing them up to the level of the 5-methylcytosine sites. Thus, the 5-methylcytosine sites (*A6*, *A15* and *A34*) no longer appear as hotspots. Because uracil-DNA glycosylase has been shown to function in the base excision repair of uracil, these results demonstrate that cytosine deamination occurs *in vivo*; the failure to repair these lesions leads to an increase in the mutation rate.

Methylcytosine residues have also been shown to be hotspot loci when cells are mutagenized with 2-aminopurine (2AP)[6–8]. Could 2AP be stimulating the deamination of cytosine and methylcytosine residues? Perhaps the 2AP incorporation into DNA perturbs the structure of the DNA, making it more susceptible to cytosine deamination. Lindahl has shown that the DNA-cytosine deamination rate constant increases more than 100-fold when DNA is denatured[9]. This model does not necessarily assume the actual mispairing of 2AP with cytosine; formation of a 2AP:T base pair might also induce the deamination of nearest-neighbour cytosine residues. We have tested this hypothesis. The right-hand column of Table 2 shows that the *ung* mutation does not affect the mutability of methylcytosine residues compared with other cytosine residues in the presence of 2AP. Thus, with the Ung$^-$ strain, 80% of the 2AP-induced amber mutations are at the three methylated cytosines, which compares favourably with the wild-type Ung$^+$ (GM1) strain, in which 60% of the transitions resulting in amber mutations are at the methylated site, and with GM1+2AP[6–8], in which 85% of the amber mutations are at the methylated cytosines. These results argue that 2AP does not induce deamination.

Visualization of an unwound DNA duplex

Struther Arnott, P. J. Bond & Rengaswami Chandrasekaran

Department of Biological Sciences, Purdue University, West Lafayette, Indiana 47907

Certain dyes[1,2] and drugs[3,4] with planar aromatic components can intercalate these into stacks of base pairs and thereby bind tightly to DNA duplexes. Intercalation at one site usually precludes intercalation between the base pairs immediately adjacent[5]. This exclusion implies that two distinct nucleoside conformations are needed in the dinucleoside phosphates which include the intercalation site. The simplest distinction would involve no more than quantitative differences in the (usually *anti*) conformations at the glycosidic bonds[6]. This could be reinforced by additional, qualitative differences in the furanose ring puckerings (C-2′-*endo* and C-3′-*endo*)[7]. For the most pronounced difference there could be qualitative differences (*syn* and *anti*) in the conformations of the glycosidic bonds as well as in the conformations of the sugar rings. The model discussed here is an example of this most emphatic distinctiveness, as the nucleosides at the 5′ ends of the intercalation sites are C-3′-*endo* and *syn* and at the 3′ ends are C-2′-*endo* and *anti*. X-ray diffraction analysis suggests that a completely unwound allomorph of the DNA duplex can persist in oriented fibres when stabilized by certain platinum-containing intercalators. In the untwisting of (usually) right-handed DNA double helices, unwound duplexes are presumably fleeting intermediates.

Previous precise visualizations of intercalation in DNA came from extrapolatory modelling[6–9] inspired mainly[8,9], but not exclusively[6,7], by X-ray diffraction studies of crystals containing self-complementary dinucleoside monophosphate duplexes complexed with intercalators. The accuracy of particular models of intercalation into DNA itself can be determined[10,11] by X-ray diffraction studies of fibres of calf thymus DNA saturated with a variety of platinum derivatives. The fibres are uniaxially oriented and their diffraction patterns, of which Fig. 1 is an example, show a layer line with 10.2 Å spacing, in striking agreement, as the original authors[10,11] emphasized, with a neighbour exclusion model. This is exactly the length expected of a unit of structure involving an intercalator sandwiched between two base pairs (Fig. 2*a*) which are then directly stacked on the base pairs of the next intercalator sandwich (Fig. 2*b–d*). Also, some of the fibres are polycrystalline so that the layer lines on the diffraction patterns are populated with fairly sharp Bragg reflections. Their spacings and intensities are satisfactorily explained by a model whose molecular conformation and packing are rather different from those proposed earlier[10]. An important conclusion of our study is that the DNA duplexes in these complexes are completely unwound and therefore not double helices. We have therefore an unprecedented opportunity to visualize a most unusual allomorph of double-stranded DNA.

We have confined our detailed analysis to the diffraction pattern (Fig. 1) provided by the DNA · $[(\text{bipy})\text{Pt}(\text{en})]^{2+}$ complex; however, our interpretation of the patterns from the DNA complexes with the other platinum-containing intercalators would be essentially the same.

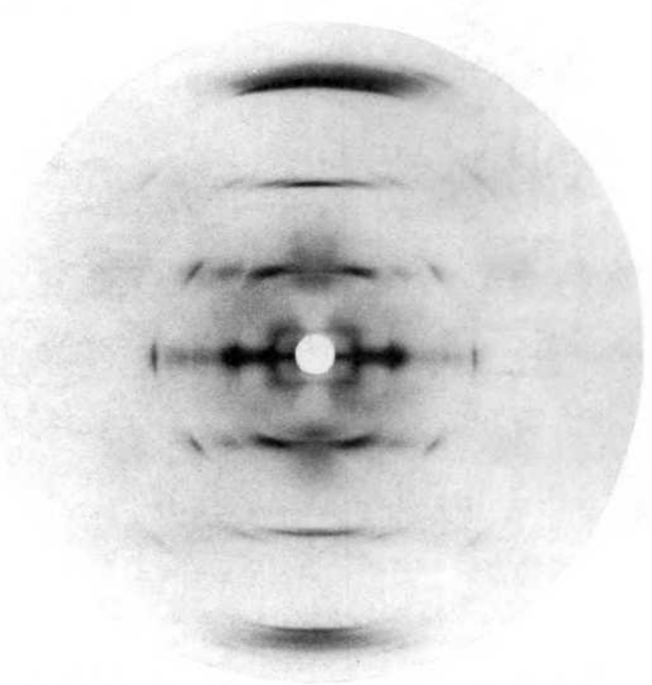

Fig. 1 The X-ray diffraction pattern from a uniaxially oriented, polycrystalline fibre of calf thymus DNA saturated with intercalating $[(\text{bipy})\text{Pt}(\text{en})]^{2+}$ cations. The layer line spacings indicate an axial repeat of 10.2 Å. The Bragg reflections can be indexed on the basis of a rectangular unit cell $11.5\times20.0\times10.2$ Å^3.

Table 1 Comparison of the conformation angles of L DNA in the DNA · [(biby)Pt(en)]$^{2+}$ complex with those of S DNA

Conformation angle (deg)	L DNA		S DNA*	
	XpX†	XpX	CpG	GpC
θ(C4′–C3′–O3′–P)	−84	171	−72	−103
θ(C3′–O3′–P–O5′)	98	125	102	−91
θ(O3′–P–O5′–C5′)	82	−60	52	−110
θ(P–O5′–C5′–C4′)	−162	−133	−153	−168
θ(O5′–C5′–C4′–C3′)	180	−139	178	54
θ(C5′–C4′–C3′–O3′)	76	147	76	147
θ(O4′–C1′–N9–C4)†	26	167	89	—
θ(O4′–C1′–N1–C2)†	26	167	—	−159

L DNA is the trivial name we have given to the ladder-like structure, and S DNA is the polymeric version of the left-handed duplex.

* From ref. 14.

† X can be a purine or a pyrimidine.

The 30 independent Bragg reflections in Fig. 1 can be indexed adequately on the basis of a rectangular unit cell with dimensions (s.d.) $a = 19.95(15)$ Å, $b = 11.52(05)$ Å, $c = 10.20(05)$ Å. There are no reflections requiring the (six times) larger trigonal unit cell suggested earlier[10].

Clearly, the new unit cell cannot accommodate quasi-cylindrical DNA double helices with diameters at all like the traditional values of 21 ± 4 Å. This should not be surprising because the layer line spacings also are not compatible with a helical molecular structure. If successive, 10.2 Å-long units of structure were related by helical symmetry there should be layer lines with spacings $10.2(N/n)$ Å where N and n are integers and $N > 1$. In fact, $N = 1$ and all the layer lines have spacings $(10.2/n)$ Å, $n = 1, 2, 3 \ldots$, implying that the structural unit is repeated by simple translation along the chain axis.

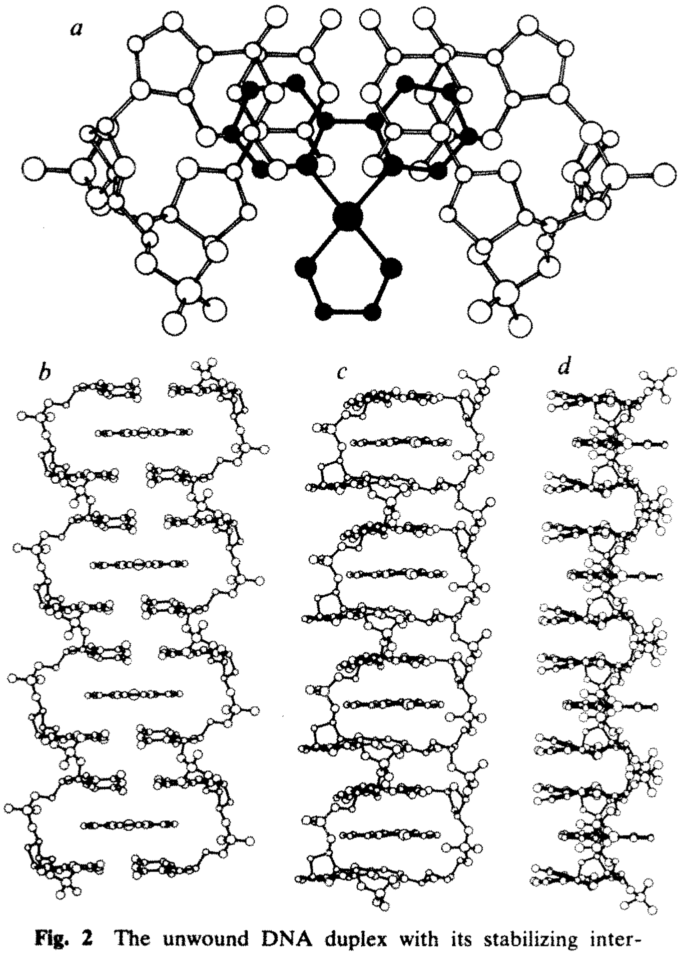

Fig. 2 The unwound DNA duplex with its stabilizing intercalators. *a* Shows the view parallel to the *c* axis of the stacking arrangement of an intercalator between two base pairs. Because this unit is repeated by simple translation along the *c* axis and the base pairs are almost perpendicular to this axis, the base pairs in the excluded site overlap one another in the same way as appears here; *b*–*d* contain three views perpendicular to the *c* axis, including the view down the diad axis (*b*) and views after successive rotations of 45° about *c*.

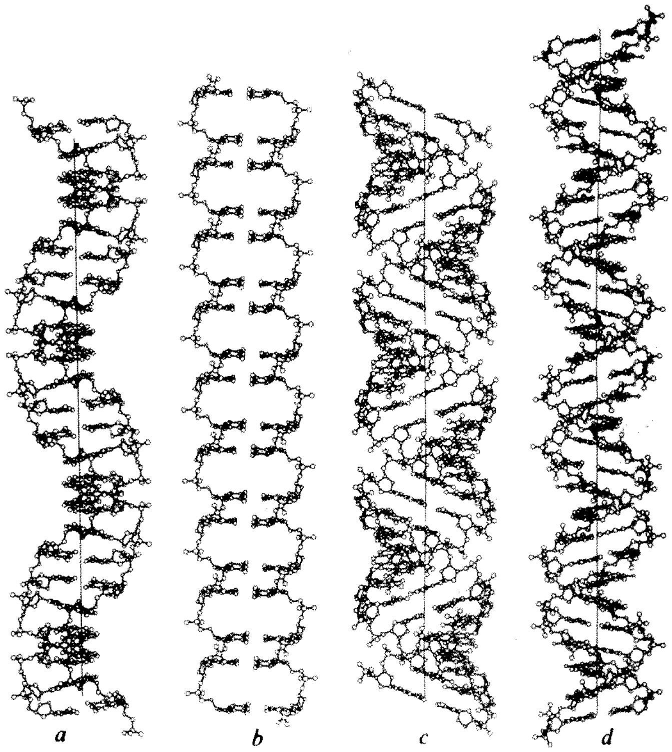

Fig. 3 Comparison of the morphologies of the most underwound (left-handed) DNA double helix (*a*), the unwound duplex (*b*), a right-handed double helix of the A family (*c*) and the most overwound (right-handed) double helix (which belongs to the B family) (*d*).

Bond *et al.*[10] were unable to build a stereochemically reasonable model duplex containing intercalated dinucleotide structure units except as N-fold helices with $N \geq 7$. In these experiments all glycosidic conformations were *anti*. By contrast, we have found that it is quite easy to construct a stereochemically acceptable model of the required '1-fold helix' if the glycosidic conformations along the polynucleotide chain are alternately *syn* and *anti*. The best arrangement associates a C-3′-*endo* furanose with the *syn* nucleoside and a C-2′-*endo* furanose with the *anti* nucleoside as in the left-handed screw structures observed with certain oligonucleotides[12,13] and DNA polymers[14]. Indeed, the segment involving stacked base pairs has the same kind of nucleotide conformations (see Table 1) as CpG in the left-handed (6_5) helical form of poly(dG-dC) · poly(dG-dC) (ref. 14). Not surprisingly, the GpC conformation in the 6_5 helix is not retained in the nucleotide which has to straddle the intercalation site. Extension of the chain and the achievement of no net winding after two nucleotides is contrived (see Table 1) by having *trans* conformations around C3′–O3′ (*gauche minus* in the 6_5 helix), P–O3′ (*gauche minus* in the 6_5 helix) and C4′–C5′ (*gauche plus* in the 6_5 helix).

In constructing the model of the DNA duplex in this complex, we assumed that the chains are antiparallel and conformationally identical. There are, therefore, diad axes half way between successive base pairs and perpendicular to the long axis of the molecule. We have further assumed that the diad axis within the [(bipy)Pt(en)]$^{2+}$ cation coincides with the DNA diad which is in the intercalation site. This leaves two possible dispositions for the intercalator. We find that the one which places the platinum atoms in the minor groove (Fig. 2*a*) seems to be preferable from both steric and diffraction considerations.

The small cross-section of the unit cell clearly shows that it can be traversed by no more than one intercalated duplex, oriented so that the minor groove is approximately bisected by the *b* axis. The diffraction pattern has some continuous intensity as well as Bragg reflections on each layer line, suggesteing a 'statistical' crystal structure[15]. The best arrangement we have found has rows of identically oriented molecules lined up along *a* 20-Å apart. About one-third of the rows separated by 11.5 Å in the *b* direction will also be mutually translated $c/2 = 5.1$ Å in the *c* direction and the molecules in the two rows mutually rotated by 30° about *c*. Such an arrangement would result in no steric anomalies and provide a good explanation of both the Bragg and the non-Bragg diffraction. For the Bragg reflections the conventional crystallographers' residual *R* has an encouragingly low value of 0.31 after a least-squares refinement[16] of the complex in which the polynucleotide chains are treated as a linked-atom system and the $[(\text{bipy})\text{Pt}(\text{en})]^{2+}$ intercalator as a rigid body free to move along and rotate about the diad axis which it is assumed to share with the DNA duplex.

In the refined structure the mean plane of each base pair of the DNA duplex is tilted 4° from being perpendicular to *c*. The bases in the base pairs are not coplanar but are 'propeller-twisted' with an angle of 22° between their planes. The intercalators are also tilted (in their case 5°).

Polynucleotide duplexes with Watson–Crick base pairs have quite polymorphic secondary structures (Fig. 3). Apparently this is not generally accepted because few of the many and varied allomorphs have been exploited in visualizing DNA and RNA duplexes in dynamic and interactive modes. Yet it is almost 30 yr since the identification[17] of A and B DNA indicated what a wide range of structure might be achieved by polynucleotide duplexes. A and B-DNA are helical structures with very distinct axial translations (h) and rotations (t) per nucleotide: $h, t =$ 2.56 Å, 32.7° in the former and 3.38 Å, 36.0° in the latter. Many allomorphs have now been trapped in oriented fibres and had their conformations defined[18]. All were right-handed double helices with $2.56\ \text{Å} \leqslant h \leqslant 3.38\ \text{Å}$ and $30.0° \leqslant t \leqslant 45.0°$. Recently, these ranges have been extended dramatically by the discovery of further wound right-handed helices[19] (with $t =$ 48.0°) and the underwound (left-handed) helices[14] (with $\langle t \rangle -$ 30.0°) anticipated by the NMR[20] and single crystal[12,13] studies of oligo(dG–dC) · oligo(dG–dC).

The present structure with $\langle h \rangle = 5.1$ Å and $\langle t \rangle = 0.0^{o}$ is a further example of the polymorphism of polynucleotide duplexes. Clearly, the partially stacked polynucleotide component of the complex could have only a brief lifetime in the absence of the stabilizing intercalator. Therefore, we have visualized one of the higher energy states available to DNA. In the present context this state has been exploited by a synthetic intercalator, but obviously it is a state which is available also for interaction with native molecules.

The structure of this complex also adds pointedly to the contention[6,8,9] that there is no single conformational strategy whereby polynucleotide duplexes contrive to accommodate intercalators. Further, the local unwinding resulting from intercalation can be much larger than is often supposed.

We thank Professor S. J. Lippard for materials and discussion. The research was supported by NIH grant GM17371 to S.A.

Metallothionein occurs in roots of *Agrostis* tolerant to excess copper

Wilfried E. Rauser & Nester R. Curvetto*

Department of Botany and Genetics, University of Guelph, Guelph,
Ontario, Canada N1G 2W1

Metallothioneins have an important function in metal metabolism in animals[1]. These low molecular weight proteins have high contents of half-cystinyl residues (up to 33%) which can bind metals such as Zn, Cu, Cd, Hg or Ag in mercaptide complexes[1]. In normal conditions animal tissues have low concentrations of metallothioneins, but these increase on administration of metal[2–4], a reaction which is consistent with their suggested role in detoxification mechanisms[2,5,6]. Various plant genotypes exhibit tolerance to excesses of metals[7], and Jowett[8] proposed that such genotypes contain compounds capable of specific metal chelation. Metallothioneins could serve such a role. We report here that copper-thionein occurs in the roots of a clone of *Agrostis gigantea* Roth tolerant to excess copper[9]. This is the first unequivocal demonstration of a metallothionein in a vascular plant. These unusual proteins may have a role in metal metabolism in plants and could be important in the elucidation of the mechanism of metal tolerance.

Apical tillers of clone 4 of *Agrostis gigantea* were transplanted into tanks containing complete nutrient solution and allowed to develop roots for 3 weeks[9]. Plants were then exposed for 1 week to 16 μM $CuSO_4$ in the nutrient solution. Roots were harvested, washed three times in large volumes of cold deionized water and blotted with paper towelling. The roots were either used at once or frozen in liquid nitrogen for later use. All operations for extracting and isolating proteins were carried out at 0–4 °C with solutions purged with N_2 and in enclosures flushed with N_2. A typical separation of heat-denatured root extract on DEAE Biogel A is shown in Fig. 1. The protein was resolved into material not adsorbed to the ion exchanger (fraction A) and a prominent peak of copper-binding protein that was eluted only after adding NaCl (fraction B). Metallothioneins characteristically adsorb strongly to DEAE[3,10]. Fraction B from this and other isolations was purified by electrophoresis on 3-mm thick gel slabs of 10% w/v polyacrylamide with Tris-glycine *p*H 8.3 as electrode buffer[11]. In a typical run where 165 mg fraction B product was applied, a single dark brown band 5 mm wide was evident after migrating 10 cm. The dark brown material was eluted from the gel and analysed for molecular weight (MW), amino acid composition and metal content. Fraction B protein showed a major band at a MW of 14,400 and lesser bands at 9,800, 6,200 and 5,400 after SDS-polyacrylamide gel electrophoresis.

From the amino acid composition listed in Table 1 it is clear that fraction B protein has a high half-cystine content, a key feature of metallothioneins[1,2,10]. Acidic amino acids predominated and, along with cysteine, glycine and serine, accounted for 67.5% of the residues compared to 70.2% for yeast Cu-thionein[12]. The ratio of half-cystine to copper was 1.9–2.4 to 1 in accord with the stoichiometry found for Cu-thionein from

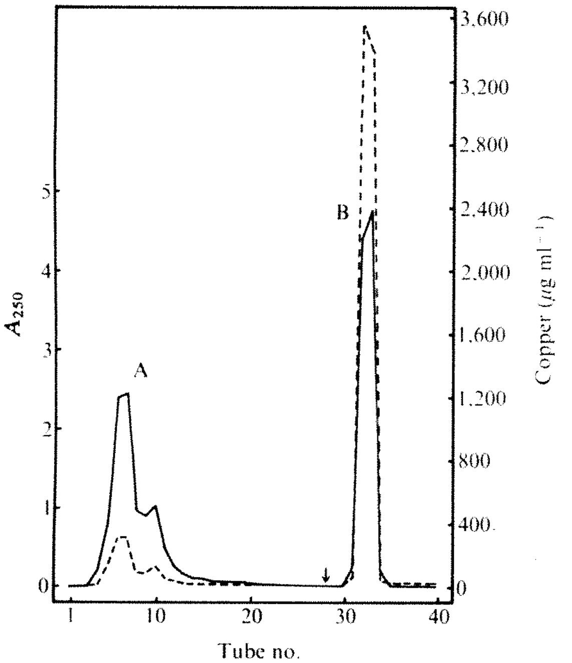

Fig. 1 Ion-exchange chromatography of copper-binding proteins from *Agrostis gigantea*. 60 g of frozen roots were homogenized with 60 ml 10 mM Tris-HCl, *p*H 8.0, 5 mM NaCl, 5 mM 2-mercaptoethanol in a mortar and pestle. The homogenate was strained through cheesecloth and centrifuged at 20,000*g* for 30 min. Heat denaturation of the supernatant was done by rapid heating at 60 °C for 3 min while stirring under a stream of N_2. The preparation was cooled in an ice bath and centrifuged at 20,000*g* for 30 min. The supernatant was concentrated to 5 ml by ultrafiltration on a Diaflo UM2 membrane (Amicon) and washed three times with a total of 50 ml 5 mM Tris-HCl, *p*H 8.6. The washed concentrate was applied to a DEAE Biogel A column (1.5 × 25 cm) equilibrated with 5 mM Tris-HCl, *p*H 8.6. Proteins were eluted with the same buffer at a flow rate of 70 ml h^{-1} with fraction volumes of 8 ml. At tube 28 (arrow) the elution buffer was changed to one containing 1 M NaCl. ——, Protein; --------, copper.

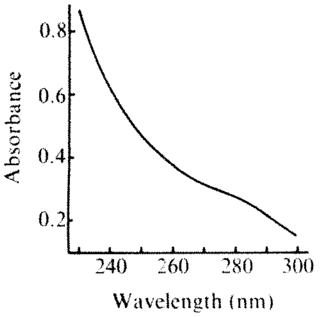

Fig. 2 UV absorption spectrum of fraction B protein in 5 mM Tris-HCl, *p*H 8.6.

Table 1 Amino acid composition of copper-binding proteins from *Agrostis gigantea*

	Fraction A	Fraction B
Half-cystine*	4.8	18.4
Aspartate	12.8	10.0
Glutamate	13.4	19.0
Glycine	11.7	11.9
Serine	8.6	8.2
Threonine	5.9	2.9
Proline	7.5	5.8
Alanine	9.0	6.0
Valine	6.4	4.2
Methionine	1.0	0.7
Isoleucine	3.6	1.5
Leucine	5.9	3.6
Tyrosine	1.1	0.6
Phenylalanine	2.0	1.5
Lysine	3.5	3.3
Histidine	1.4	0.8
Arginine	1.4	1.6

The material in fractions A and B from DEAE Biogel A separations was purified electrophoretically on slab gels, dialysed exhaustively against 5 mM Tris-HCl, *p*H 8.6, and then hydrolysed in N_2-saturated 6 M HCl at 110 °C for 24 h. Values are expressed as per cent of the total number of residues.

* Only 0.6–0.7 residue % was found as cysteic acid.

yeast[12], but markedly different from the sulphur to metal stoichiometry ratio of 3 : 1 known for Cd- and Zn-thioneins of animal origin. Fraction B protein contained copper and zinc, but copper comprised 93–98% of the bound metal. The low tyrosine and lack of tryptophan account for the low absorption at 280 nm (Fig. 2). This UV spectrum resembles that of chicken liver metallothionein fully loaded with copper[13]. The properties of thermal stability, low molecular weight, high half-cystine content, metal binding and UV spectrum are consistent with the designation of fraction B protein as a Cu-binding metallothionein as was done for the yeast protein[12]. The amino acid composition of fraction B protein resembles that of Cu-thionein from yeast[12]; however, both differ from equine Cd- and Zn-thioneins[14]. This divergence raises the possibility that the proteins binding copper might be set apart from the Cd- and Zn-thioneins even though they all have the unique function of binding abundant metal.

The nature of the Cu-binding material in fraction A is less clear. The amino acid composition of electrophoretically purified fraction A protein (Table 1) indicates that it is not an aggregate of Cu-thionein as has been suggested by others[13,15,16]. The copper content was much lower at a cysteine to copper ratio of 0.5 : 1, yet zinc comprised only 3–6% of the bound metal. Electrophoresis in SDS gels showed bands of 5,400, 11,600 and 52,300 MW against a background of Coomassie blue-staining material which reached the start of the gel.

Quantitative estimates of the amount of Cu-thionein in the roots of *Agrostis gigantea* were not possible. Protein estimations by either biuret or dye binding[17] methods were increasingly unreliable as the metallothionein was purified. Occlusion of material on the ultrafilter gave copper losses of 12–17% and there were even greater losses during dialysis of protein concentrates. More reliable methods are required to determine how much Cu-thionein occurs in the roots of *Agrostis gigantea* before any more can be inferred about its involvement in the mechanism of copper tolerance.

We thank Dr T. K. Smith for performing the amino acid analyses. This study was supported by NSERC grant A4921.

MATTERS ARISING

Superheavy-element fission tracks in iron meteorites

BULL'S careful search[1] for superheavy element (SHE) fission tracks in silicate inclusions within iron meteorites seems to have given a null result. He finds an upper limit of 10^{-12} kg per kg for the original abundance of SHEs in the class 1A Odessa iron meteorite. As this is many orders of magnitude below what we postulated[2] from considerations of early heat sources in the Moon and from a highly speculative interpretation of elemental abundances in iron meteorites[3], Bull's result may be accepted as proof that superheavy elements either did not exist or did not play any part in the early Solar System. His observations therefore merit further study. His result refers to the date at which track retention becomes possible, that is when the temperature has fallen to ~200 °C. Now although the Rb–Sr, K–Ar dates of silicate inclusions in iron meteorites range up to ~4,600 Myr, they are not to be interpreted simply as the 'age' of iron meteorites nor are they the dates of the emplacement of the silicate grains. The process by which silicate inclusions get into iron meteorites is unknown: but they must certainly enter while the temperature of the iron is near to its melting point. Cooling rates of iron meteorites are determined by metallographic study and for the Odessa meteorite it is 1.5 °C Myr^{-1} in the range 700–300 °C. The meteorite might, therefore, only reach track retention temperatures 800 Myr after the emplacement of the silicate crystals. Taking the half life of SHEs determined from the decay of the ancient lunar magnetic field[4] as 100 Myr, the original abundance of SHEs in the iron would have decayed by nearly 3 orders of magnitude. This, of course, assumes that the rate of cooling at higher temperatures and at lower temperatures is the same. In fact if, as we suppose, SHEs have played a dominant part in the early thermal history of the parent bodies of meteorites, the cooling rates at higher temperatures may have been slower and the diminution in the abundance of SHEs at the time when track retention became possible greater than we have estimated here. Another possible explanation of Bull's results is, of course, that SHEs on the condensation of grains in the early Solar System were never fully taken up by the iron. This explanation seems probable in the case of the Odessa meteorite as IA iron meteorites have been interpreted as not originating in the iron core in a sizeable asteroid-like body. Probably only in a completely melted sizeable body would the molten iron, mixing with other crystals, dissolve the SHEs. The IA meteorites have reasonably been interpreted in terms of a model in which iron condenses from the nebula and forms small bodies within a much larger silicate parent body. If this model is correct, then the existence of ^{244}Pu fission tracks would have a simple explanation. Bull's studies ought to be done on the IIAB iron meteorites which are more reasonably assumed to come from the cores of entirely melted parent bodies, but the difficulty is that there are no silicate grains to record fission tracks. *Note added in proof*: We are, of course, aware that if the tracks inside the diopside crystals are due to the decay of Pu^{244}, synthesized with the other elements in stellar nucleogenesis processes just before the condensation of the primeval Solar System nebula, our first argument, that the presumed SHE tracks have disappeared due to annealing processes, collapses. But we wonder whether this identification, which, as Bull so clearly explains, is arrived at by a process of elimination, should be accepted without question. Extrapolation of the Periodic Table[1] does not show that all the SHE are siderophile and perhaps some of them, with longer half life, went into the mineral phase.

We agree that our suggested thermal history are necessarily speculative—as are all others—but the track retention temperatures of minerals, such as the quoted 400 °C for diopside, are based on laboratory annealing experiments.[5] But this extrapolation to 4,000 Myr assumes that the same excitation process can be assumed as in laboratory annealing; but it is characteristic of solid state physics phenomena that processes with different excitation energies are dominant over different ranges of temperature and time.

BULL REPLIES—Runcorn *et al.* have proposed two explanations for the lack of superheavy element (SHE) fission tracks which I observed in silicates from the Odessa iron meteorite[1].

First, they point out that a thermal history for Odessa can be constructed in which the meteorite reaches track retention temperatures only after a time corresponding to many half lives for the SHEs (taken to be ~100 Myr) has elapsed. This explanation, however, fails to account for the large excess of fission tracks distributed throughout the diopside grains in Odessa. These exceed the number accruing through the decay of ^{238}U in the lifetime of the Solar System by a factor of ~100 and the most plausible source of this excess is the decay of ^{244}Pu which, significantly, has a half life which is very close to that assumed for the SHEs. This means that any cooling which was slow enough to allow most of the SHEs to decay would also result in the loss of most of the Pu and the very large excess of fission tracks in the diopside would be difficult to account for unless this mineral was very much enriched in Pu relative to U (an initial ratio of Pu/U of ~10 would be needed compared to values of ~0.01–0.1, inferred from fission Xe measurements on chondritic whitlockites[2]). As to the thermal history proposed by Runcorn *et al.*, I would point out that the track retention temperature of diopside is higher than 200 °C, probably nearer 400 °C and that there is considerable uncertainty as to the metallographic cooling rates.

The second explanation by Runcorn *et al.* is that the IA irons never took up many SHEs. This point may be valid in that the group IA meteorites are not typical irons and there is evidence that they were never melted. The pallasites, however, are believed to be fragments of a core boundary region and pallasitic metal probably represents core material. In Brenham the superheavy content of the metal was less than 10^{-15} kg per kg at the time of track retention but unfortunately we cannot as yet place firm constraints on when track retention occurred.

Finally, note that silicate inclusions are occasionally found in other iron meteorites groups and a study of these should provide further clues to the abundance of SHEs in the early Solar System.

Grand unification theories and the large numbers hypothesis

BARROW[1] has recently used the large number hypothesis (LNH) in connection with the proton lifetime.

I wonder about the meaning of his result in light of the fact that he has based his computation on a closed Friedman universe, while Dirac has explicitly shown that "A model with a maximum size for the Universe is not permitted"[2], that is, is disallowed by the LNH.

V. CANUTO

Institute for Space Studies,

New York, New York 10025

1. Barrow, J. D. *Nature* **282**, 698 (1979).
2. Dirac, P. A. M. *Proc. R. Soc.* **A338** (1974).

CURRENT ideas based on SU(5) gauge theory suggest the violation of baryon conservation. The proton lifetime, τ_p, is predicted to have various values between 10^{30} and 10^{37} yr. Barrow[1] has noticed that the dimensionless ratio of τ_p so predicted, to the Planck time $\tau_{p1} = (Gh/c^5)^{\frac{1}{2}}$, is not very different from the Universe baryon number $N \sim 10^{79}$. Assuming that the two numbers are equal, he can then assign to τ_p the more definite value of

$$(hc/Gm_p^2)^{\frac{1}{2}} H_0^{-1} \sim 10^{30} \quad \text{yr}$$

where m_p is the proton rest mass, H_0 the present Hubble 'constant', and factors of the order of unity have been omitted.

We consider instead of τ_{p1} a time unit that involves a property of the particle itself. The simplest choice is $\tau_m = h(m_p c^2)$ (so that for particles which remain massless $\tau_m \rightarrow \infty$). Intuitively, τ_m is, of course, the minimum lifetime of one proton before its inertial mass can be measured as $\geqq m_p$. Furthermore, we speculate on the lifetime τ'_p for its decay hypothetically to some unspecified particles of lower masses under gravitational interaction. The plausibility that all particles with rest masses have finite lifetimes has been considered[3]. All may eventually decay to gravitons on sufficiently long time scales for which charge conservation is violated; photons may not be massless. Maybe changeability is so prevalent in the physical world that all symmetries are ultimately broken spontaneously. Now, on dimensional grounds τ'_p may be expected to be given by a similar expression as τ_p, with the mediating boson mass replaced by the Planck mass $(hc/G)^{\frac{1}{2}}$ at which gravitational unification should occur, and with the coupling constant α_x substituted by another which is similarly of the order of 1/137. The result is $\tau'_p \sim 10^{50}$ yr.

We then find that τ'_p/τ_m is again of the same order as the baryon number in the Hubble sphere (or in the Universe). If $\tau'_p/\tau_h = fN$, where f is some factor such as $3^2/8\pi$ and numerically of the order of unity, then

$$\tau'_p \sim (hc/Gm_p^2) H_0^{-1}.$$

However, some of the cosmological coincidences, such as the above two, may really be coincidences and 'explicable' by the anthropic principle[2] or speculatively as 'historical' data[3]. This can be true although others are derivable (for example, the coincidences involving the Universe photon–baryon ratio: from SU(5) theory[4]). Future experimental verifications such as of the value of τ_p and excepting a decreasing G, therefore do not confirm the large number hypothesis. Some large dimensionless numbers may equal H_0^{-1}/τ_m or its square only in the present epoch. If the Universe is indeed closed, it has extremal scale factors which are unrelated to its age expressed in atomic units. Thus the hypothesis is inconsistent with[5] a closed Friedmann universe[1].

5. Dirac, P. A. M. *Proc. R. Soc.* **A338,** 439 (1974).

BARROW REPLIES—A large numbers hypothesis (LNH) is not incompatible with a closed finite universe. The original statement of the LNH by Dirac[1] in 1938 was: "Any two of the very large dimensionless numbers occurring in Nature are connected by a simple mathematical relation, in which the coefficients are of the order of magnitude unity." To derive some predictions from this hypothesis one must accumulate a group of large dimensionless quantities of similar magnitude and equate them. The issue of whether or not a 'closed' universe is compatible with the hypothesis depends crucially on the type of large number that is chosen. Dirac's original[1] choice included the ratio of $e^2 m_e c^3 \sim 10^{-23}$ s, (the time for light to traverse the classical electron radius) to the presently inferred age of the Universe, $t_0 \sim 10^{17}$ s. This particular large number therefore incorporates an explicit time dependence through the changing value of t_0. The hypothesis that it be equal to other dimensionless collections of traditional constants with similar magnitude requires that one of the latter also possess an explicit time dependence. Dirac chose to incorporate the time dependence into Newton's gravitation 'constant', G. If the Universe were finite (either 'closed' or 'open' but with finite volume through topological identifications), then the LNH would also seem to require the total number of protons in the Universe ($\sim 10^{80}$) to increase as t^2 in violation of energy conservation. For this reason Dirac[1] required an open (infinite) cosmological model. However, it is only the choice of a 'large number' possessing an explicit time dependence that suggests such a conclusion, not the LNH itself.

If one chooses large numbers in a less anthropocentric fashion then one naturally replaces the time scale t_0 by t_m, the proper time to the expansion maximum in a closed universe. The quantity t_m, unlike t_0, is observer-independent and a fundamental cosmic time. Quantitatively this new choice leaves the value of the relevant large number virtually unchanged ($t_m m_e c^3/e^2 \sim 10^{40}$) because t_m is within an order of magnitude of t_0, but qualitatively its consequences are quite different: No varying 'constants', additional conformal degrees of freedom or unconventional physics become involved and a closed universe is actually necessary for consistency. Formulated in this manner the LNH simply claims that otherwise unrelated groups of constants possessing similar dimensionless magnitudes are actually equal. This is why I used the time t_m and a 'closed' universe in my formulation. It is, of course, equally legitimate to pursue the more speculative and complicated course that follows from choosing to incorporate t_0 into the large numbers. An 'open' universe would then be a necessary and testable prediction.

Tang derives an interesting estimate for the time scale of a possible gravitational decay of the proton, τ'_p. It depends linearly on the dimensionless gravitational coupling Gm_p^2/hc. A more natural candidate for this time scale might be provided by existing theory[2]—the time for a proton to quantum tunnel inside its own Schwarzchild radius, $R_s(p) \sim Gm_p/c^2$, and then evaporate into a state of zero baryon charge by the Hawking effect[3–5]. One might crudely estimate this time scale as $\tau''_p \sim [R_s^2(p)nc]^{-1}$ where $n \sim (h/m_p c)^{-3}$ is roughly the nuclear density. This estimate gives a decay time varying as the square of the gravitational coupling and considerably in excess of the lifetime suggested by grand unified gauge theories:

$$\tau''_p \sim \left(\frac{hc}{Gm_p^2}\right)^2 \left(\frac{h}{m_p c}\right) \sim 10^{48} \quad \text{yr}$$

BOOK REVIEWS

More uncertainty for the common man

J.S. Bell

Other Worlds: Space, Superspace and the Quantum Universe. By Paul Davies. Pp.208. (Dent: 1980.) £7.50.

THE aim of this book is to "face squarely the full impact of fundamental quantum theory on our conception of the world [and] not simply to review a notoriously difficult branch of modern physics, but to turn instead to broader issues. What is man? What is the nature of reality? Is the Universe we inhabit a random accident or the outcome of a delicate selection process?". And all this for a reader with "no previous knowledge of science or philosophy". Professor Davies does not lack ambition.

In fact, I doubt that the book will mean much to a scientific ignoramus; it is more for a reader whose mind is not quite blank before words like 'electromagnetic', 'atom', 'galaxy' and so on. But, with just a minimum of basic scientific culture, it will be possible to get from the book some idea of what quantum theory is, of what an enormous break it is seen to be with what went before, and of how physicists have not yet really digested it.

The first chapters take the reader for a race, a bit breathless, through some of the main ideas of classical mechanics, relativity and quantum theory. We are told of how physicists have come to think of the world as a "game of chance in which we are not merely spectators but players" — in that we now have fundamental laws which are indeterministic in character and whose formulation (in the orthodox contemporary view, in so far as it is coherent) seems to require reference to the observer; of the uncertainty principle and the exclusion principle; of the Dirac sea and the antiparticle; of how space-time itself must be subject to quantum fluctuations and be 'foamy' on a small scale. Repeatedly we are told how very bizarre and incomprehensible it all is.

In later chapters the story unfolds of the remarkable ideas advanced by remarkable physicists in trying to comprehend it all — Bohr's idea that we must renounce all attempts to visualize the atomic and subatomic world and must be content with a formalism that allows statistical predictions to be made about macroscopic events in macroscopic equipment; Wigner's concept that human consciousness plays an essential dynamical role in the world, in 'reducing the wave function'; Wheeler's idea that the very existence of the world, at any time, may somehow be caused by the existence of an observer at some time; the 'anthropic principle' of Dicke and Carter, that much in the observed world is fixed by the fact that it is being observed, because with even minor changes the world could not have produced observing creatures like us.

Above all we learn of the 'many-universes' interpretation of quantum mechanics, of Everett and De Witt, according to which all universes that might exist do exist. If they all exist, then the existence among others of relatively few tailored for our comfort is no mystery, and of course it is only in one of these few that we could find ourselves. Professor Davies is clearly attracted to the many-universes interpretation — and derives from it the title of his book — but correctly makes clear that it is taken seriously only by a handful of physicists. A final chapter dwells on the mystery of time, and especially the absence from our equations of anything corresponding to our impression of the passing of time. One must admire the intellectual intrepidity, and subtlety, of the author in "finding no reason to suppose that the future does not already exist, even though it is not yet determined, and even though the observer will have a hand in structuring it . . . ".

All this is vividly done. Perhaps even a little too vividly. Sometimes the confidence, even the complacency, of the assertions can be irritating. "We must acknowledge . . . " and "We have seen that . . . " really mean only that some qualitative considerations might suggest the entertainment of one possibility among others. But often the unqualified statement is modified a little later, or even has been qualified earlier — a distinction perhaps of little moment to one with such an Olympian view of time. In the closing sentences of his book the author allows that our subjective impression might be more reliable as regards time's passing than our equations. And his assertion that most scientists would agree that ". . . past, present, and future are merely linguistic conventions . . ." has been qualified already in the prologue, where it is said of such ideas that "most scientists live a sort of dual life, accepting them in the laboratory, but rejecting them without thought in daily life". Yes indeed.

On the whole the book gives a good impression of what is thought about these questions by physicists who consider them. But there is an exception, and it is a serious one. It concerns the views of Einstein in general and the Einstein–Podolsky–Rosen argument in particular. As regards Einstein's general reservations about quantum mechanics, Professor Davies propagates the view that they centred on indeterminism: "So unpalatable did this inherent chanciness seem to Albert Einstein that he refused to believe it throughout his life, dismissing the idea with the famous retort 'God does not play dice'". Perhaps the quotability of this famous retort is partly to blame for the fact that Einstein's more considered views are less well known. Compare the summing-up above with the following by Pauli. He is writing to Born in 1954:

> . . Einstein does not regard the concept of 'determinism' to be as fundamental as it is frequently held to be (as he told me emphatically many times) . . . he *disputes* that he uses as a criterion for the admissibility of a theory the question: — Is it rigorously deterministic? — . . . he was *not at all* annoyed with you, but only said you were a person who will not listen".

The Einstein–Podolsky–Rosen (EPR) argument comes up in Chapter 6: "So far we have deliberately been rather cavalier about notions like the real world. . . . In this chapter we shall face up squarely to the fundamental questions raised by the quantum revolution . . . ". In particular, we face up squarely to the possibility that "the apparently capricious and random fluctuations of microsystems do not represent an intrinsic indeterminacy in Nature, but are simply manifestations of a hidden level of structure . . . ". And then the EPR correlations are presented as the fundamental argument against such a possibility! While for EPR they were an entirely convincing argument for precisely such a possibility! The discussion exhibits the perplexity of one who refuses to contemplate the possibility that quantum mechanical description, of a photon in particular, is incomplete. It was the position of EPR that such perplexity could be relieved just by admitting the hypothesis in question. That Professor Davies misses the point not only of the original work, but of the renewed discussion and the associated experimental programme, is clear from the following: "The truly mind-boggling implications. . . are apparent if we use two parallely orientated polarizers . . . ". On the contrary, the mind is boggled only by polarizers which are not parallel. The results with parallel polarizers are easily explicable along Einsteinian lines. The results with off-parallel polarizers are not. That is the new point, unknown to EPR, which inspired the experimental programme of recent years to which the author seems to refer.

While I claim that Professor Davies is wrong on these points, it would certainly be unjust to pillory him on account of them. He makes these mistakes, if they are indeed mistakes, in the company of many other distinguished physicists. He could claim to be reporting a consensus! I enjoyed the book, despite all the reservations, and expect it to be enjoyed by many. The author provides a lively account, accessible with very little technical background, of what is being said about some momentous and inevitable questions. And if he sometimes leads into error, he does not lead into a minority. □

J. S. Bell is a physicist working at CERN in Geneva.

Data book on zinc

Roy M. Harrison

Zinc in the Environment. Edited by J. O. Nriagu. Part 1 *Ecological Cycling,* pp.453; Part 2 *Health Effects,* pp.480. (Wiley-Interscience: 1980.) Each volume £27.50, $59.85.

MOST non-specialists will probably associate the subject of metals in the environment with possible adverse human health effects; indeed in the cases of metals such as lead, cadmium and mercury the main stimulus for research has arisen from concerns over toxic symptoms arising from excessive environmental exposure. Zinc provides a very different case, however. Adverse health effects found in the general population result more often from zinc deficiency, rather than from toxicity due to elevated exposure. Indeed, despite the ubiquitousness of zinc in our environment, numerous well-documented cases of serious zinc deficiency syndrome have arisen amongst groups of people in many different parts of the world. Instances of zinc intoxication in humans are comparatively rare, arising only from extreme exposure conditions not normally experienced by the general population, and in some instances probably due to the cadmium impurity invariably present in technical-grade zinc.

The essentiality of zinc in mammalian metabolism coupled with its considerable toxicity, especially to aquatic biota, make the study of zinc in the environment an important matter which has been rather neglected in comparison with the intensive research efforts expended upon other environmental metals. This two-volume compilation by Nriagu may help to redress the balance; it is an extremely valuable collection of both factual information and numerical data on environmental zinc, and provides a useful source book.

Part I covers the production and uses of zinc, the environmental concentrations and pathways of the metal and its cycling within, and effects upon, near-shore marine, freshwater and forest ecosystems. Part II deals primarily with human health effects of zinc, but also includes the effects of zinc upon terrestrial and aquatic flora and fauna.

As in other recent books edited by Nriagu, the emphasis is upon detailed, but frequently uncritical reviews of the literature. Contributions are drawn from a large number of specialist authors and are fairly well up to date, with references up to 1978 included. The editor has imposed a fairly high degree of uniformity of style, and the book gives wide coverage of the topic with few omissions or overlaps. In these regards the book is of far greater value to the reader than the now-common review volumes cobbled together from the proceedings of a symposium and purporting to provide complete coverage of a topic.

Zinc in the Environment cannot be recommended as light reading for the individual requiring a brief overview of the subject. It will, however, be regarded as essential by many research workers in the field and will, in my view, represent an invaluable source of information for a good many years to come. □

Roy M. Harrison is a Lecturer in the Department of Environmental Sciences at the University of Lancaster.

En route to a classic of ornithology

Raymond O'Connor

Handbook of the Birds of Europe, the Middle East and North Africa: The Birds of the Western Palearctic. Vol.II. Edited by Stanley Cramp. Pp.695. (Oxford University Press: 1980.) £30, $85.

THIS is the second volume of *The Birds of the Western Palearctic*, the ambitious multi-volume work intended as the successor to Witherby's *Handbook of British Birds*, though with a wider geographical brief than the British Isles of the 1939 work.

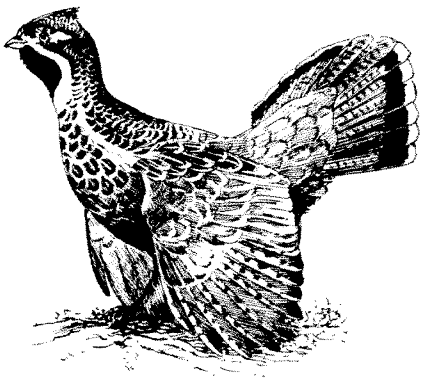
The success of Vol.I testifies to the overwhelming acceptance of its general approach and format, and Vol.II follows the same pattern. The volume treats those species belonging to the Accipitriformes, Falconiformes, Galliformes and Gruiformes. Each species account begins with a general consideration of field characters followed by detailed discussion of the plumage characteristics of the recognizable age-classes. Sections on habitat, distribution, population, movements, food, behaviour and breeding follow, and each account is concluded with a listing of plumage and morphology data. The approach is entirely specific except for brief introductions to each family. The editors have rightly persisted with the format of Vol.I with only minor modifications, though I wish they would quote author initials when citing authors of the same surname. Another minor irritant is the failure to reproduce the explanatory material given in the first volume. As a reference work the *Handbook* should not require one to consult two hefty tomes to locate one's target information within Vol.II.

One general feature of this work is that its treatment of a topic is determined very much by the nature of the material available. For the kestrel, *Falco tinnunculus*, for example, nest site frequencies are tabulated for German and British studies, regional differences are described between northern and southern Britain, seasonal variation in clutch size is cited on the basis of a Swiss study, egg loss rates are quantified for Dutch and English populations, and breeding success to food supply correlations are mentioned for a Norwegian study. With the Western Palearctic as their geographical remit, the authors are entitled to their use of studies from different areas but I find two shortcomings in this approach. First, is the reader to assume that effects cited in a regional study are common to the whole region? The editors disclaim the validity of such assumption from the outset, correctly cautious but unhelpful to the reader. May we, for example, assume that British kestrels follow the Swiss pattern of a seasonal decline in clutch size or is it the case that the question has not been examined for the British population? Second, the absence of reference, for example to habitat differences in clutch and brood sizes, means what? — that there are no such differences or that there are no studies of this aspect of the species' breeding biology? With so much of the volume's layout standardized I regret the lack of systematic treatment of these finer points.

I also have mixed feelings about the treatment of species behaviour, mostly as to whether or not the text devoted to the subject is in keeping with that afforded more ecological topics. On diet, the authors have avoided the presentation of anecdotal data forced on Witherby, so thankfully the literature will be spared a further succession of notes of the 'Additional food items taken by the Greater Gas-bill' type. With behaviour, however, this danger has not been avoided as successfully. Having said this, I admit fully the usefulness of having the lucid descriptive accounts of what is known of the various species. Whilst some species have extensive coverage, for example seven full pages for the peregrine, *Falco peregrinus*, many run to only one or two columns of text and provide a valuable indication of the gaps in our knowledge.

The line drawings of C.J.F. Coombs illustrating the sections on behaviour are, on the whole, successful in providing schematic illustration of the behaviours of interest, without at the same time losing all of the natural 'jizz' of the birds. He deserves special credit for meeting a difficult task well. The colour plates are beautiful and for the game birds, especially, convey real expression. I was less taken by the plates illustrating perched raptors and was reminded by several of the 'in flight' illustrations of this group of nothing so much as of aircraft recognition charts. I personally would find the Peterson *Field Guide* (Collins, 1954) technique of pointers directed to the critical recognition features of help in using these illustrations, despite the reference rather than 'in field' purpose of this book.

If the work has a significant weakness, as opposed to the more trivial criticisms mentioned above, it is in relating the fieldwork and natural history to a broad theoretical background. Within its taxonomic scope this volume provides a magnificent synthesis of facts but not of knowledge. Examples abound. Female raptors are noted as taking a larger share of territorial defence as the nest cycle progresses from laying through to nestlings, but nowhere is there reference to the parental investment theories of Trivers nor to the study of Barash (*Wilson Bull.* **87**, 367–373; 1975) whose paper makes explicit the relevance of these theories to the nest defence pattern. Similarly, the parent–young bonds of the sparrowhawk, *Accipiter nisus*, are described as being typical of *Accipiter* in character and that of kestrels as "largely typical of falcons" but the reader is left to his own initiative to return to the family introductions to seek a description of these typical patterns. Even where general patterns are recognized as existing and deserving of theoretical explanation, as with the reversed sexual size dimorphism of the accipiters and falcons, the authors duck the question, giving references without even a hint of the nature of the theories to be found therein. This refusal to acknowledge that there is a 'Why' to the 'Whats' of bird-watching is, to my mind, the great weakness of this book. It undoubtedly reflects the composition of the editorial board for the *Handbook* and their individual interests, as well as the composition of the 'serious bird-watcher' market at which it is aimed. However, if ornithology has (as I believe to be the case) more to offer to the ecological and evolutionary sciences than has the study of any other single taxonomic group (with the possible exception of entomology) the replacement for Witherby's *Handbook* ought to display at least a nodding acquaintanceship with these sciences.



How easy it is to criticize! The volume lives up to the standards set by Vol.I and, in turn, by the Witherby classic. It brings so much information together that I could not be without a personal copy of this storehouse of avian natural history. Put alongside a copy of Welty's *Life of Birds* (W.B. Saunders, 1975) it will provide the serious bird-watcher with most of what he should know about the groups covered. My real regret is that at the present rate of writing (with three years between the publication of Vol.I and II) it will be 1995 before an authoritative compendium on the passerines is available. On their form to date Cramp and his colleagues will then have completed a classic of ornithological compilation. □

A plea for 2,4,5-T

Alastair Hay

The Science of 2,4,5-T and Associated Phenoxy Herbicides. By Rodney W. Bovey and Alvin L. Young. Pp.462. (Wiley: 1980.) £21.40, $46.90.

"Few agricultural chemicals have a longer safety record in the field than the phenoxy herbicides, including 2,4,5-T". This conclusion, stated baldly by the authors in the opening pages, sets the tone for this, the latest book on the subject.

As the authors note in their first chapter, the use of 2,4,5-T (2,4,5-trichlorophenoxy acetic acid) has been a controversial matter in many countries for the past ten years. That controversy has centred, in the main, on the presence in 2,4,5-T of an extremely toxic contaminant, 2,3,7,8-tetrachlorodibenzo-p-dioxin (dioxin). The dioxin contaminant, produced as an unwanted by-product in the manufacture of 2,4,5-trichlorophenol — from which 2,4,5-T is made — is a known teratogen and carcinogen in animals. However, dioxin is only present in most 2,4,5-T preparations in concentrations less than 0.1 ppm and in Britain, according to a recent government statement, in amounts less than 0.01 ppm.

Is all the fuss about 2,4,5-T justified? Bovey and Young think not. It is their view that much of the criticism of the herbicide is misinformed and based on biased, selective citation of reports. The authors consider many of these reports in some depth, and present evidence to show that allegations against 2,4,5-T are ill-founded. For example, two incidents linked to 2,4,5-T — an alleged increase in human illnesses in Globe, Arizona, and the deaths of reindeer in Lapland, both of which occurred in 1970 — were later shown to have no connection with the herbicide. Local doctors practising in the Globe area said that close investigation revealed no significant increase in illnesses linked to herbicide spraying. And the reindeer deaths in Sweden were eventually attributed to starvation rather than exposure to 2,4,5-T.

To support their argument the authors have provided a detailed review of the chemistry, toxicology and ecological effects of the compounds in question. The value of their work lies in its comprehensive coverage of the literature describing the properties of 2,4,5-T and the related herbicide 2,4-D (2,4-dichlorophenoxy acetic acid) in microorganisms, higher plants and animals, including human beings. Methods of detecting the herbicide in biological specimens are considered, as are the problems associated with its application.

Inevitably, authors of a book such as this must at some time make a decision when to stop reviewing the literature. Here, with coverage up to 1978, they have therefore missed some of the more important epidemiological studies on dioxin exposure in industry and silviculture.

Recently published studies of people exposed to dioxin in industry offer apparently conflicting evidence. The first investigation, of workers exposed to the chemical at the Monsanto company in West Virginia in 1949, clears dioxin — for the moment — of causing any increase in the mortality rate in the men; deaths in this group were in fact lower than would be expected. The second study, of workers exposed to dioxin in an accident in West Germany, suggests that the chemical could be the cause of an increase in gastro-intestinal cancer. A third survey, of workers employed in the forestry industry in Sweden, also claims that exposure to dioxin-contaminated 2,4,5-T could have increased the incidence of deaths from cancer. The authors of this study claim that silviculture workers exposed to 2,4,5-T have a six-fold higher incidence of soft tissue sarcomas (see *Nature* **283**, 613; 1980).

In their concluding chapters Bovey and Young detail the processes involved in registering new chemicals and list many suitable alternatives to phenoxy herbicides — although, as stated earlier, their view is that the phenoxy herbicides are not a great hazard. The economic consequences of dispensing with them is assessed as follows: an increase in farm production costs of $290 million, and the requirement of an additional 20 million hours of family labour to clear the foliage the herbicides keep down so effectively. However, it is not clear whether these figures are based on a situation where alternative herbicides are employed or one where no herbicides are used at all.

On phenoxy herbicide use for military purposes, the authors are quite explicit. Their use "in an armed conflict [in Vietnam] has jeopardised their continued use in world agriculture". The authors are not convinced that the use of 2,4,5-T in Vietnam — recognized to have had a dioxin content of 0.05–47 ppm — has caused birth defects among the general population, as has been claimed by Vietnamese scientists and doctors. However, Bovey and Young note that many scientists still hold different views on this subject and that more evidence is required before the issue can be resolved. The authors also claim that the incineration of the unused herbicide stocks from Vietnam means that "it is no longer an issue". Using herbicide destined for Vietnam may not be an issue — but the legacy of its use in that country is still very much in the public eye, following claims by former US veterans that the herbicide has damaged their health.

It remains to be seen whether reviews currently being conducted by government bodies in the UK and USA will come to the conclusion that the use of present formulations of 2,4,5-T also poses a health risk. Whatever the verdict, the authors make the plea that the suspension of 2,4,5-T and other products based on trichlorophenol "should not jeopardise other phenoxy herbicides". By all accounts the others are not in jeopardy. □

Odours and vertebrate ecology

Vincent B. Wigglesworth

The Ecology of Vertebrate Olfaction. By D. Michael Stoddart. Pp. 234. (Chapman and Hall: 1980.) £15, $29.95.

THE purpose of this book was to put together an inclusive account of all the ways in which the lives of other vertebrates are guided by the richly scented world that is beyond our ken. Comparative anatomy of the olfactory system suggests that we differ from our more osmatic relatives in quantity rather than in quality; in the restricted area of our olfactory epithelium in comparison with the capacious chambers of other animals. As far as sensitivity is concerned, it sounds quite impressive to point out that the human female at the height of her sexual cycle can perceive the odour of synthetic musk at a concentration of 1 in 1,000 million; but this achievement fades beside the claim that the eel can detect β-phenylethyl alcohol at concentrations as low as 3×10^{-18}M, representing the dilution of 1ml of the alcohol in a volume of water equal to 58 times that of Lake Constance (Bodensee, the 60km lake on the Swiss–German border) — which will provide the eel with about three molecules in its olfactory sac at one time.

A survey of the chemistry of vertebrate scents reads like a catalogue of organic chemicals, but on closer analysis it seems that virtually all are refined waste products of metabolism and few or none are synthesized *de novo*. Moreover, although the glands from which they are liberated can be concentrated in many different parts of the body, they seem always to be modified, often scarcely modified, sebaceous glands, the secretory products of which are influenced by diet.

The book provides a detailed account of the multifarious roles of olfaction — the detection of food by herbivores and carnivores; the attraction of a mate and the advertisement of sexual state; the induction of oestrus and ovulation; the conduct of courtship and mating; the discrimination of families, populations and races (thus aiding sexual isolation between species); the maintenance of social hierarchy and territoriality; the detection of predators; the transmission of warning signals or active defence; and homing and navigation.
